12

13 **Abstract**

14 It is expected that hyperresolution land modeling substantially innovates the simulation
15 of terrestrial water, energy, and carbon cycles. The major advantage of hyperresolution
16 land models against conventional one-dimensional land surface models is that
17 hyperresolution land models can explicitly simulate lateral water flows. Despite many
18 efforts on data assimilation of hydrological observations into those hyperresolution land
19 models, how surface water flows driven by local topography matter for data assimilation
20 of soil moisture observations has not been fully clarified. Here I perform two minimalist
21 synthetic experiments where soil moisture observations are assimilated into an integrated
22 surface-groundwater land model by an ensemble Kalman filter. I discuss how differently
23 the ensemble Kalman filter works when surface lateral flows are switched on and off. A
24 horizontal background error covariance provided by overland flows is important to adjust
25 the unobserved state variables (pressure head and soil moisture) and parameters (saturated
26 hydraulic conductivity). However, the non-Gaussianity of the background error provided
27 by the nonlinearity of a topography-driven surface flow harms the performance of data
28 assimilation. It is difficult to efficiently constrain model states at the edge of the area
29 where the topography-driven surface flow reaches by linear-Gaussian filters. It brings the

30 new challenge in land data assimilation for hyperresolution land models. This study
31 highlights the importance of surface lateral flows in hydrological data assimilation.

32

33

34 **1. Introduction**

35 Hyperresolution land modeling is expected to improve the simulation of terrestrial water,
36 energy, and carbon cycles, which is crucially important for meteorological, hydrological
37 and ecological applications (see Wood et al. (2011) for a comprehensive review). While
38 conventional land surface models (LSMs) assume that lateral water flows are negligible
39 at the coarse resolution ($>25\text{km}$) and solve vertical one-dimensional Richards equation
40 for the soil moisture simulation (e.g., Sellers et al. 1996; Lawrence et al. 2011), currently
41 proposed hyperresolution land models, which can be applied at a finer resolution ($<1\text{km}$),
42 explicitly consider surface and subsurface lateral water flows (e.g., Maxwell and Miller
43 2005; Tian et al. 2012; Shrestha et al. 2014; Niu et al. 2014). The fine horizontal resolution
44 can resolve slopes, which are drivers of a lateral transport of water, and realize the fully
45 integrated surface-groundwater modeling. Previous works indicated that a lateral
46 transport of water strongly controls latent heat flux and the partitioning of
47 evapotranspiration into base soil evaporation and plant transpiration (e.g., Maxwell and

48 Condon 2016; Ji et al. 2017; Fang et al. 2017). This effect of a lateral transport of water
49 on land-atmosphere interactions has been recognized (e.g., Williams and Maxwell 2011;
50 Keune et al. 2016).

51

52 Data assimilation has contributed to improving the performance of LSMs by fusing
53 simulation and observation. The grand challenge of land data assimilation is to improve
54 the simulation of unobservable variables using observations by propagating observations'
55 information into model's high dimensional state and parameter space. In previous works
56 on the conventional 1-D LSMs, many land data assimilation systems (LDASs) have been
57 proposed to accurately estimate model's state and parameter variables, which cannot be
58 directly observed, by assimilating satellite and in-situ observations. For example, the
59 optimization of LSM's unknown parameters (e.g., hydraulic conductivity) has been
60 implemented by assimilating remotely sensed microwave observations (e.g., Yang et al.
61 2007; Yang et al. 2009; Bandara et al. 2014; Bandara et al. 2015; Sawada and Koike 2014;
62 Han et al. 2014). Kumar et al. (2009) focused on the correlation between surface and root-
63 zone soil moistures to examine the potential of assimilating surface soil moisture
64 observations to estimate root-zone soil moisture. Sawada et al. (2015) successfully
65 improved the simulation of root-zone soil moisture by assimilating microwave brightness

66 temperature observations which include the information of vegetation water content.
67 Gravity Recovery and Climate Experiment total water storage observation has been
68 intensively used to improve the simulation of groundwater and soil moisture (e.g., Li et
69 al. 2012; Houborg et al. 2012). Improving the simulation of state variables such as soil
70 moisture and biomass by LDASs has contributed to accurately estimating fluxes such as
71 evapotranspiration (e.g. Martens et al. 2017) and CO₂ flux (e.g., Verbeeck et al. 2011).
72 However, in most of the studies on the conventional 1-D LDASs, observations impacted
73 state variables and parameters only in a single model's horizontal grid which is identical
74 to the location of the observation. The assumption that the water flows are restricted to
75 vertical direction in LSMs makes it difficult to propagate observation's information
76 horizontally. It limits the potential of land data assimilation to fully use land hydrological
77 observations.

78

79 The hyperresolution land models, which explicitly solve surface and subsurface lateral
80 flows, provide a unique opportunity to examine the potential of land data assimilation to
81 propagate observation's information horizontally in a model space and efficiently use land
82 hydrological observations. Previous works successfully applied Ensemble Kalman Filters
83 (EnKF) to 3-D Richards' equation-based integrated surface-groundwater models. For

84 example, Camporese et al. (2009) and Camporese et al. (2010) successfully assimilated
85 synthetic observations of surface pressure head and streamflow into the Catchment
86 Hydrology (CATHY). Ridler et al. (2014) successfully assimilated Soil Moisture and
87 Ocean Salinity satellite-observed surface soil moisture into the MIKE SHE distributed
88 hydrological model (see also Zhang et al. (2015)). Kurtz et al. (2016) coupled the Parallel
89 Data Assimilation Framework (PDAF) (Nerger and Hiller 2013) with the Terrestrial
90 System Modelling Framework (TerrSysMP) (Shrestha et al. 2014) and successfully
91 estimate the spatial distribution of soil moisture and saturated hydraulic conductivity in
92 the synthetic experiment (see also Zhang et al. (2018)). In addition, Kurtz et al. (2016)
93 indicated that their EnKF approach is computationally efficient in high-performance
94 computers. Those studies have significantly contributed to fully assimilating the new
95 high-resolution soil moisture observations such as Sentinel-1 (e.g., Paroscia et al. 2013)
96
97 Although the data assimilation of hydrological observations into hyperresolution land
98 models has been successfully implemented in the synthetic experiments, it is unclear how
99 topography-driven surface lateral water flows matter for data assimilation of soil moisture
100 observations. Previous studies on data assimilation with high resolution models mainly
101 focused on assimilating groundwater observations (e.g., Ait-El-Fquih et al. 2016;

102 Rasmussen et al. 2015; Hendricks-Franssen et al. 2008). There are some applications
103 which focused on the observation of soil moisture and pressure head in shallow
104 unsaturated soil layers. However, in those studies, topography-driven surface flow has
105 not been considered in the experiment (Kurtz et al. 2016) or the role of them in
106 assimilating observations into the hyperresolution land models has not been quantitatively
107 discussed (Camporese et al. 2010; Camporese et al. 2009). This study aims at clarifying
108 if surface lateral flows matter for data assimilation of soil moisture observations into
109 hyperresolution land models by a minimalist numerical experiment.

110

111

112 **2. Methods**

113 2.1. Model

114 ParFlow is an open source platform which realizes fully integrated surface-groundwater
115 flow modeling (Kollet and Maxwell 2006; Maxwell et al. 2015). This model can be
116 efficiently parallelized in high performance computers and has been widely used as a core
117 hydrological module in hyperresolution land models (e.g., Maxwell and Kollet 2008;
118 Maxwell and Condon 2016; Fang et al. 2017; Kurtz et al. 2016; Maxwell et al. 2011;
119 Williams and Maxwell 2011; Shrestha et al. 2014). Since I used this widely adopted solver

120 as is and added nothing new to the model physics, I described the method of ParFlow to
121 simulate integrated surface-subsurface water flows briefly and omitted the details of
122 numerical methods. The complete description of ParFlow can be found in Kollet and
123 Maxwell (2006), Maxwell et al. (2015) and references therein.

