Abstract.

The influence of the initial soil moisture conditions on extreme climate extreme over West Africa was investigated using the fourth generation of Regional Climate Model version 4 (non-hydrostatic) coupled to the version 4.5 of the Community Land Model (RegCM4-CLM4.5) at 25 km spatial resolution. Sensitivity studies were performed for five years (2001-2005), with initial soil moisture conditions prescribed on June 1 and simulations performed over four months (120 days) from June to September (JJAS). The Results were presented for two extreme years 2003 (above normal precipitation year) and 2004 (below normal precipitation year) to estimate the impact limits of internal forcing of initial soil moisture on the new non-hydrostatic dynamical core of RegCM4. We initialized the control runs with the reanalysis soil moisture of the European Centre Meteorological Weather Forecast's reanalysis of the 20th century data (ERA20C), while for the dry and wet experiments, we initialized the soil moisture at the maximum and minimum value over West Africa studied domain, respectively. The impact on extreme precipitation indices of the initial soil moisture, especially over the central Sahel, is linear; that is, dry (wet) experiments decrease (increase) precipitation extreme indices only for precipitation indices related to the number of precipitation events, not for those related to the event intensity. Initial soil moisture conditions unequally affect the daily minimum and maximum temperatures. A stronger impact is found on the maximum temperature than the minimum temperature. Over the entire West African domain, wet (dry) experiments cause a decrease (increase) in maximum temperature. The impact of initial soil moisture conditions on the indices related to the minimum temperature (TNx and TNn indices) is linear only for TNx index over central Sahel, that is, dry (wet)

32 experiments cause an increase (a decrease) in the TN_x index. The performance of RegCM4-
33 CLM4.5 in simulating the ten extreme rainfall and temperature indices used in this study are
34 also highlighted.

35

36 **1 Introduction**

37 West Africa experienced large rainfall variability during the late 1960s. This variability often
38 leads to flooding events, severe drought, and regional heatwaves, which have major
39 economic, environmental, and societal impacts (Easterling et al., 2000; Larsen, 2003). In
40 recent years, climate extremes have attracted much interest because they are expected to occur
41 more frequently (International Panel on Climate Change (IPCC), 2012) than changes in the
42 mean climate. Yan and Yang (2000) showed that for many cases, the extreme climate changes
43 were five to ten times greater than climate mean change. Many key factors or physical
44 mechanisms could be the cause of the increase in climate extremes (Nicholson, 1980; Le
45 Barbé et al., 2002), such as the effect of increasing greenhouse gases in the atmosphere on the
46 intensification of hot extremes (IPCC, 2007), sea surface temperature (SST) anomalies
47 (Fontaine and Janicot 1996; Folland et al., 1986), and land surface conditions (Philippon et
48 al., 2005; Nicholson (2000)). In addition, smaller-scale physical processes, including the
49 interactions of land–atmosphere coupling, can lead to changes in climate extremes. For the
50 European summer, the influence of soil moisture on land–atmosphere coupling using a
51 regional climate model and focused on the extremes and trends in precipitation and
52 temperature have been studied by Jaeger and Seneviratne (2011). For extreme temperatures,
53 their studies have shown that interactions of soil moisture and climate have a significant
54 impact, while for extreme precipitation, they only influence the frequency of wet days. Over
55 Asia, Liu et al. (2014) studied the impact on subsequent precipitation and temperature of soil
56 moisture anomalies using a regional climate model. They showed that wet (dry) experiences
57 decrease (increase) the hot extremes, decrease (increase) the drought extremes, and increase
58 (decrease) the cold extremes in a zone with strong soil moisture–atmospheric coupling.
59 However, none of these studies examined the impacts of the initial soil moisture conditions on
60 subsequent climate extremes using a regional climate model over West Africa. In part 1, the
61 influence of initial soil moisture on the climate mean was based on a performance assessment
62 of the Regional Climate Model coupled with the complex Community Land Model
63 (RegCM4-CLM4.5) performed by Koné et al. (2018), where the ability of the model to

64 reproduce the climate mean has been validated. In Part 2, before starting to study the
65 influence of initial soil moisture on climate extremes, it was necessary to assess the
66 performance of RegCM4-CLM4.5 in simulating the ten (10) indices of temperature and
67 precipitation extremes used in this study. This has never been done before in West Africa with
68 this version of RegCM with a non-hydrostatical scheme; therefore, we separated the work in
69 two parts, a first one assessing the ability of the model to simulate the climate extreme
70 indices, and a second one investigating how and what is the time limit of the effect of initial
71 soil moisture condition on the magnitude or duration of these climate extremes. The
72 manuscript is organized as follows: Section 2 describes the RegCM4 model, the experimental
73 design, and the methodology used in this study; Section 3 presents results of the two parts of
74 the work and Section 4 documents the main conclusions.

75 **2. Model, experimental design and methodology**

76 **2.1 Model description and numerical experiment**

77 The fourth generation of the Regional Climate Model (RegCM4) of the International Centre
78 for Theoretical Physics (ICTP) is used in this study. Since this version, physical
79 representations have been subject to a continuous process of implementation and
80 development. The release used in this study was RegCM4.7. The non-hydrostatic dynamical
81 core of the MM5 (Mesoscale Model version 5, Grell et al., 1994) was ported to RegCM4
82 while maintaining the existing hydrostatic core. RegCM4 is a limited-area model using a
83 vertical grid sigma hydrostatic pressure coordinate and a horizontal grid of the Arakawa B-
84 grid (Giorgi et al., 2012). The radiation scheme is from the NCAR-CCM3 (National Center
85 for Atmospheric Research and the Community Climate Model Version 3) (Kiehl et al., 1996),
86 and the aerosol representation is from Zakey et al. (2006) and Solmon et al. (2006). The large-
87 scale precipitation scheme used in this study is from Pal et al. (2000); the moisture scheme is
88 called the SUBgrid EXplicit moisture scheme (SUBEX), which considers the sub-grid
89 variability in clouds. The accretion and evaporation processes for stable precipitation are from
90 Sundqvist et al. (1989). The sensible heat and water vapour in the planetary boundary layer
91 over land and ocean, as well as the turbulent transport of momentum, is reported by Holtslag
92 et al. (1990). The heat and moisture and momentum of ocean surface fluxes are from Zeng et
93 al. (1998). Convective precipitation and land surface processes in RegCM4.7 are represented
94 in several options. Based on Koné et al. (2018), the convective scheme of Emanuel (1991) is
95 used. The parameterization of land surface processes is from CLM4.5 (Oleson et al., 2013). In