124

125 In the subsurface, ParFlow solves the variably saturated Richards equation in three
126 dimensions.

$$127 \quad S_S S_W(h) \frac{\partial h}{\partial t} + \phi S_W(h) \frac{\partial S_W(h)}{\partial t} = \nabla \cdot \mathbf{q} + q_r \quad (1)$$

$$128 \quad \mathbf{q} = -\mathbf{K}_s(\mathbf{x}) k_r(h) [\nabla(h+z) \cos\theta_x + \sin\theta_x] \quad (2)$$

129 In equation (1), h is the pressure head [L]; z is the elevation with the z axis specified as
130 upward [L]; S_S is the specific storage [L^{-1}]; S_W is the relative saturation; ϕ is the
131 porosity [-]; q_r is a source/sink term. Equation (2) describes the flux \mathbf{q}
132 [LT^{-1}] by Darcy's law, and \mathbf{K}_s is the saturated hydraulic conductivity tensor [LT^{-1}]; k_r
133 is the relative permeability [-]; θ is the local angle of topographic slope (see Maxwell et
134 al. 2015). In this paper, the saturated hydraulic conductivity is assumed to be isotropic
135 and a function of z :

$$136 \quad \mathbf{K}_s = K_s(z) = K_{s,surface} \exp(-f(z_{surface} - z)) \quad (3)$$

137 where $K_{s,surface}$ is the saturated hydraulic conductivity at the surface soil, and $z_{surface}$
 138 is the elevation of the soil surface. The saturated hydraulic conductivity decreases
 139 exponentially as the soil depth increases (Beven 1982). A van Genuchten relationship
 140 (van Genuchten 1980) is used for the relative saturation and permeability functions.

$$141 \quad S_W(h) = \frac{S_{sat} - S_{res}}{(1 + (\alpha h)^n)^{\left(1 - \frac{1}{n}\right)}} + S_{res} \quad (4)$$

$$142 \quad k_r(h) = \frac{\left(1 - \frac{(\alpha h)^{n-1}}{(1 + (\alpha h)^n)^{\left(1 - \frac{1}{n}\right)}}\right)^2}{(1 + (\alpha h)^n)^{\frac{\left(1 - \frac{1}{n}\right)}{2}}} \quad (5)$$

143 where α [L⁻¹] and n [-] are soil parameters, S_{sat} is the relative saturated water content
 144 and S_{res} is the relative residual saturation.

145

146 Overland flow is solved by the two-dimensional kinematic wave equation. The dynamics
 147 of the surface ponding depth, h [L], can be described by:

$$148 \quad \mathbf{k} \cdot [-K_s(z)k_r(h) \cdot \nabla(h + z)] = \frac{\partial \|h, 0\|}{\partial t} - \nabla \cdot \|h, 0\| \mathbf{v}_{sw} + q_r \quad (6)$$

149 In equation (6), \mathbf{k} is the unit vector in the vertical and $\|h, 0\|$ indicates the greater value
 150 of the two quantities following the notation of Maxwell et al. (2015). This formulation
 151 results in the overland flow equation being represented as a boundary condition to the
 152 variably saturated Richards equation (Kollet and Maxwell 2006). If $h < 0$, equation (6)
 153 describes that vertical fluxes across the land surface is equal to the source/sink term q_r
 154 (i.e., rainfall and evapotranspiration). If $h > 0$, the terms on the right-hand side of equation

155 (6), which indicate water fluxes routed according to surface topography, are active. \mathbf{v}_{sw}
156 is the two-dimensional depth-averaged water flow velocity [LT^{-1}] and estimated by the
157 Manning's law:

$$158 \quad \mathbf{v}_{sw,x} = \left(\frac{\sqrt{S_{f,x}}}{n_M} h^{\frac{2}{3}} \right), \mathbf{v}_{sw,y} = \left(\frac{\sqrt{S_{f,y}}}{n_M} h^{\frac{2}{3}} \right) \quad (7)$$

159 where $S_{f,x}$ and $S_{f,y}$ are the friction slopes [-] for the x- and y-direction, respectively;
160 n_M is the Manning's coefficient [$TL^{-1/3}$]. In the kinematic wave approximation, the
161 friction slopes are set to the bed slopes. The methodology of discretization and the
162 numerical method to solve equations (1-7) can be found in Kollet and Maxwell (2006).

163

164

165 **2.2. Data Assimilation**

166 In this paper, the ensemble Kalman filter (EnKF) was applied to assimilate soil moisture
167 observations into ParFlow. The EnKF has widely been applied to hyper-resolution land
168 models (e.g., Camporese et al. (2009); Camporese et al. (2010); Ridler et al. (2014);
169 Zhang et al. (2015); Kurtz et al. (2016); Zhang et al. (2018)). I examined if surface lateral
170 flows matter for data assimilation of soil moisture observations into hyperresolution land
171 models using this widely adopted data assimilation method.

172

173 The Parflow model can be formulated as a discrete state-space dynamic system:

$$174 \quad \mathbf{x}(t + 1) = f(\mathbf{x}(t), \boldsymbol{\theta}, \mathbf{u}(t)) + \mathbf{q}(t) \quad (8)$$

175 where $\mathbf{x}(t)$ is the state variables (i.e. pressure head), $\boldsymbol{\theta}$ is the time-invariant model
176 parameters (i.e. saturated hydraulic conductivity), $\mathbf{u}(t)$ is the external forcing (i.e.,
177 rainfall and evapotranspiration), and $\mathbf{q}(t)$ is the noise process which represents the
178 model error. In data assimilation, it is useful to formulate an observation process as
179 follows:

$$180 \quad \mathbf{y}^f(t) = \mathcal{H}(\mathbf{x}(t)) + \mathbf{r}(t) \quad (9)$$

181 where $\mathbf{y}^f(t)$ is the simulated observation, \mathcal{H} is the observation operator which maps
182 the model's state variables into the observable variables, and $\mathbf{r}(t)$ is the noise process
183 which represents the observation error. The purpose of EnKF (and any other data
184 assimilation methods) is to find the optimal state variables $\mathbf{x}(t)$ based on the simulation
185 $\mathbf{y}^f(t)$ and observation (defined as \mathbf{y}^o) considering their errors ($\mathbf{q}(t)$ and $\mathbf{r}(t)$)

186

187 The general description of the Kalman filter is the following:

$$188 \quad \mathbf{x}^f(t) = \mathcal{M}[\mathbf{x}^a(t - 1)] \quad (10)$$

$$189 \quad \mathbf{x}^a(t) = \mathbf{x}^f(t) + \mathbf{K}[\mathbf{y}^o - \mathcal{H}(\mathbf{x}^f(t))] \quad (11)$$

$$190 \quad \mathbf{K} = \mathbf{P}^f \mathcal{H}^T (\mathcal{H} \mathbf{P}^f \mathcal{H}^T + \mathbf{R})^{-1} \quad (12)$$

191 $\mathbf{P}^a = (\mathbf{I} - \mathbf{K}\mathcal{H})\mathbf{P}^f$ (13)

192 I follow the notation of Houtekamer and Zhang (2016). Superscripts f and a are forecast
 193 and analysis, respectively. In equation (10), a forecast model \mathcal{M} (ParFlow in this study)
 194 is used to obtain a prior estimate at time t, $\mathbf{x}^f(t)$, from the estimation at the previous time
 195 $\mathbf{x}^a(t-1)$. In equation (11), a prior estimate $\mathbf{x}^f(t)$ is updated to the analysis state,
 196 $\mathbf{x}^a(t)$, using new observations y^o . The Kalman gain matrix \mathbf{K} , calculated by equation
 197 (12), gives an appropriate weight for the observations with an error covariance matrix \mathbf{R} ,
 198 and the prior with an error covariance matrix \mathbf{P}^f . \mathbf{P}^a is an updated analysis error
 199 covariance. To calculate \mathbf{K} , the observation operator \mathcal{H} is needed to map from model
 200 space to observation space. It should be noted that the equations (10-13) give an optimal
 201 estimation only when the model and observation errors follow the Gaussian distribution.
 202 When the probabilistic distribution of the error in either model or observation has a non-
 203 Gaussian structure, results of the Kalman filter are suboptimal. This point is important to
 204 interpret the results of this study.

205

206 EnKF is the Monte Carlo implementation of equations (10-13). To compute the Kalman
 207 gain matrix, \mathbf{K} , ensemble approximations of $\mathbf{P}^f\mathcal{H}^T$ and $\mathcal{H}\mathbf{P}^f\mathcal{H}^T$ can be given by:

208 $\mathbf{P}^f\mathcal{H}^T \equiv \frac{1}{k-1} \sum_{i=1}^k (\mathbf{x}_i^f - \overline{\mathbf{x}}^f) (\mathcal{H}\mathbf{x}_i^f - \overline{\mathcal{H}\mathbf{x}}^f)^T$ (14)

209 $\mathcal{H}P^f\mathcal{H}^T \equiv \frac{1}{k-1}\sum_{i=1}^k(\mathcal{H}\mathbf{x}_i^f - \overline{\mathcal{H}\mathbf{x}^f})(\mathcal{H}\mathbf{x}_i^f - \overline{\mathcal{H}\mathbf{x}^f})^T$ (15)

210 where \mathbf{x}_i^f is the i th member of a k -member ensemble prior and $\overline{\mathbf{x}^f} = \frac{1}{k}\sum_{i=1}^k \mathbf{x}_i^f$ and

211 $\overline{\mathcal{H}\mathbf{x}^f} = \frac{1}{k}\sum_{i=1}^k \mathcal{H}\mathbf{x}_i^f$.

212

213 Once $\overline{\mathbf{x}^a} = \sum_{i=1}^k \mathbf{x}_i^a$ (\mathbf{x}_i^a is the i th member of a k -member ensemble analysis) and $P^a =$

214 $\frac{1}{k-1}\sum_{i=1}^k(\mathbf{x}_i^a - \overline{\mathbf{x}^a})(\mathbf{x}_i^a - \overline{\mathbf{x}^a})^T$ are computed by equations (10-15), there are many

215 choices of an analysis ensemble. Although equations (10-15) can calculate the mean and

216 variance of the ensemble members, they do not tell how to adjust the state of the ensemble

217 members in order to realize the estimated mean and variance. There are many proposed

218 flavors of EnKF and one of the differences among them is the method to choose the

219 analysis \mathbf{x}_i^a . In this paper, the Ensemble Transform Kalman Filter (ETKF; Bishop et al.

220 2001; Hunt et al. 2007) was used to transport forecast ensembles to analysis ensembles.

221 ETKF has been used for hyperresolution land data assimilation (e.g., Kurtz et al. 2016).

222 Please refer to Hunt et al. (2007) for the complete description of the ETKF and its

223 localized version, the Local Ensemble Transform Kalman Filter (LETKF). The open

224 source available at <https://github.com/takemasa-miyoshi/letkf> was used in this study as

225 the ETKF code library.

226

227 In many ensemble Kalman filter systems, the ensemble spread, \mathbf{P}^a , tends to become too
228 underdispersive to stably perform data assimilation cycles without any ensemble inflation
229 methods (Houtekamer and Zhang, 2016). To overcome this limitation, \mathbf{P}^a is arbitrarily
230 inflated after data assimilation. In this paper, the relaxation to prior perturbation method
231 (RTPP) of Zhang et al. (2004) was used to maintain an appropriate ensemble spread. In
232 the RTPP, the computed analysis perturbations are relaxed back to the forecast
233 perturbations:

$$234 \mathbf{x}_{i,new}^a - \overline{\mathbf{x}}^a = (1 - \alpha)(\mathbf{x}_i^a - \overline{\mathbf{x}}^a) + \alpha(\mathbf{x}_i^f - \overline{\mathbf{x}}^f), \quad 0 \leq \alpha \leq 1 \quad (16)$$

235 where α was set to 0.975 in this study. If $\alpha = 1$, the analysis spread is identical to the
236 background spread. Many studies show that the ensemble inflation works well when α
237 remains fairly close to 1 (see also the comprehensive review by Houtekamer and Zhang
238 2016).

239

240 In the data assimilation experiments, I adjusted pressure head by data assimilation so that
241 \mathbf{x}^f is pressure head. Since the surface saturated hydraulic conductivity was also adjusted,
242 \mathbf{x}^f includes log-transformed $K_{s,surface}$. I assimilated volumetric soil moisture
243 observations so that \mathbf{y}^f and \mathbf{y}^o are simulated and observed volumetric soil moisture,
244 respectively. The van Genuchten relationship converts the adjusted state variables \mathbf{x}^f to

245 the observable variables \mathbf{y}^f and can be recognized as an observation operator \mathcal{H} .
246 However, since volumetric soil moisture \mathbf{y}^f has already been calculated by Parflow, I did
247 not need the van Genuchten relationship in data assimilation.

248

249

250 **2.3. Kullback-Leibler divergence**

251 To evaluate the non-Gaussianity of the background error sampled by an ensemble, I used
252 the Kullback-Leibler divergence (KLD) (Kullback and Leibler 1951):

$$253 \quad D_{KL}(p, q) = \sum_i p(i) \log \frac{p(i)}{q(i)} \quad (17)$$

254 where $D_{KL}(p, q)$ is the KLD between two probabilistic distribution functions (PDFs), p
255 and q . If two PDFs are equal for all i , $D_{KL}(p, q) = 0$. A large value for $D_{KL}(p, q)$
256 indicates that the two PDFs, p and q , substantially differ from each other. Therefore,
257 the KLD can be used as an index to evaluate the closeness of two PDFs. In this study, I
258 compared the PDF of the ensemble simulation (p in equation (17)) with the Gaussian PDF
259 which has the mean and variance of the ensembles (q in equation (17)). A large value for
260 $D_{KL}(p, q)$ indicates the state variables simulated by ensembles do not follow the
261 Gaussian PDF. It should be noted that the KLD is not symmetric ($D_{KL}(p, q) \neq D_{KL}(q, p)$).
262 The KLD has been used to quantitatively evaluate the Gaussianity of the sampled

263 background error in the studies on data assimilation (e.g., Kondo and Miyoshi 2019; Duc
264 and Saito 2018).

265

266

267 **3. Synthetic experiments**

268 In this study, I performed two synthetic experiments. In the synthetic experiments, I
269 generated the synthetic truth of the state variables by driving ParFlow with the specified
270 parameters and input data. Then the synthetic observations were generated by adding the
271 Gaussian white noise to this synthetic truth. The performance of data assimilation was
272 evaluated by comparing the estimated state and parameter values by ETKF with the
273 synthetic truth. This synthetic experiment has been recognized as an important research
274 method to analyze how data assimilation works (e.g., Moradkhani et al. 2005; Camporese
275 et al. 2009; Vrugt et al. 2013; Kurtz et al. 2016; Sawada et al. 2018)

276

277

278 **3.1. Simple 2-D slope with homogeneous hydraulic conductivity**

279 **3.1.1. Experiment Design**

280 The synthetic experiment was implemented to examine how topography-driven surface
281 lateral flows contribute to efficiently propagating observation's information horizontally
282 in the data assimilation of soil moisture observation. Two synthetic reference runs were
283 created by Parflow. The 2-D domain has a horizontal extension of 4000m and a vertical
284 extension of 5m. The domain of the virtual slope was horizontally discretized into 40 grid
285 cells with a size of 100m and vertically discretized into 50 grid cells with a size of 0.10m.
286 The domain has a 25% slope. In two synthetic reference runs, it heavily rains only in the
287 upper half of the slope ($2000\text{m} < x < 4000\text{m}$). Although this rainfall distribution is
288 unrealistic, the effect of surface lateral flows on data assimilation can clearly be discussed
289 in this simplified problem setting. More realistic rainfall distribution will be used in the
290 next synthetic experiment (see section 3.2). A constant rainfall rate of 50mm/h was
291 applied for 3 hours and then the period with no rainfall and evaporation of 0.075mm/h
292 lasted for 117 hours. This 120-hour rain/no rain cycle was repeatedly applied to the
293 domain. There is no rainfall in the lower half of the slope ($0\text{m} < x < 2000\text{m}$). The
294 configurations described above were schematically shown in Figure 1a. The parameters
295 of the van Genuchten relationship, alpha and n, were set to $1.5 [\text{m}^{-1}]$ and 1.75, respectively.
296 Those values are in the reasonable range estimated by the published literature (e.g.,
297 Ghanbarian-Alavijeh et al. 2010). The porosity, ϕ in equation (1), was set to 0.40. The

298 Manning's coefficient, n_M in equation (5), was set to 5.52×10^{-6} [$\text{m}^{-1/3}\text{h}$]. These
299 clayey soil properties described above are applied to the whole domain. The groundwater
300 table was located at $z=3\text{m}$ and the hydrostatic pressure gradient was assumed for the
301 initial pressure heads in the unsaturated soil layers.

302

303 The difference between two synthetic reference runs is the value of saturated hydraulic
304 conductivity. The surface saturated hydraulic conductivity, $K_{s,surface}$ in equation (3),
305 was set to 0.005 [m/h] in one reference, and 0.02 [m/h] in the other. These surface
306 saturated hydraulic conductivities described above are applied to the whole domain.
307 Figure 1 shows the difference of the response to heavy rainfall between the two synthetic
308 reference runs. In the case of the low saturated hydraulic conductivity (hereafter called
309 the LOW_K reference), larger surface lateral flows are generated than the case of the high
310 saturated hydraulic conductivity (hereafter called the HIGH_K reference). In the LOW_K
311 reference, the topography-driven surface lateral flows reach the left edge of the domain
312 (Figure 1b). In the HIGH_K reference, supplied water moves vertically rather than
313 horizontally and the topography-driven surface flow reaches around $x = 1000\sim 1500\text{m}$
314 (Figure 1d).

315

316 For the data assimilation experiment, an ensemble of 50 realizations was generated. Each
317 ensemble member has different saturated hydraulic conductivity and rainfall rate.
318 Lognormal multiplicative noise was added to surface saturated hydraulic conductivity
319 and rainfall rate of the synthetic reference runs. This specification of uncertainty in
320 rainfall was also adopted in Crow et al. (2011). The two parameters of the lognormal
321 distribution, commonly called μ and σ , were set to 0 and 0.15, respectively. These
322 parameters were chosen to give the sufficiently large error in precipitation and saturated
323 hydraulic conductivity. In addition, this setting makes the rainfall PDF similar to the
324 Gaussian distribution, which is important to interpret the results of the experiments (see
325 the discussion section). The initial groundwater depth of each ensemble member was
326 drawn from the uniform distribution from 2.0m to 3.5m. The hydrostatic pressure gradient
327 was assumed for the initial pressure heads in the unsaturated soil layers.