96 each grid cell of CLM4.5, there are sixteen different plant functional types and ten soil layers
97 (Lawrence et al., 2011; Wang et al., 2016). The integration of RegCM4 over the West African
98 domain is shown in Fig. 1 with eighteen vertical levels and 25 km of horizontal resolution
99 (182 × 114 grid points; from 20°W–20°E and 5°S–21°N). The European Centre for Medium-
100 Range Weather Forecasts reanalysis (EIN75; Uppala et al., 2008; Simmons et al., 2007)
101 provides the initial and boundary conditions. The sea surface temperatures (SSTs) are derived
102 from the National Oceanic and Atmosphere Administration optimal interpolation weekly
103 (NOAA; OI_WK) (Reynolds et al., 1996). The topography is derived from the United States
104 Geological Survey (USGS) Global Multi-resolution Terrain Elevation Data (GMTED;
105 Danielson et al., 2011) at a spatial resolution of 30 arc-s, which is an update of the Global
106 Land Cover Characterization (GTOPO; Loveland et al., 2000) dataset.
107 The initial soil moisture sensitivity does not exceed four months (Hong and Pan., 2000; Kim
108 and Hong, 2006). (Hong and Pan., 2000; Kim and Hong, 2006). As mentioned in Part I, we
109 performed sensitivity studies on the initial soil moisture conditions over the West African
110 domain for June–July–August–September (JJAS) from 2001 to 2005 with a focus on two
111 contrasting years, 2003 (above normal precipitation year) and 2004 (below normal
112 precipitation year). The two years, 2003 and 2004 (respectively, the wettest and driest years
113 among the five years), were selected to estimate the limits of the impact of internal soil
114 moisture forcing on the new non-hydrostatic dynamical core of RegCM4. Several previous
115 studies used two extreme years for their sensitivity study of initial soil moisture conditions on
116 the models (e. g., Hong et al., 2000; Kim and Hong, 2006). We set up an ensemble of three
117 experiments, each with simulations starting from June 1 to September 30. For each
118 experiment, we applied (i) a reference initial soil moisture condition, (ii) a wet initial soil
119 moisture condition, and (iii) a dry initial soil moisture condition. Kang et al. (2014) compared
120 different land surface schemes (BATS and CLM3) and different spin-up periods to simulate
121 June–July–August precipitation and recommended a 7-day spin-up period. In this study, we
122 used CLM4.5 as the land surface scheme (Oleson et al., 2013), which has a more complex
123 design. The first seven days (Kang et al., 2014) were excluded from the analysis as a spin-up
124 period. We used the soil moisture from the reanalysis of the European Centre Meteorological
125 Weather Forecast's Reanalysis of the 20th century (ERA20C) to initialize the control runs.
126 Wet and dry experiments were initialized for the soil moisture (in volumetric fraction m³•m⁻³)

127 3) at the maximum (= 0.489) and minimum (= 0.117.10-4) soil moisture values over West
128 Africa derived from the ERA20C soil moisture dataset.

129 **2.2 Validation datasets and evaluation metrics**

130 Our investigation focused on the air temperature at 2 m and the precipitation over the West
131 African domain during JJAS for 2003 and 2004. The simulated precipitation fields are
132 validated with two observation datasets: the Climate Hazards Group Infrared Precipitation
133 Stations (CHIRPS) dataset from the University of California at Santa Barbara, available from
134 1981 to 2020 with 0.05° high-resolution data and the Tropical Rainfall Measuring Mission
135 3B43V7 (TRMM) dataset with 0.25° high-resolution data available from 1998 to 2013
136 (Huffman et al., 2007). We validated the 2-m temperature using two observation datasets: the
137 NOAA CPC global daily temperature from the Global Telecommunication System (GTS),
138 gridded at a horizontal resolution of 0.5° from 1979 to 2020 (Fan Y. and Huug van den Dool,
139 2008), and daily temperature from ERA-Interim (EIN) reanalysis at 0.25° of horizontal
140 resolution available from 1979 to 2020 (Dee et al., 2011). To compare the model simulations
141 with the observation datasets, we re-gridded all the products to 0.22° × 0.22° using a bilinear
142 interpolation method (Nikulin et al., 2012).

143 The performance of RegCM4-CLM4.5 to simulate the extreme indices was evaluated using
144 four selected sub-regions (Fig. 1) based on the previous work of Koné et al. (2018), which
145 correspond to different annual precipitation cycle features. We used the mean bias (MB),
146 which captures the small-scale differences between the simulation and observation. The
147 pattern correlation coefficient (PCC) is also used as a spatial correlation between model
148 simulations and observations to indicate the large-scale similarity degree.

149 To quantify the impact of soil moisture anomalies on climate extremes, in their work over
150 Asia, Liu et al. (2014) used the MBs in five subregions. In our study, we used the MBs and
151 the probability density functions (PDF, Gao et al. (2016); Jaeger and Seneviratne (2011)) for
152 this purpose to better capture how many grid points are impacted by initial soil moisture and
153 their highest value.

154 Significance of differences was tested for the control vs. sensitivity experiments. We used a
155 two-tailed Student's t-test at each grid point as in Liu et al. (2014) over Asia. Owing to the
156 multiplicity problem of independent tests and the spatial dependency of neighboring! grid
157 points, the significant results can only be seen as a crude estimate. Therefore, we perform the

158 land point area-weighted fraction with a statistical significance of 10% and display the
159 seasonal extreme indices maps for 2003 and 2004.

160

161 **2.3. Extreme rainfall and temperature indices**

162 In this study, to investigate the changes in precipitation and temperature in terms of duration,
163 occurrence, and intensity, six extreme temperature and four extreme rainfall indices were
164 examined using daily minimum and maximum temperature and daily rainfall data (Table 1).
165 These ten extreme indices are recommended by the Expert Team on Climate Change
166 Detection and Indices (ETCCDI, Peterson et al., 2001). We estimated the monthly values of
167 the indices, which allowed us to investigate seasonal variations.