328

329 The virtual hourly observations were generated by adding the Gaussian white noise whose
330 mean is zero to the volumetric soil moisture simulated by the synthetic reference runs.
331 The observation error (the standard deviation of the added Gaussian white noise) was set
332 to $0.05 \text{ m}^3/\text{m}^3$. It was assumed that the volumetric soil moistures can be observed in every
333 model's soil layer from surface to the depth of 1m at the specific location. These soil

334 moisture observations can be obtained in the in-situ observation sites (e.g., Dorigo et al.,
335 2017). In the section 3.2, I will assume that only surface soil moisture observation can be
336 accessed, which is more realistic since satellite sensors can observe only surface soil
337 moisture. I assumed that the small part of the domain can be observed. The two scenarios
338 of the observation's location are provided. In the first scenario (hereafter called the UP_O
339 scenario), the volumetric soil moisture at the upper part of the slope ($x = 2500\text{m}$) was
340 observed. In the UP_O scenario, I could observe the volumetric soil moisture in the upper
341 part of the slope where it heavily rains and tried to infer the soil moisture in the lower part
342 of the slope where it does not rain by propagating the observation's information downhill.
343 In the second scenario (hereafter called the DOWN_O scenario), the volumetric soil
344 moisture at the lower part of the slope ($x = 1500\text{m}$) was observed. In the DOWN_O
345 scenario, I could observe the volumetric soil moisture in the lower part of the slope where
346 it does not rain and tried to infer the soil moisture in the upper part of the slope where it
347 heavily rains by propagating the observation's information uphill.

348

349 Since I had the two synthetic reference runs (the HIGH_K and LOW_K references) and
350 the two observation scenarios (the UP_O and DOWN_O scenarios), I implemented totally
351 four data assimilation experiments. Table 1 summarizes the data assimilation experiments

352 implemented in this study. For instance, in the HIGH_K-UP_O experiment, I chose the
353 HIGH_K reference and generated an ensemble of 50 realizations from the HIGH_K
354 reference. The soil moisture observations were generated from the HIGH_K reference at
355 the location of $x = 2500\text{m}$ and assimilated into the model every hour. The simulated
356 volumetric soil moisture of the data assimilation experiment was compared with that of
357 the HIGH_K reference.

358

359 In addition to the data assimilation (DA) experiments, I implemented the NoDA
360 experiment (also called the open-loop experiment in the literature of the LDAS study) in
361 which the ensemble was used but no observation data were assimilated. Please note that
362 in the NoDA experiment, the true rainfall rate and saturated hydraulic conductivity were
363 unknown so that I could not accurately estimate the synthetic true state variables. I will
364 evaluate how this negative impact of uncertainties in rainfall and saturated hydraulic
365 conductivity can be mitigated by data assimilation in the DA experiment.

366

367 As evaluation metrics, root-mean-square-error (RMSE) was used:

368
$$\text{RMSE} = \sqrt{\frac{1}{k} \sum_{i=1}^k (F_i - T)^2} \quad (18)$$

369 where k is the ensemble number, F_i is the volumetric soil moisture simulated by the i -th
370 member in the DA or NoDA experiment, T is the volumetric soil moisture simulated by
371 the synthetic reference run. I used all ensemble members to calculate RMSE because I
372 should evaluate not only if the ensemble mean is consistent to the synthetic truth, but also
373 if the extremely large ensemble spread simulated in the NoDA experiment is
374 appropriately reduced.

375

376 To evaluate the impact of data assimilation, the improvement rate (IR) was defined and
377 calculated by the following equation:

$$378 \quad IR = \frac{\overline{RMSE}_{DA} - \overline{RMSE}_{NoDA}}{\overline{RMSE}_{NoDA}} \quad (19)$$

379 where \overline{RMSE}_{DA} and \overline{RMSE}_{NoDA} are time-mean RMSE of the DA and NoDA
380 experiments, respectively. The negative IR indicates that data assimilation positively
381 impacts the simulation of soil moisture. The metrics described above was calculated in
382 the whole domain. In the DA experiment, soil moisture values before the update by ETKF
383 (i.e. initial guess) were used to calculate the metrics.

384

385 Four of 120-hour rain/no rain cycles were applied so that the computation period was 480
386 hours. The spin-up results in the first 120 hours were not used to calculate the evaluation

387 metrics. Since the steady state of groundwater level is not the scope of this paper, the long
388 spin-up is not absolutely necessary.

389

390

391 **3.1.2. Results**

392 Figure 2a shows the IR of the LOW_K-UP_O experiment. The time series of the DA and
393 NoDA experiment and the synthetic reference run in the LOW_K-UP_O experiment can
394 be found in Figure S1. The data assimilation efficiently propagates the information of the
395 observations located in the upper part of the slope (see the black arrow in Figure 2a) both
396 horizontally and vertically. Despite the uncertainty in rainfall and hydraulic conductivity,
397 RMSE is reduced by data assimilation not only directly under the observation but also the
398 lower part of the slope where it does not rain. The estimated $K_{s,surface} \approx 0.00508$ [m/h]
399 by ETKF is mostly identical to the synthetic truth. However, the increase of RMSE by
400 data assimilation can be found at the left edge of the domain, which is far from the location
401 of the observation. The impact of data assimilation on the surface soil moisture simulation
402 is small because the volumetric soil moisture's RMSE of the NoDA experiment in this
403 surface soil layer is already small ($\leq 0.01\text{m}^3/\text{m}^3$) in the case of the LOW_K reference so
404 that any improvements do not make sense.

405

406 Figure 2b shows the IR of the LOW_K-DOWN_O experiment (see also Figure S2 for
407 time series). The IR's spatial pattern of the LOW_K-DOWN_O experiment is similar to
408 that of the LOW_K-UP_O experiment except for the left edge of the domain. It is
409 promising that I can accurately infer soil moisture in the region where it heavily rains
410 from the shallow soil moisture observations in the region where it does not rain. The
411 estimated $K_{s,surface} \approx 0.00512$ [m/h] by ETKF is mostly identical to the synthetic truth.

412

413 Figure 3a shows the difference of time-mean RMSEs (\overline{RMSE}_{DA} in equation (18))
414 between the LOW_K-UP_O and LOW_K-DOWN_O experiments. Although observing
415 the lower part of the slope slightly improves the soil moisture simulation at the left edge
416 of the domain compared with observing the upper part of the slope (the reason for it will
417 be explained later), there are few differences between the UP_O and DOWN_O scenarios
418 in the case of the LOW_K reference. The soil moisture observations have large
419 representativeness and I can efficiently infer soil moisture in the soil columns which are
420 horizontally and vertically far from the observations.

421

422 Figure 2c shows the IR of the HIGH_K-UP_O experiment (see also Figure S3 for time
423 series). The data assimilation significantly reduces RMSE of the soil moisture simulation
424 directly under the observations (see the black arrow in Figure 2c), which indicates that
425 the data assimilation efficiently propagates the information of the observations vertically.
426 The saturated hydraulic conductivity estimated by ETKF is mostly identical to the
427 synthetic truth ($K_{s,surface} \approx 0.0204$ [m/h]). However, the impact of the data assimilation
428 on the soil moisture simulation in the lower part of the slope around $x=1500$ m is marginal
429 although there are large RMSE in the NoDA experiment ($>0.05\text{m}^3/\text{m}^3$) at the edge of the
430 area where topography-driven surface flow reaches in the HIGH_K reference (see Figure
431 1d).

432

433 Figure 2d shows the IR of the HIGH_K-DOWN_O experiment (see also Figure S4 for
434 time series). Although the observations in the lower part of the slope (see the black arrow
435 in Figure 2d) significantly contribute to improving the soil moisture simulation in the
436 downstream area of the observation and accurately estimating $K_{s,surface} \approx 0.0208$
437 [m/h], the impact of the data assimilation on the shallow soil moisture simulation around
438 $x=500\sim 1000$ m is marginal. As I found in the LOW_K-DOWN_O experiment, the shallow
439 soil moisture observations in the region where it does not rain can improve the soil

440 moisture simulation in the region where it heavily rains. However, the IR of the HIGH_K-
441 DOWN_O experiment in the upper part of the slope is smaller than that of the LOW_K-
442 DOWN_O experiment (see Figure 2b and 2d).

443

444 The high representativeness of the observations which I found in the case of the LOW_K
445 reference (i.e. the small difference of RMSEs between two observation scenarios) cannot
446 be found in the case of the HIGH_K reference. Figure 3b shows the difference of time-
447 mean RMSEs ($\overline{RMSE_{DA}}$ in equation (18)) between the HIGH_K-UP_O and HIGH_K-
448 DOWN_O experiments. Compared with the LOW_K reference case (Figure 3a), there
449 are significant differences between the UP_O and DOWN_O scenarios in the case of
450 higher saturated hydraulic conductivity. In this case, the vertical propagation of the
451 observations' information is more efficient than the horizontal propagation.