168 **3. Results and discussion**

169 **3.1. Seasonal extreme rainfall**

170 In this section, we analyse six extreme rainfall indices based on daily precipitation in
171 RegCM4 simulations over West Africa. All precipitation indices were calculated for JJAS in
172 2003 and 2004. Table 2 summarizes the PCC and the MB of all precipitation indices studied
173 in this section for TRMM observation and model simulations derived from control
174 experiments with reanalysis of the initial soil moisture ERA20C with respect to CHIRPS
175 observations, calculated for the west Sahel, central Sahel, Guinea coast, and the entire West
176 African domain during JJAS 2003 and 2004.

177

178 **3.1.1 The index of the number of the wet days (R1mm index)**

179 Figure 2 shows the mean values of the number of wet days (R1mm index, in days) from
180 CHIRPS (Fig. 2a, d) and TRMM (Fig. 2b, e) observations and their corresponding simulated
181 control experiments (Fig. 2c, f) with the initial soil moisture derived from ERA20C
182 reanalysis. We have chosen CHIRPS because of its high resolution, mainly because this
183 product has been widely assessed and used for the study of extreme events in West Africa by
184 Bichet et al. (2018a, b) and Didi et al. (2020). The two observation datasets CHIRPS (Fig. 2a,
185 d) and TRMM (Fig. 2b, e) show a similar large-scale pattern over the West African domain
186 with a PCC up to 0.98 (Table 2). The maximum values of the R1mm index were located over
187 mountainous regions such as the Cameroon Mountains, Jos Plateau, and Guinea Highlands,
188 while the minimum values of the R1mm index were found over the Sahel with the number of
189 wet days decreasing gradually from south to north. However, although the large-scale patterns

were similar, at the local scale, some differences were found in terms of the magnitude and spatial extent of these maxima and minima. The TRMM datasets underestimated the number of wet days over the central and west Sahel, and they were overestimated over the Guinea coast for both JJAS 2003 and JJAS 2004 (Table 2). A strongest underestimation was observed over the central Sahel with MB of approximately -6.76 and -7.51 days for JJAS 2003 and JJAS 2004, respectively (Table 2). However, the strongest overestimation was found over the Guinea coast with MB reached 8.89 and 10.44 days for JJAS 2003 and JJAS 2004, respectively (Table 2).

The control experiments (Fig. 2c, f) reproduced well the large-scale structure of the observed rainfall, with PCC values of 0.96 and 0.95 for JJAS 2003 and JJAS 2004, respectively (Table 2) over the entire West African domain, but did exhibit some spatial extent and magnitude biases at the local scale. The control experiment displayed a large and quite homogeneous area of maximum values of the R1mm index below 12° N latitude. The control experiments overestimate the number of wet days over most of the studied domains (Table 2). The largest MBs were found over the Guinea coast with MB more than 53.16 and 55.46 days for JJAS 2003 and JJAS 2004, respectively (Table 2). This overestimation of the number of wet days in RegCM4 was also found by Thanh et al. (2017) with RegCM4 for Asia.

Figure 2 (second panel) displays additional changes in the R1mm index for JJAS 2003 and JJAS 2004 for dry (Fig. 2g and i, for JJAS 2003 and JJAS 2004, respectively) and wet experiments (Fig. 2h and j, for JJAS 2003 and JJAS 2004, respectively) compared to their associated control experiments; the dotted area shows changes with statistical significance at the 10% level. The dry experiments (Fig. 2g, i) decrease the R1mm index while the wet experiments (Fig. 2h, j) favour an increase in the R1mm index, especially over central Sahel and a small part of west Sahel. The impact of initial soil moisture on R1mm was linear over central Sahel. However, over the Guinea coast sub-region, both wet and dry experiments showed a significant increase in R1mm.

For a better quantitative evaluation, Fig. 3 displayed the PDF distributions of the changes in the R1mm index over the studied domains (Fig. 1), during JJAS 2003 and 2004. Table 4 summarizes the maximum values of changes obtained on the PDF's for extreme precipitation indices used in this study. The results essentially confirmed the linear impact found over central Sahel (Fig. 3a). Over west Sahel, the Guinea coast, and the West African domain (Fig. 3b, c, and d), both dry and wet experiments led to an increase in the R1mm index. The

222 strongest R1mm index increase (decrease) was observed in wet (dry) experiments over west
223 (central) Sahel, with a maximum change of approximately 12 days (-5.19 days) for JJAS 2003
224 (Table 4).

225 Summarizing the results of this section, RegCM4 overestimates the number of wet days over
226 most of the studied domains. A linear impact on the R1mm index for the dry (wet)
227 experiments was found over the central Sahel, with a decrease (increase) in R1mm index.
228 These results were compatible with previous work that sustained a strong land-atmosphere
229 coupling in areas between wet and dry climate regimes (Zhang et al., 2011; Koster et al.,
230 2006. The strongest R1mm index increase (decrease) was observed in wet (dry) experiments
231 over west (central) Sahel, with a maximum change of approximately 12 days (-5.19 days) for
232 JJAS 2003.

233

234 **3.1.2 Simple daily intensity index (SDII).**

235 We analyzed in this section the SDII index which gives the amount of precipitation mean on
236 wet days (daily precipitation $>1\text{mm}$). Figure 4 (first panel) is the same as Fig.2 (first panel)
237 but shows the amount of precipitation mean on wet days (SDII index, in $\text{mm}.\text{day}^{-1}$). Over the
238 entire West African domain, the two observations products CHIRPS (Fig.4a, d) and TRMM
239 (Fig.4b, e) presented a similar large-scale pattern with a PCC about 0.86 for both JJAS 2003
240 and JJAS 2004 (Table 2). However, the maxima SDII index values are quite different in term
241 of spatial extension and magnitude. Over the coastline of the Gulf of Guinea, CHIRPS
242 datasets (Fig.4a, d) depicted the highest values of SDII index, more than $25\text{ mm}.\text{day}^{-1}$. While
243 the SDII index values, in TRMM datasets not exceed $12\text{ mm}.\text{day}^{-1}$ over most part of this
244 region. Over the central and west Sahel, TRMM datasets showed large sparse values of SDII
245 index up to $20\text{ mm}.\text{day}^{-1}$, while CHIRPS datasets not exceed $12\text{ mm}.\text{day}^{-1}$ for both JJAS 2003
246 and JJAS 2004. The largest underestimations of TRMM dataset with respect to CHIRPS
247 were found over the Guinea coast sub-region with MB more than -5.24 and -6.44 $\text{mm}.\text{day}^{-1}$
248 (for JJAS 2003 and JJAS 2004, respectively; Table 2). However, strongest overestimations
249 were observed over central Sahel with MB reaching 3.67 and 2.07 $\text{mm}.\text{day}^{-1}$ (for JJAS 2003
250 and JJAS 2004, respectively; Table 2).