452

453 The relatively low efficiency of the data assimilation and the low representativeness of
454 the soil moisture observations in the case of the HIGH_K reference are caused by the
455 non-Gaussian background error distribution. I calculated KLD by comparing the PDF of
456 the NoDA ensemble (p in equation (17)) with the Gaussian PDF which has the mean and
457 variance of the NoDA ensemble (q in equation (17)). Figure 4 shows that the NoDA

458 ensemble in the case of the HIGH_K reference has stronger non-Gaussianity than the case
459 of the LOW_K reference especially in the shallow soil layers. The strong non-Gaussianity
460 of the NoDA ensemble generated from the HIGH_K reference can be found at the edge
461 of the area where the topography-driven surface flow reaches (Figure 1d). Figure 5 shows
462 that there is the bifurcation of the ensemble in this region when the ensemble is generated
463 from the HIGH_K reference. The process of topography-driven surface flows is switched
464 on if and only if the surface soil is saturated (see equation (6)) so that the ensemble tends
465 to be bifurcated into the members with surface flows and without surface flows. As I
466 mentioned in section 2.2, in the ETKF, the estimation of the state and parameter variables
467 is optimal if and only if the model's error has the Gaussian PDF and the relationship
468 between observed variables and unobserved variables is linear. Therefore, the non-
469 Gaussianity of the prior ensemble induced by the strong non-linear dynamics of surface
470 lateral flows makes the ETKF inefficient. It is more difficult to reconstruct 3-D fields of
471 soil moisture in high conductivity soils since the 1-D vertical water movement is more
472 dominant. The absolute RMSE of the NoDA experiment in the HIGH_K reference is
473 larger than the LOW_K reference in many places (not shown). Please note that the non-
474 Gaussianity can also be found in the LOW_K reference at the edge of the domain
475 ($x=500\text{m}$) due to the non-linear dynamics of surface lateral flows, which causes the

476 degradation of the soil moisture simulation in the LOW_K-UP_O experiment (see Figure
477 2a).

478

479

480 One of the major simplifications in this experiment is spatially homogeneous surface
481 saturated hydraulic conductivity. The optimization of it can efficiently improve the soil
482 moisture simulation in the whole domain. However, the optimization of this
483 homogeneous surface saturated hydraulic conductivity has a limited impact on the soil
484 moisture simulation. Figure S5 shows the IR of the HIGH_K-DOWN_O experiment
485 where the parameter optimization by ETKF is switched off. Even if I do not optimize the
486 surface saturated hydraulic conductivity, I could obtain the similar IR to the original
487 experiment and the shallow soil moisture observations in the region where it does not rain
488 can improve the soil moisture simulation in the region where it heavily rains. The
489 horizontal propagation of the observations' information shown in this experiment was
490 brought out not only by the estimation of spatially homogeneous saturated hydraulic
491 conductivity but also by the adjustment of state variables (i.e., pressure head and
492 volumetric soil moisture).

493

494 Please note that the improvement of the soil moisture simulation cannot be found if the
495 topography-driven surface flow is neglected. Figure S6 shows the IR of the LOW-
496 K_DOWN-O experiment where the topography-driven surface flow is neglected in the
497 ParFlow simulation. Please note that although many conventional land surface models
498 neglected or parameterized lateral flows, this assumption can be applied only in the coarse
499 spatial resolution ($>25\text{km}$), which is not the case of this experimental setting. The
500 imperfect model physics of ParFlow substantially degrades the skill to simulate soil
501 moisture and data assimilation cannot compensate this degradation. This point will also
502 be discussed in the section 3.2 more deeply.

503

504 **3.2. Simple 3-D slope with heterogeneous hydraulic conductivity**

505 **3.2.1. Experiment design**

506 To further demonstrate how land data assimilation works with topography-driven surface
507 lateral flows, I implemented another synthetic experiment which is more realistic than
508 that shown in section 3.1. The 3-D domain has a horizontal extension of $4000\text{ m}\times 4000\text{ m}$
509 and a vertical extension of 3 m . The domain was horizontally discretized into 40×40 grid
510 cells with a size of $100\text{ m}\times 100\text{ m}$ and vertically discretized into 30 grid cells with a size
511 of 0.1 m . The domain has a 10% slope in both x and y directions (see Figure 6a). The

512 parameters of the van Genuchten relationship, porosity and Manning's coefficient were
513 set to the same variables for the synthetic experiment in section 3.1.

514

515 The spatially heterogeneous surface saturated hydraulic conductivity was generated
516 following Kurtz et al. (2016). The field of $\log_{10}(K_{s,surface})$ was generated by two-
517 dimensional unconditioned sequential Gaussian simulation. A Gaussian variogram with
518 nugget, sill, and range values of $0.0 \log_{10}(\text{m/h})$, $0.1 \log_{10}(\text{m}^2\text{h}^2)$, and 12 model
519 grids (1200m), respectively was used to simulate the spatial distribution of
520 $\log_{10}(K_{s,surface})$. A constant value of $-2.30 \log_{10}(\text{m/h})$ (i.e. 0.005 (m/h)) was added
521 to the generated field so that the mean of the logarithm of surface saturated hydraulic
522 conductivity was set to -2.30 (i.e. $0.005(\text{m/h})$). This method to generate the field of the
523 saturated hydraulic conductivity has been used previously (e.g., Kurtz et al. 2016).
524 Subsurface saturated hydraulic conductivity was calculated by equation (3). An ensemble
525 of 51 realizations of $\log_{10}(K_{s,surface})$ was generated and one of them was chosen as a
526 synthetic reference (Figure 6a). The remaining 50 members were used for data
527 assimilation experiments.

528

529 A rainfall rate $R(x,y)$ (mm/h) was modelled by a logistic function:

530
$$R(x, y) = \frac{R_{max}}{1+100\exp(-0.2 \times \frac{x+y}{2})} \quad (20)$$

531 where x and y are horizontal grid numbers ($1 \leq x \leq 40, 1 \leq y \leq 40$). In the synthetic
532 reference, the maximum rainfall rate in the domain, R_{max} , was set to 50 (mm/h) (Figure
533 6b). This rainfall rate was applied for 3 hours and then the period with no rainfall and
534 evaporation of 0.075mm/h lasted for 117 hours. For data assimilation experiment, an
535 ensemble of 50 realization of $R(x, y)$ was generated by adding a lognormal
536 multiplicative noise to R_{max} of the synthetic reference. The two parameters of the
537 lognormal distribution, commonly called μ and σ , were set to 0 and 0.15, respectively.
538

539 Figure 6c shows the distribution of surface soil moisture in the synthetic reference run.
540 Strong rainfall rate applied in the upper part of the slope generates the topography-driven
541 surface lateral flows. The virtual hourly observations were generated by adding the
542 Gaussian white noise, whose mean is zero and standard deviation is $0.05 \text{ m}^3/\text{m}^3$, to the
543 volumetric surface soil moisture simulated by the synthetic reference run. Unlike the
544 experiment in section 3.1, only surface soil moisture can be observed in this synthetic
545 experiment, which makes this experiment more realistic since satellite sensors can
546 observe only surface soil moisture. Three different observing networks with different
547 observation densities were used (Figure 7). The observing networks shown in Figure 7a,

548 7b, and 7c have totally 1, 9, and 361 observations and are called obs1, obs9, and obs361,
549 respectively.

550

551 In the DA experiments, those virtual observations of surface soil moisture were
552 assimilated every hour to adjust pressure head and saturated hydraulic conductivity. As I
553 did in the section 3.1, the NoDA experiments were also implemented. The two different
554 configurations of ParFlow were used for both DA and NoDA experiments. In the first
555 configuration, called OF (Overland Flow), Parflow explicitly solves overland flows. In
556 the second configuration, called noOF, Parflow assumes the flat terrain for surface flows
557 so that no overland flows are generated. Since the synthetic reference run explicitly
558 considers the topography-driven surface flow, the configuration of noOF assumes that the
559 model physics is imperfect. I implemented 8 numerical experiments which are
560 summarized in Table 2. For example, the OF_DA_obs9 experiment is the data
561 assimilation experiment with the observing network shown in Figure 7b, in which
562 Parflow explicitly solves the topography-driven surface flow. The noOF_NoDA is the
563 model run without assimilating observations, in which Parflow does not consider the
564 topography-driven surface flow.

565

566

567 **3.2.2. Results**

568 Figure 8a shows the RMSE of soil moisture simulation of a second soil layer (i.e. 10-
569 20cm soil depth) in all 8 experiments (the same conclusion described below can be
570 obtained by analyzing all of shallow soil layers). When Parflow explicitly solves the
571 topography-driven surface flow, data assimilation substantially reduces RMSE of the soil
572 moisture simulation (green bars in Figure 8a). The OF_DA_obs361 experiment has the
573 smallest RMSE so that a denser observing network is beneficial to estimate soil moisture,
574 although there is the stalled improvement from the OF_DA_obs1 experiment to the
575 OF_DA_obs9 experiment (the reason for it will be explained later). Figure 8b shows the
576 RMSE of the estimation of saturated surface hydraulic conductivity in all 8 experiments.
577 Data assimilation also reduces the uncertainty in model's parameters (green bars in Figure
578 8b). However, the OF_DA_obs361 experiment has larger RMSE than the other DA
579 experiments. This is because the adjustment of hydraulic conductivity in the
580 OF_DA_obs361 experiment greatly mitigates not only the errors induced by uncertainty
581 in hydraulic conductivity but those induced by uncertainty in rainfall rate. In the OF
582 configuration, there are two sources of errors, rainfall rate and hydraulic conductivity.
583 However, data assimilation can adjust only hydraulic conductivity in this study. Although

584 it is expected that the adjustment of hydraulic conductivity mainly mitigates the errors of
585 simulated volumetric soil moisture induced by uncertainty in hydraulic conductivity, it
586 also greatly mitigates those induced by uncertainty in rainfall rate by adjusting the
587 parameter in the incorrect direction when the number of observations is large. Therefore,
588 the assimilation of a large number of observations degrades the estimation of saturated
589 hydraulic conductivity despite the improvement of the soil moisture simulation.

590

591 The noOF_NoDA experiment has larger RMSE than the OF_NoDA experiment due to
592 the negligence of the topography-driven surface flow. In the noOF configuration, data
593 assimilation also improves the soil moisture simulation (red bars in Figure 8a). The
594 noOF_DA_obs361 experiment outperforms the OF_NoDA experiment so that data
595 assimilation with a dense observing network can compensate the negative impact of
596 neglecting the topography-driven surface flow. Although data assimilation positively
597 impacts the parameter estimation, the denser observing network cannot reduce RMSE of
598 hydraulic conductivity estimation (red bars in Figure 8b). The negative impact of the
599 dense observations in the noOF_DA_obs361 experiment on the parameter estimation is
600 larger than in the OF_DA_obs361 experiment. In addition to rainfall rate and hydraulic
601 conductivity, the imperfect model physics (i.e., no topography-driven surface flow) is the

602 source of error in the noOF configuration. The assimilation of a large number of
603 observations degrades the estimation of saturated hydraulic conductivity because it
604 greatly mitigates the impact of all systematic errors which comes from three different
605 sources only by adjusting hydraulic conductivity.

606

607 Figure 9 shows the difference of RMSE of the soil moisture simulation between the DA
608 experiments and the OF_NoDA experiment. In the DA configuration, the improvement
609 of the soil moisture estimation can be found in a large area even if there is a single
610 observation in the center of the domain (Figure 9a). Figure 9b shows that the increase of
611 the number of observations substantially improves the soil moisture simulation in the
612 region which is affected by topography-driven surface flow (see also Figure 6c). However,
613 the skill to simulate soil moisture is severely degraded in the lower-left corner of the
614 domain, which causes the stalled improvement from the OF_DA_obs1 experiment to the
615 OF_DA_obs9 experiment shown in Figure 8a. Figure 9c shows that although the far
616 denser observing network can slightly mitigate this degradation, increasing the number
617 of observations cannot efficiently solve this issue. This degradation is caused by the
618 bifurcation of ensemble members at the edge of the area where topography-driven surface
619 flow reaches (Figure S7). Figure 10 shows KLD in the OF_NoDA and noOF_NoDA

620 experiments. Figure 10a clearly shows that the ensemble simulation of volumetric soil
621 moisture generates the strong non-Gaussianity at the edge of the area where topography-
622 driven surface flow reaches, which harms the efficiency of the ETKF. This finding is
623 consistent to what I found in the previous experiment in section 3.1.

624

625 In the noOF configuration, there are large errors in the area around $500 \leq x, y \leq 1500$
626 (not shown) since the increase of soil moisture in this area is caused by the topography-
627 driven surface flow which is neglected in the noOF configuration. Figures 9d and 9e show
628 that the sparse observations cannot completely remove this degradation caused by
629 imperfect model physics. Figure 9f shows that the noOF_DA_obs361 can outperform the
630 OF_NoDA experiment in exchange for the degradation of the parameter estimation as I
631 found in Figure 8. The unstable behavior of the ETKF found in the OF configuration does
632 not occur when the topography-driven surface flow is neglected since the ensemble
633 simulation does not generate the non-Gaussian background distribution (Figure 10b).
634 Although ETKF can significantly improve the simulation skill of the hyperresolution land
635 model in many cases, I found its limitation when it is applied to the problems with the
636 topography-driven surface lateral flows. Figure 10 clearly indicates that this limitation
637 appears only if lateral water flows are explicitly considered.

638

639

640

641 **4. Discussion**

642 In this study, I revealed that the hyperresolution integrated surface-subsurface
643 hydrological model gives the unique opportunity to effectively use soil moisture
644 observations to improve the soil moisture simulation in terms of a horizontal propagation
645 of observation's information in a model space. I found that the explicit calculation of the
646 topography-driven surface flow has an important role in propagating the information of
647 soil moisture observation horizontally by data assimilation even if there is considerable
648 heterogeneity of meteorological forcing. It is possible that the soil moisture observations
649 in the area where it does not heavily rain can improve the soil moisture simulation in the
650 severe rainfall area.

651

652 This potential cannot be brought out in the conventional 1-D LSM where sub-grid scale
653 surface runoff is parameterized and the surface flows in one grid do not move to the
654 adjacent grids. I found that neglecting the topography-driven surface flow causes
655 significant bias in the soil moisture simulation and this bias cannot be completely

656 mitigated by data assimilation especially in the case of a sparse observing network.

657 However, I found that even if the model uses imperfect physics which neglects the

658 interaction between topography-driven surface lateral flows and subsurface soil moisture,

659 assimilating soil moisture observations into the model's three-dimensional state and

660 parameter space can improve the skill to estimate soil moisture and hydraulic conductivity.

661 This finding implies that the conventional 1-D LSM with full 3-D data assimilation may

662 be a computationally cheap and reasonable choice in some cases although many land data

663 assimilation systems with the conventional 1-D LSM currently update state variables only

664 in a single model's horizontal grid which is identical to the location of the observation.

665

666 The conventional ensemble data assimilation (i.e. ETKF) severely suffers from the non-

667 Gaussian background error PDFs caused by the strongly nonlinear dynamics of the

668 topography-driven surface flow although it has been widely used by previous studies (e.g.,

669 Camporese et al. (2009); Camporese et al. (2010); Ridler et al. (2014); Zhang et al. (2015);

670 Kurtz et al. (2016); Zhang et al. (2018)). The efficiency of ETKF to propagate the

671 information of observations horizontally in the model space is limited in the edge of the

672 area where the topography-driven surface flow reaches. Please note that the low

673 representativeness of the soil moisture observations in the case of the HIGH_K reference

674 shown in section 3.1 is due to the limitation of the Kalman filter that the error PDFs need
675 to follow the Gaussian distribution to get the optimal estimation so that the increase of
676 the ensemble size cannot solve this issue. I implemented the data assimilation experiment
677 in the case of the HIGH_K reference with an ensemble size of 500, which is 10 times
678 larger than the original experiments shown in section 3.1, and found no significant
679 improvement of the soil moisture simulation (not shown). Some studies revealed that
680 volumetric soil moisture distributions follow the Gaussian distribution better than
681 pressure head so that they recommend updating soil moisture as a state variable (e.g.,
682 Zhang et al. (2018)). However, in this study, I found that volumetric soil moisture
683 distributions have bimodal structure and do not follow the Gaussian distribution. The
684 limitation of ensemble Kalman filters found in this study does not depend on the updated
685 state variables.

686

687 In addition, I found ensemble clustering in which the ensemble members are split into a
688 single outlier and the others (see Figures S1-S4). The previous studies found that this
689 ensemble clustering is generated by the non-Gaussian PDF (Anderson 2010; Amezcua et
690 al. 2012). Ensemble clustering shown in the analysis timeseries also implies that the non-

691 Gaussian PDF plays an important role in the data assimilation of the hyperresolution land
692 model.

693

694

695 The spatially dense soil moisture observations are needed to efficiently constrain state
696 variables at the edge of surface flows. High resolution soil moisture remote sensing based
697 on satellite active and passive combined microwave observations at the 1 km spatial
698 resolution (e.g., He et al. 2018) and the assimilation of those data (Lievens et al. 2017)
699 may be important in the era of the hyperresolution land modeling. High resolution
700 observations of surface inundated water from satellite imagery with a spatial resolution
701 finer than 100 m (e.g., Sakamoto et al. 2007; Arnesen et al. 2013) may also be useful.
702 However, the numerical experiment in section 3.2 implies that the dense observing
703 network of surface soil moisture cannot completely remove the negative impact of the
704 non-Gaussian background PDF.

705

706 As a possible heuristic approach to avoid the negative impact of the non-Gaussian
707 background PDF, I can omit to update the state variables in the edge of the area where
708 topography-driven surface flow reaches. The numerical experiments clearly indicate that

709 the negative impact of the non-linear physics and non-Gaussian PDF is found only in the
710 edge of flooding areas so that it is beneficial to simply omit to update the state variables
711 in this area. It is similar but not conceptually identical to the localization method, in which
712 the spurious correlation sampled by an ensemble is eliminated by spatially restricting the
713 impact of assimilating observation (e.g., Rasmussen et al. 2015; Anderson 2007; Bishop
714 and Hodyss 2009).