251 The control experiments (Fig. 4 c, f) reproduced well the large-scale pattern of observation
252 products with a PCC reaching 0.73 and 0.77 (in JJAS 2003 and JJAS 2004, respectively;
253 Table 2) over the West African domain. However, at the local scale, some biases were
254 observed. Over most of the studied domains, the magnitude of the SDII was underestimated,

255 not exceeding $10 \text{ mm}\cdot\text{day}^{-1}$, except over the Cameroon Mountains (Fig. 4c, f). Therefore,
256 precipitation events were less extreme in the control experiments. The largest MBs were
257 located over the Guinea coast with MBs more than -13.62 and $-14.65 \text{ mm}\cdot\text{day}^{-1}$ (for JJAS
258 2003 and JJAS 2004, respectively; Table 2).

259 Figure 4 (second panel) is the same as Fig. 2 (second panel), but the display changes in the
260 amount of mean precipitation on wet days. Unlike the R1mm index, a change in the SDII was
261 not linear over most of studied domains. In general, a similar mixture of both increase and
262 decrease is shown for dry and wet experiments over most of the studied domains (Fig. 4,
263 second panel).

264 Figure 5 displays PDFs of changes in SDII, as in Fig. 3. The PDFs showed a maximum
265 change value centered approximately on zero (Table 4), indicating that change in the amount
266 of mean precipitation on wet days for wet and dry experiments is not significant.

267 In summary, RegCM4 underestimated the amount of mean precipitation on wet days over all
268 the domain studies. It is worth noting that precipitation events simulated by RegCM4 with the
269 current parameterization were less extreme, and the SDII did not exceed $10 \text{ mm}\cdot\text{day}^{-1}$ over the
270 entire West African domain. The impact of precipitation amount on wet days of the dry and
271 wet experiments is not significant and is not sensitive to the contrast of year over the entire
272 studied domain.

273 **3.1.3 Maximum number of consecutive dry days (CDD index).**

274 The duration of consecutive dry days (CDD index), which represents the maximum number of
275 consecutive dry days with precipitation less than $1 \text{ mm}\cdot\text{day}^{-1}$ was analyzed in this section.
276 Figure 6 (first panel) is the same as Fig. 2 (first panel) but shows the maximum number of
277 CDD (in days). CHIRPS datasets located the largest CDD index values over the Sahara, more
278 than 50 days (Fig. 6a, d). The lowest values were found over the Guinea coast, with CDD
279 index values, less than 8 days. Over the West African domain, both the CHIRPS and TRMM
280 datasets showed quite similar large-scale features over the entire West African domain with
281 PCC more than 0.92. However, at the local scale, the observation datasets exhibited some
282 disparities. In general, these disparities related only to the spatial extent, especially over the
283 Sahel region. In JJAS 2003, the band of CDD index values was in the range of [10; 20] days
284 and extended farther into the Sahel region for TRMM than CHIRPS. For JJAS in 2004,
285 TRMM observations (Fig. 6b, e) presented a narrower band of minimum CDD index values
286 over the Guinea coast around latitude 10° N than CHIRPS, which extended over the Guinea
287 coast. TRMM observations underestimated the CDD index over the entire West African

288 domain, with MB approximately -2.29 and -1.75 days (for JJAS 2003 and JJAS 2004,
289 respectively; Table 2).

290 The control experiments (Fig. 6c, f) over the entire West African domain, reproduced well the
291 large-scale pattern of the observed rainfall with a PCC more than 0.85 and 0.89 (for JJAS
292 2003 and JJAS 2004, respectively; Table 1). However, in terms of magnitude, some
293 differences were observed at the local scale. In general, the control experiments overestimated
294 the CDD index over most studied domains, except over the Guinea coast (Table 2). A
295 strongest overestimation CDD index was observed over west Sahel with MB reaching more
296 than 14.49 and 17.51 days (for JJAS 2003 and JJAS 2004, respectively; Table 2). The current
297 model parameterization increase the drought extreme over most of the studied domains,
298 except over the Guinea coast (Table 2).

299 Figure 6 (second panel) is the same as Fig. 2 (second panel) but shows changes in the
300 maximum lengths of consecutive dry spells (through the CDD index). The initial soil moisture
301 impact on CDD index was linear over the central and west Sahel (Fig. 6, second panel), and
302 the dry (wet) experiments increase (decrease) the maximum lengths of consecutive dry spells
303 (CDD index). However, particularly over the Guinea coast, the dry and wet experiments led
304 to a decrease in CDD index.

305 Figure 7 is the same as Fig. 3 but displays the PDF distribution of the changes in the CDD
306 index. The impact on the CDD index was linear over the central and west Sahel. A strongest
307 increase (decrease) in the CDD index was observed over the central (west) Sahel in dry (wet)
308 experiments with maximum change value reaching 3.80 (-12.73) days in JJAS 2004 (2003)
309 (Table 4).

310 In summary, RegCM4 overestimates the maximum number of consecutive dry days over most
311 studied domains, except over the Guinea coast. The linear impact on CDD index was
312 observed over the central and west Sahel, however, over the Guinea coast, the dry and wet
313 experiments led to a decrease in CDD index.

314 **3.1.4 Maximum number of consecutive wet days (CWD index).**

315 The persistence of wet spells (CWD index) which represents the maximum number of
316 consecutive wet days with precipitation $\geq 1 \text{ mm.day}^{-1}$ is investigated in this section. Figure 8
317 (first panel) is the same as Fig.2 (first panel) but shows the CWD index. The observation
318 products TRMM (Fig.8b, e) and CHIRPS (Fig.8a, d) depicted a similar large-scale pattern
319 with the PCCs reached 0.90 and 0.87 (resp. for JJAS 2003 and JJAS 2004, Table 2). CHIRPS
320 observation located the maximum of CWD index over the mountain regions such as

321 Cameroon Mountains, Jos plateau and Guinea highlands and it is more than 20 days. While
322 the minimum values of CWD index were found over most of the area above the latitude 17°N
323 and did not exceed 4 days (Fig.8a, d). In general, the differences between TRMM and
324 CHIRPS observation concerned the maxima magnitude and its extent, which are more
325 pronounced in TRMM than CHIRPS. Generally, TRMM overestimated the CWD index over
326 most of the studied domains compared to CHIRPS, except over central Sahel (Table 2). The
327 strongest overestimation was found over the Guinea coast region with MB more than 2.47 and
328 2.38 days (resp. for JJAS 2003 and JJAS 2004, Table 2).

329 The control experiments well reproduced the large-scale pattern over the entire West African
330 domain, with PCCs values approximately 0.81 and 0.87 (resp. for JJAS 2003 and JJAS 2004,
331 Table 2). However, at the local scale the control experiments exhibit some biases in the
332 minimum and maximum CWD index values in term of magnitude and spatial extent. Control
333 experiments overestimated the CDD index over most of domains studied (Fig. 8 c, f). We
334 noted that, this overestimation area coincides with the excessive values of R1mm index
335 (Fig.2c, f). The strongest overestimation was found over the Guinea coast, reaching 59.21 and
336 60.51 days (resp. for JJAS 2003 and JJAS 2004, Table 2).

337 Figure 8 (second panel) is the same as Fig.2 (second panel), but displays changes in CWD
338 index. As for R1mm index, over the central Sahel, the impact was linear, the dry (wet)
339 experiments decrease (increase) CWD index for both JJAS 2003 and JJAS 2004. This result
340 confirms the strong soil moisture impact over the transition zones with a climate between dry
341 and wet regimes (Zhang et al., 2011; Koster et al., 2006). However, over Guinea and the west
342 Sahel, the changes were not linear, both dry and wet experiments lead to cause an increase, in
343 JJAS 2003 and JJAS 2004 (Fig. 8B, c).

344 Figure 9, as in Fig.3, but shows the PDF distribution of changes in CWD index. The linear
345 impacts were observed over the central Sahel for both JJAS 2003 and JJAS 2004, and over
346 west Sahel only in JJAS 2004 (Table 4). The strongest increase (decrease) on CWD index was
347 found over central Sahel with maximum change reaching 15.58 (-4.48) days in wet (dry)
348 experiments in JJAS 2004.

349 Summarizing the results of this section, as in R1mm and CDD indices, the CWD index was
350 linear over the central Sahel for both JJAS 2003 and JJAS 2004, and over the west Sahel in
351 JJAS 2004, that is, the dry (wet) experiments decrease (increase) the CWD index. The model
352 RegCM4 overestimates the duration of wet days over most of studied domains. This

353 overestimation is linked with an excessive number of wet days as documented by Diaconescu
354 et al. (2014).

355

356 **3.1.5 Maximum one-day precipitation accumulation (RX1day index).**

357 The maximum one-day precipitation accumulation (RX1day index) during JJAS 2003 and
358 JJAS 2004 is assessed in this section. Figure 10 (first panel) shows the spatial distribution of
359 the RX1day index. The observation datasets TRMM (Fig. 10b, e) and CHIRPS (Fig. 10 a, d)
360 present notable differences in terms of the spatial extent of the maximum values of the
361 RX1day index, although their large-scale pattern was similar with PCC of more than 0.84 for
362 both JJAS 2003 and JJAS 2004 (Table 2). Over the Guinea and Sahel regions, the spatial
363 extent of RX1day index maximum values more than 80 mm was large in the TRMM datasets,
364 while CHIRPS datasets showed it confined over the coastline of the Gulf of Guinea. TRMM
365 observations overestimated the RX1day index over the most of studied domains. The largest
366 RX1day index was found over the central Sahel, with MB reaching 35.78 and 31.66 (for JJAS
367 2003 and JJAS 2004, respectively; Table 2).

368 The control experiments captured the spatial pattern with PCC values of 0.50 and 0.4 (JJAS
369 2003 and JJAS 2004, respectively; Table 2). This low coefficient of PCC was also obtained
370 by Thanh et al. (2017) over Asia with RegCM4 (correlation < 0.3). The model simulations
371 failed to capture the magnitude and spatial extent of the RX1day index maxima values. The
372 control experiments underestimated the RX1day index over most of studied domains. The
373 RX1day index was underestimated throughout studied domains; this was also due to the
374 excessive light precipitation, simulated by the current physical parameterization of RegCM4.
375 The largest underestimation was located over the Guinea coast and the west Sahel. For
376 instance, over the west Sahel, the MB was approximately -38.07 and -36.67 mm (JJAS 2003
377 and JJAS 2004, respectively; Table 2).

378 Figure 10 (second panel) is similar to Fig. 2 (second panel), but displays changes in the
379 RX1day index. For the SDII, the impact of initial soil moisture anomalies on the RX1day
380 index was not linear, and a similar mixture of increase and decrease in RX1day index is
381 shown for dry and wet experiments over most of the studied domains (Fig. 10, second panel).

382 Figure 11 is similar to Fig. 3, but shows the PDF distribution of changes in the RX1day index.
383 The impact on RX1day index increase for both dry and wet experiments and was found over
384 most of studied domains (Fig.11). The strongest increase in RX1day index was observed over
385 Guinea in wet experiments 26.14 and 14.93 for JJAS 2003 and JJAS 2004, respectively.

386 In summary, RegCM4 underestimates the maximum one-day precipitation accumulation over
387 most of studied domains. The impact on RX1day index increase for both dry and wet
388 experiments and was found over most of studied domains.