715

716 Reducing the uncertainty in rainfall positively impacts the efficiency of data assimilation
717 since the bifurcation of simulated soil moisture found in Figure 5c is originally induced
718 by the uncertainty in rainfall. Although assimilating land hydrological observations to
719 improve the rainfall input has been intensively investigated (e.g., Sawada et al. 2018;
720 Herrnegger et al. 2015; Crow et al. 2011; Vrugt et al. 2008), it has yet to be applied to
721 hyperresolution land models. Please note that the parameters of the lognormal distribution
722 to model the uncertainty in rainfall were specified to make the rainfall PDF similar to the
723 Gaussian distribution. I chose the lognormal distribution in order not to generate negative
724 rainfall values and I intended not to introduce non-Gaussianity into the external forcing.
725 The rainfall input which follows the Gaussian PDF was transformed into the non-

726 Gaussian PDF of the background error by the strongly nonlinear dynamics of the
727 topography-driven surface flow.

728

729 To explicitly consider non-Gaussianity and non-linear relationship between observed and
730 unobserved variables induced by the topography-driven surface flow, the particle filters
731 may be useful. The particle filter can represent a probability distribution (including non-
732 Gaussian distributions) directly by an ensemble. Particle filters have been intensively
733 applied to conventional 1-D LSMs (e.g., Sawada et al. 2015; Qin et al. 2009) and lumped
734 hydrological models (e.g., Yan and Moradkhani 2016; Vrugt et al. 2013). Although
735 particle filtering in a high dimensional system suffers from the “curse of dimensionality”
736 (e.g., Snyder et al. 2008), some studies developed the methodology to improve the
737 efficiency of particle filtering (e.g., van Leeuwen 2009; Poterjoy et al. 2019). The
738 applicability of particle filtering to 3-D hyperresolution land models should be assessed
739 in the future.

740

741 Since the synthetic numerical experiments in this paper adopted the simple and
742 minimalistic setting, the findings of this paper may be exaggerated. There are no river
743 channels in the synthetic experiment so that the skill to simulate river water level and

744 discharge cannot be discussed, which is the major limitation of this study. The simple
745 representation of soil properties is also a limitation of this study. Although the prior
746 uncertainty in rainfall and saturated hydraulic conductivity was arbitrary chosen in this
747 study, the specification of the prior knowledge is not straightforward in the real-world
748 applications. In future work, the contributions of the topography-driven surface runoff
749 process to the data assimilation of hydrological observations should be quantified in real-
750 world applications. In addition, in the virtual experiment of this paper, I neglected some
751 of the important land processes such as transpiration, canopy interception, snow, and
752 frozen soil. These processes affect the source term of equation (1) in hyper-resolution
753 land models (e.g., Shrestha et al. 2014). Since the inclusion of the neglected processes do
754 not change the structure of the original ParFlow, the findings of this study can be robust
755 to the models which include these processes. Although they are generally not primary
756 factors in the propagation of overland flows generated by extreme rainfall, which has a
757 shorter timescale than the neglected processes, those processes should be considered in
758 the future.

759

760 The other limitation of this study is that I could not thoroughly evaluate the skill of the
761 ensemble data assimilation to quantify the uncertainty of its prediction. Following

762 Abbazadeh et al. (2019), I calculated the 95% exceedance ratio and found that the
763 ensemble forecast was systematically overconfident (not shown). In the synthetic
764 experiments of this study, the number of rainfall events was small, and the timing and
765 magnitude of rainfall were not diversified. Due to this limited amount of data, it is difficult
766 to deeply discuss the accuracy of the quantified uncertainty by data assimilation. While
767 the skill of lumped hydrological models was often evaluated by the probabilistic
768 performance measures such as the 95% exceedance ratio (e.g., Abbazadeh et al. (2019)),
769 the uncertainty quantification of the simulation of hyper-resolution land models is in its
770 infancy. How surface lateral flows affect the accuracy of the uncertainty quantification by
771 data assimilation should be investigated using more realistic data.

772

773

774 **5. Conclusions**

775 The simplified synthetic experiments of this study indicate that topography-driven lateral
776 surface flows induced by heavy rainfalls do matter for data assimilation of hydrological
777 observations into hyperresolution land models. Even if there is extreme heterogeneity of
778 rainfall, the information of soil moisture observations can be propagated horizontally in
779 the model space and the soil moisture simulation can be improved by the ensemble

780 Kalman filter. However, the nonlinear dynamics of the topography-driven surface flow
781 induces the non-Gaussianity of the model error, which harms the efficiency of data
782 assimilation of soil moisture observations. It is difficult to efficiently constrain model
783 states at the edge of the area where the topography-driven surface flow reaches by linear-
784 Gaussian filters, which brings the new challenge in land data assimilation for
785 hyperresolution land models. Future work will focus on the real-world applications using
786 intense in-situ soil moisture observation networks and/or high-resolution satellite soil
787 moisture observations.

1119

1120

1121

122

123

Table 1. Configuration of the data assimilation experiments in section 3.1.

	hydraulic conductivity [m/h]	observation's location [m]
LOW_K-UP_O	0.005	2500
LOW_K-DOWN_O	0.005	1500
HIGH_K-UP_O	0.02	2500
HIGH_K-DOWN_O	0.02	1500

124

125

Table 2. Configuration of the data assimilation experiments in section 3.2

	overland flows	observing network
noOF_NoDA	none	no data assimilation
noOF_DA_obs1	none	Figure 7a
noOF_DA_obs9	none	Figure 7b
noOF_DA_obs361	none	Figure 7c
OF_NoDA	simulated	no data assimilation
OF_DA_obs1	simulated	Figure 7a
OF_DA_obs9	simulated	Figure 7b
OF_DA_obs361	simulated	Figure 7c

126

127

128

129

131

132 **Figure 1.** Distributions of volumetric soil moisture simulated by the synthetic reference runs. (a) The133 distribution of volumetric soil moisture [m^3/m^3] simulated by the LOW_K synthetic reference run at $t = 0\text{h}$.

134 The schematic of the configuration of the synthetic reference runs is also shown (see also section 3). (b) same

135 as (a) but at $t = 130\text{h}$. (c,d) same as (a,b) but for the HIGH_K synthetic reference run.

136

137

138

Figure 2. The improvement rates of the (a) LOW_K-UP_O, (b) LOW_K-DOWN_O, (c) HIGH_K_UP_O,

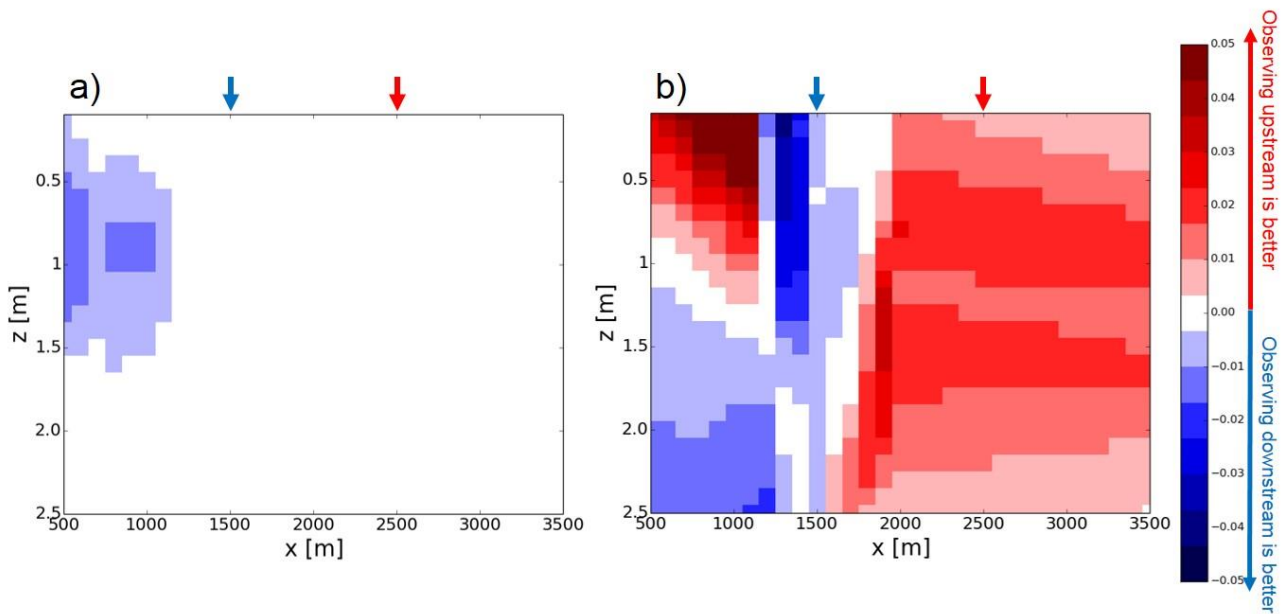

139

(d) HIGH_K-DOWN_O experiments (see Table 1 and section 3). Black arrows show the locations of the soil

140

moisture observations in each experiment.