389

390 **3.1.6 Precipitation percent due to very heavy precipitation days (R95pTOT index)**

391 In this section, we investigated the precipitation percentage due to very heavy precipitation
392 days during JJAS 2003 and JJAS 2004. Figure 12 (first panel) is the same as Fig. 2 (first
393 panel), but shows the spatial distribution of the R95pTOT index. TRMM (Fig. 12b, e) and
394 CHIRPS observations (Fig. 12a, d) presented a similar spatial pattern over the entire West
395 African domain, with a PCC value of 0.91 for both JJAS 2003 and JJAS 2004 (Table 2).
396 However, some biases in spatial extent were noticed for R95pTOT index maxima. TRMM
397 observation extended the maximum R95pTOT index over the Guinea and Sahel regions (Fig.
398 10, first panel), while CHIRPS confined them over the Guinea coast. Overall, TRMM showed
399 a dominant overestimation compared to CHIRPS over the West African domain by
400 approximately 16.54% and 18.54 % (JJAS 2003 and JJAS 2004, respectively; Table 2). The
401 control experiments (Fig. 12c, f) capture the spatial pattern with PCC values of 0.59 and 0.55
402 (JJAS 2003 and JJAS 2004, respectively; Table 2). As with SDII and RX1day indices, the
403 control experiments underestimated the values of the R95pTOT index, while they
404 overestimated the R1mm index. This was also due to the current physical parameterisation
405 scheme of the RegCM4 model, which results in a positive bias for the number of wet days
406 with a low precipitation threshold (e. g., 1 mm•day⁻¹), and a negative bias for the indices of
407 the number of wet days with a higher precipitation threshold (e.g., 10 mm•day⁻¹, not shown
408 here).

409 The control experiments underestimated the R95pTOT index over the different studied
410 domains. The largest underestimation of the R95pTOT index was located over the Guinea
411 coast with MB more than -43.22 and -46.61 % (for JJAS 2003 and JJAS 2004, respectively;
412 Table 2).

413 Figure 12 (second panel) is similar to Fig. 2 (second panel), but displays changes in the
414 R95pTOT index. Both dry and wet experiments tended to cause an increase in the R95pTOT
415 index over the orographic regions. Therefore, the initial soil moisture conditions, whether dry
416 or wet, tended to reinforce extreme floods.

417 Figure 13 is the same as Fig. 3 but shows the PDF distribution of changes in the R95pTOT
418 index indicating an increase in the R95pTOT index for both wet and dry experiments over

419 most of the studied domains. The strongest increase in R95pTOT index was found over the
420 west Sahel and Guinea coast with maximum change values around 4.03% (JJAS 2004) and
421 4.33% (JJAS 2003), respectively (Table 4).

422 In summary, RegCM4 underestimates the precipitation percentage due to very heavy
423 precipitation days over the West African domain. The initial soil moisture conditions, whether
424 dry or wet, accentuate the precipitation percent due to very heavy precipitation days. This
425 result is consistent with Liu et al.'s (2014) work over Asia using RegCM4. The impact on
426 R95pTOT index led to an increase in wet and dry experiments over most of the studied
427 domains.

428

429 **3.2. Seasonal temperature extreme indices**

430 In this section, using daily maximum and minimum temperatures, we analyze four extreme
431 temperature indices (Table 1) in RegCM4 simulations over West Africa. All temperature
432 indices were calculated for JJAS 2003 and JJAS 2004. Table 3 summarizes the PCC and MB
433 of all temperature indices studied in this section for EIN reanalysis and model simulations
434 derived from control experiments with initial soil moisture from ERA20C reanalysis, with
435 respect to GTS observations, calculated over the domains presented in Fig. 1, during the JJAS
436 2003 and JJAS 2004.

437

438 **3.2.1. Maximum value of daily maximum temperature (TXx index)**

439 In this section, we analyze the TXx index, which gives the hottest day's temperature during
440 JJAS 2003 and JJAS 2004. Figure 14 (first panel) shows the TXx index (in °C) from GTS
441 observations (Fig. 14a, d) and EIN reanalysis (Fig. 14b, e) for JJAS 2003 and JJAS 2004 and
442 their corresponding simulated control experiments (Fig. 14c, f) with the initial soil moisture
443 of the reanalysis ERA20C. The GTS observation showed the highest values of the TXx index
444 observed over the Sahara, at more than 46 °C. The lowest values (less than 32 °C) were found
445 over the Guinea coast (Fig. 14a, d). Fan Y. and Huug van den Dool (2008) in their work
446 showed that the Reanalysis 2 m temperature data sets may not be suitable for model forcing
447 and validation. We have chosen NOAA-CPC GTS observation dataset as reference in this
448 study over ERA-Interim reanalysis, because NOAA-CPC GTS consists of a blending of
449 satellite-based data collection and in situ data archive available in the GTS (Global
450 Telecommunication System). The EIN reanalysis has similar large-scale patterns with a PCC

451 value of 0.99 over the entire West African domain (Table 3). However, some local biases are
452 shown for magnitude and spatial extent of these maxima and minima. The reanalysis of the
453 EIN (Fig. 14b, e) shows lower values (less than 28 °C) of the TXx index over a large area
454 along the Guinea coastline compared to GTS datasets. Conversely, GTS observation
455 presented higher values of the TXx index (up to 48 °C) over a large area compared to the EIN
456 reanalysis (Fig.14a, d), which showed a negative bias of the TXx index over most of the
457 studied domains (Table 3).

458 The control experiments (Fig. 14c, f) reasonably replicate the large-scale patterns of the TXx
459 index values with PCCs up to 0.99 (Table3) over the entire West African domain; however,
460 they exhibited some biases at a local scale. The control experiments were closer to the
461 maximum and minimum values displayed in the GTS observation. The control simulations
462 overestimated the TXx values over the central and west Sahel, and over the Guinea coast
463 (Table 3). The greatest overestimation was found over the west Sahel with MB of
464 approximately 3.02 and 2.02 °C (for JJAS 2003 and JJAS 2004, respectively; Table 3).
465 However, the biases obtained for the TXx index in this study were much lower than those
466 obtained by Thanh et al. (2017), who used RegCM4 over Asia where it reached 8 °C.

467 Figure 14 (second panel) displays changes in the TXx index for JJAS 2003 and JJAS 2004 for
468 dry (Fig. 14g, i for JJAS 2003 and JJAS 2004, respectively) and wet experiments (Fig. 14h, j
469 for JJAS 2003 and JJAS 2004, respectively) with respect to their corresponding control
470 experiments; the dotted area shows changes with a statistical significance of 10%. The impact
471 of the initial soil moisture conditions on the TXx index was linear over most of studied
472 domains; that is, the dry experiments led to an increase in the TXx index values, while the wet
473 experiments favoured a decrease in the TXx index values.

474 The PDF distributions of TXx index changes for JJAS 2003 and JJAS 2004 over (a) the
475 central Sahel, (b) West Sahel, (c) Guinea, and (d) West Africa derived from dry and wet
476 experiments compared to the corresponding control experiments are shown in Fig. 15. Table 5
477 summarizes the maximum values of changes obtained on the PDF's for extreme temperature
478 indices used in this study. As mentioned above, the results confirmed the linear impact on the
479 TXx index over most of studied domains (Fig. 15). The strongest decrease (increase) in the
480 TXx index was found over the central Sahel with a maximum change values around -2.57 °C
481 (more than 1.69 °C) in wet (dry) experiments in JJAS 2004.

482 In summarizing this section, during JJAS 2003 and 2004, the RegCM4 model overestimates
483 and underestimates the hottest day's temperature over the Sahel (west and central) and Guinea
484 coast. The impact on the TXx index is linear over most of studied domains; that is, the dry
485 (wet) experiments decrease (increase) the TXx index.

486

487 **3.2.2. Minimum value of daily maximum temperature (TXn index).**

488 In this section, we investigated the TXn index which gives the lowest day's temperature
489 during JJAS 2003 and JJAS 2004. Figure 16 (first panel) is the same as Fig.14 (first panel)
490 but presents the spatial distribution of the TXn index. GTS observation (Fig.16a, d) and EIN
491 reanalysis (Fig.16b, e) display similar features with PCC reached 0.99 (for JJAS 2003 and
492 JJAS 2004, Table 3). The maxima and minima values of TXn index were located over the
493 Sahara and the Guinea coast respectively. However, there were some differences at the local
494 scale in terms of spatial extent and magnitude. The EIN reanalysis presented a larger spatial
495 extent of the maxima (greater than 36°C) and minima (less than 24°C) compared to GTS
496 observation. Generally, the EIN reanalysis showed a negative bias value over most of the
497 studied domains (for both JJAS 2003 and JJAS 2004 Table3. The strongest negative bias was
498 found over the west Sahel with MB of approximately -1.48 and -1.73°C (resp. for JJAS 2003
499 and JJAS 2004, Table 3).

500 The control experiments showed a good agreement with the GTS datasets in the large scale
501 patterns with PCC of approximately 0.99, however, the magnitude of the TXn index over
502 most of studied domains was overestimated. The strongest positive bias was observed over
503 west Sahel domain, the MB of approximately 6.56 and 5.44 °C (resp. JJAS 2003 and JJAS
504 2004, Table 3). The biases obtained in this study were lower than those of a similar study
505 carried out by Thanh et al. (2017) over Asia using RegCM4.

506 As for Fig.14 (second panel), the Figure 16 (second panel) displayed changes in TXn index.
507 The impact on TXn index of the initial soil moisture anomalies was linear over most of
508 studied domains, that is, the dry experiments led to an increase of TXn index values while the
509 wet experiments favor a decrease of TXn index values.

510 Figure 16 (second panel) is similar to Fig.14 (second panel) but displays the PDF distribution
511 of changes in TXn index. The impact on TXn index was linear over most of the domain
512 studied, although this impact is rather weak as compared to the TXx index. The strongest
513 increase (decrease) in TXn index are found over the central (west) Sahel reaching 1.03 °C (-
514 1.67°C) in dry (wet) experiments, in JJAS 2004 (JJAS 2004) (Table5).

515 In summary, RegCM4 overestimated the lowest day's temperature during JJAS 2003 and
516 JJAS 2004 over the whole West African domain. As for TXx index, the impact on TXn index
517 to soil moisture anomalies was linear over most of studied domains, that is, dry (wet)
518 experiments cause an increase (decrease) of TXn index values.

519

520 **3.2.3. Minimum value of daily minimum temperature (TNn index).**

521 In this section, we examine the TNn index, which gives the lowest temperature at night during
522 JJAS 2003 and JJAS 2004. Figure 18 (first panel) is the same as Fig. 14 (first panel) but
523 displays the spatial distribution of the TNn index. GTS observations (Fig. 18 a, d) show the
524 maxima of TNn index values above 15° N latitude, not exceeding 27 °C, while the minima
525 values are less than 17 °C and are located over the mountainous regions such as the Cameroon
526 Mountains, Jos Plateau, and Guinea Highlands. The EIN reanalysis showed a similar spatial
527 pattern as GTS observation, with a PCC value of approximately 0.99 over the entire West
528 African domain (Table 3) despite some biases at the local scale. The EIN reanalysis (Fig. 18
529 b, e) displayed the highest value of the TNn index (exceeding 27 °C) compared to GTS
530 observation, and were located over a large area above 15° N. The EIN reanalysis also showed
531 the lowest values (less than 21 °C) of the TNn index compared to the GTS observation,
532 located over the orographic regions. The EIN reanalysis overestimated the TNn index values
533 over most of the studied domains. The strongest positive bias was observed over the west
534 Sahel, the MB reached 3.43 and 2.98 °C for JJAS 2003 and JJAS 2004, respectively (Table
535 3).

536 The control experiments (Fig. 18 c, f) showed good agreement with GTS observations with
537 PCC values of approximately 0.99; however, they exhibited some biases at the local scale.
538 The control experiments overestimated the magnitude of the TNn index over most of studied
539 domains.

540 The strongest positive bias was observed over the west Sahel, the MB was approximately 3.30
541 °C and 2.55 °C for JJAS 2003 and JJAS 2004, respectively (Table 3). These positive biases
542 obtained in simulating the TXx, TXn, and TNn indices were opposite to the cold bias known
543 from RegCM4 in mean climate simulation (Koné et al., 2018, Klutse et al., 2016). It is
544 difficult to determine the origin of RegCM4 temperature biases, as they can depend on several
545 factors, such as surface energy fluxes and water, cloudiness, and surface albedo (Sylla et al.,
546 2012; Tadross et al., 2006).