141

142

143 **Figure 3.** (a) The difference of time-mean RMSEs between the LOW_K-UP_O and LOW_K-DOWN_O
 144 experiments (see Table 1 and section 3). Red (blue) color indicates that the observations in the upper (lower)
 145 part of the slope reduce time-mean RMSE by data assimilation better than those in the lower (upper) part of
 146 the slope (see also arrows which are the locations of the observations). (b) same as (a) but for the difference
 147 between the HIGH_K-UP_O and HIGH_K-DOWN_O experiments.

148

149

150 **Figure 4.** The Kullback-Leibler divergence of the NoDA experiment generated by (a) the LOW_K reference

151 and (b) the HIGH_K reference at $t = 130\text{h}$ (see also Figure 1b and 1d).

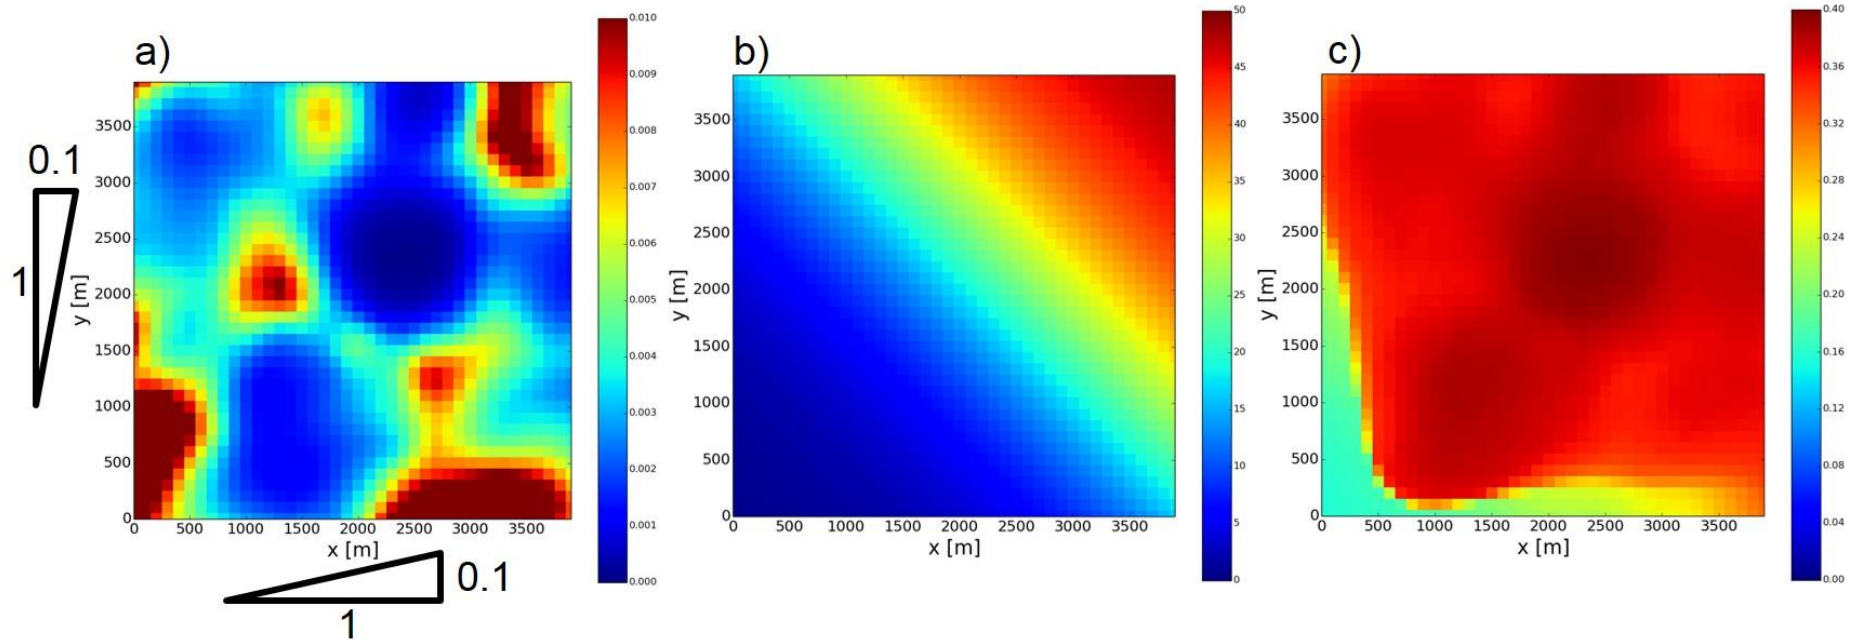

152

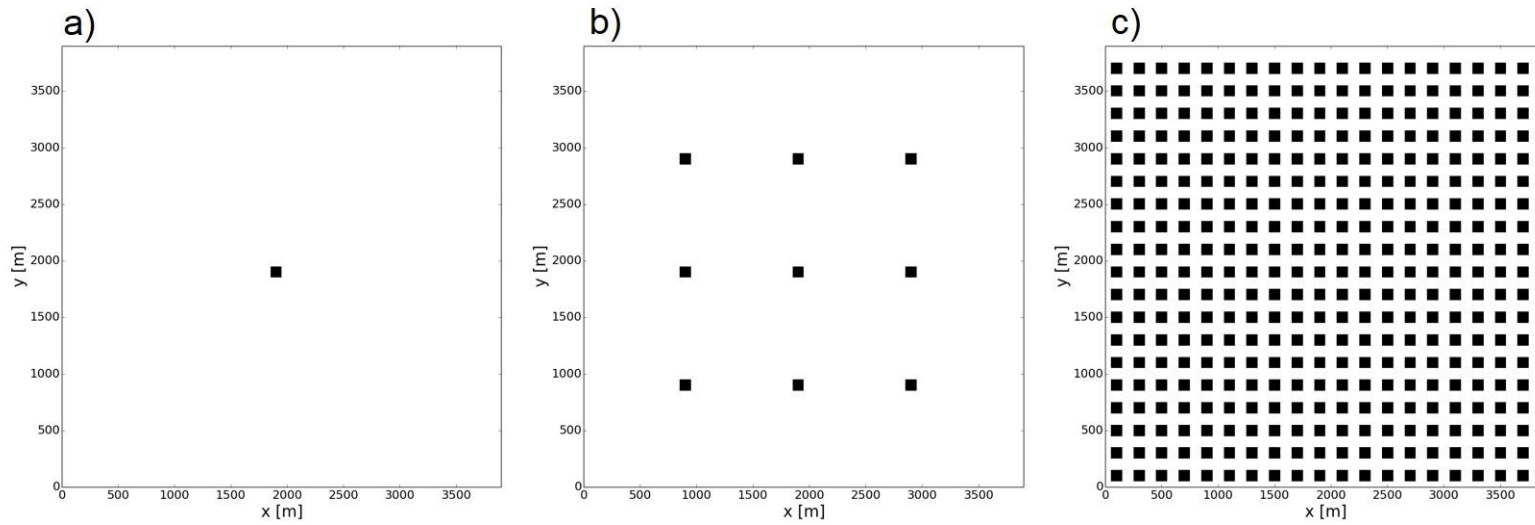

153

154 **Figure 5.** (a) The histogram (blue bars) of the volumetric soil moisture simulated by the NoDA experiment
 155 (see section 3) with the LOW_K reference at $x=1500\text{m}$, $z=0.5\text{m}$, and $t=130\text{h}$ (see also Figure 4). Red line
 156 shows the Gaussian distribution with the mean and variance sampled by the ensemble. (b) same as (a) but at
 157 $x=2500\text{m}$, $z=0.5\text{m}$, and $t=130\text{h}$. (c) same as (a) but for the HIGH_K reference. (d) same as (c) but at $x=2500\text{m}$,
 158 $z=0.5\text{m}$, and $t=130\text{h}$.

159

162 **Figure 6.** (a) Distribution of surface saturated hydraulic conductivity [m/h] in the synthetic reference. (b) Distribution of rainfall rate [mm/h] in the synthetic
163 reference. (c) Surface volumetric soil moisture [m³/m³] at t = 5 [h] in the synthetic reference.

165

166

Figure 7. Observing networks. Black boxes are observed grids. (a) obs1, (b) obs9, (c) obs361 See also section 3.2.1.

167

169

170

Figure 8. Time-mean RMSEs of the estimation of (a) soil moisture and (b) hydraulic conductivity. Red and

171

green bars are results of the noOF and OF configuration, respectively (see section 3.2.1 and Table 2).

172

173

174

175

Figure 9. Differences of time-mean soil moisture RMSEs between the DA experiments and the OF_NoDA experiment. (a) OF_DA_obs1, (b) OF_DA_obs9 (c) OF_DA_obs361 (d) noOF_DA_obs1, (e) noOF_DA_obs9, (f) noOF_DA_obs361.

177

178 **Figure 10.** The Kullback-Leibler divergence of ensemble members generated by the (a) OF_NoDA and (b)179 noOF_NoDA experiments at $t = 4$ [h].