547 Figure 18 (second panel) is the same as Fig. 14 (second panel), but displays changes in the
548 TNn index. Over the central and west Sahel, both dry and wet experiments led to a decrease.
549 Conversely, over the Guinea coast, we found an increase.

550 Figure 19 is the same as Fig. 15 but shows the PDF distribution of changes in the TNn index.
551 A linear impact was found over west Sahel and Guinea coast only in JJAS 2004, that is, wet
552 (dry) experiments increase (decrease) the TNn index (Fig.19; Table 5). The strongest increase
553 (decrease) in TNn index in wet (dry) experiment was found over Guinea coast (west Sahel),
554 with maximum change values around 0.11 °C and (−1.15 °C) in JJAS 2004 (JJAS 2003)
555 (Table 5).

556 In summary, RegCM4 overestimated the lowest temperature at night during JJAS 2003 and
557 JJAS 2004 over the different studied domains. A linear impact was found over west Sahel and
558 Guinea coast only in JJAS 2004, that is, wet (dry) experiments increase (decrease) the TNn
559 index

560 **3.2.4. Maximum value of daily minimum temperature (TNx index)**

561 In this section, we turned our attention to TNx index, which gives the warmest night
562 temperature during JJAS 2003 and JJAS 2004. Figure 20 (first panel) is the same as Fig. 14
563 (first panel), but for the TNx index. GTS observations (Fig. 20 a, d) showed that the maxima
564 of the TNx index values over the Sahara reached 40 °C, while the minima around 24 °C were
565 located over the Guinea coast sub-region. The EIN reanalysis (Fig. 20b, e) showed similar
566 large-scale patterns with PCC values of 0.99, but some biases can be noticed between the
567 GTS and EIN datasets. The EIN reanalysis underestimated the maxima (not exceeding 38 °C)
568 and minima (less than 22 °C) located over the Sahara and the orographic regions such as the
569 Cameroon Mountains, Jos Plateau, and Guinea Highlands. The EIN reanalysis displayed
570 negative MB over the Guinea coast with MB approximately −3.11 °C and −3.14 °C (JJAS
571 2003 and JJAS 2004, respectively; Table 3).

572 The control experiments (Fig. 20c, f) successfully reproduced the general features of the TNx
573 index with a PCC value of 0.99, but some differences were shown at the local scale. Unlike
574 the TNn index, the control experiments underestimated the TNx index over most of the
575 studied domains. The strongest negative bias was found over the central Sahel, MB was
576 approximately −3.35 °C and −3.32 °C (for JJAS 2003 and JJAS 2004, respectively; Table 3).
577 This underestimation of the TNx index seems to be systematically related to the cold bias in
578 RegCM4 over West Africa, which has been reported in several papers (Koné et al., 2018,
579 Klutse et al., 2016).

580 Figure 20 (second panel) is the same as Fig. 14 (second panel) but displays changes in the
581 TNx index. Like for the TNn index, the impact on the TNx index of initial soil moisture
582 conditions was somewhat linear over the central Sahel, and dry experiments led to an increase
583 in the TNx index values, while the wet experiments favoured a decrease in the TNx index
584 values. However, over the west Sahel, both wet and dry experiments led to a dominant
585 decrease. Conversely, over the Guinea coast, although the signal was weak, both dry and wet
586 experiments led to a dominant increase.

587 Figure 21 is the same as Fig. 15 but displays the PDF distributions of the changes in the TNx
588 index. Like for the TNn index, the impact on the TNx index changes was linear over the
589 central Sahel. The strongest increase (decrease) in TNx index was found over the central
590 Sahel in dry (wet) experiments with maximum change approximately 0.25 (-1.67°C) in JJAS
591 2003 (JJAS 2004) (Table 5).

592 In summary, RegCM4 underestimates the warmest night temperature during JJAS 2003 and
593 JJAS 2004 over most of studied domains. The impact on the TNx index of initial soil
594 moisture conditions was linear over the central Sahel, that is, dry (wet) experiments led to an
595 increase (decrease) in the TNx index values.

596

597 **4. Conclusions**

598 The impact on the subsequent summer extreme climate of the initial soil moisture conditions
599 over West Africa was investigated using the RegCM4-CLM4.5. In addition, the performance
600 of RegCM4-CLM4.5 in representing six extreme indices of precipitation and four extreme
601 indices of temperature over West Africa was also evaluated. Results have been presented for
602 JJAS 2003 (wet year) and JJAS 2004 (dry year). We performed sensitivity studies over the
603 West African domain, with a spatial resolution of 25 km. We initialized the control runs using
604 ERA20C reanalysis soil moisture, at its maximum and minimum values over the West Africa
605 domain, respectively, for dry and wet experiments.

606 Compared to the extreme indices of the observation datasets, the model overestimated and
607 underestimated the number of wet days for a low (1 mm.day^{-1}) and high threshold rain rate
608 (e.g., 10 mm.day^{-1} , not shown here). RegCM4 also underestimated the simple precipitation
609 intensity index (SDII), the maximum 1-day precipitation (Rx1day index), and the
610 precipitation percentage due to very heavy precipitation days (R95pTOT index). The current
611 physical parameterization scheme of the RegCM4 model used in our study results in a

612 positive bias for the number of wet days with a low precipitation threshold (e. g. 1 mm•day-
613 1), while in a negative bias for a higher precipitation threshold (e.g. 10 mm•day-1, not shown
614 here). However, RegCM4 generally overestimated the maximum number of CWD and CDD
615 over the West African domain studied. The temperature extreme indices used in this study
616 (TXx, TXn, and TNn) were also overestimated, except the TNx index, which was
617 underestimated over most of studied domains.

618 The impact on extreme precipitation indices of the initial soil moisture conditions was linear
619 only for indices related over the central Sahel to the number of precipitation events (R1mm,
620 CDD, and CWD indices) and not for those related to the amount of precipitation (SDII,
621 RX1day, and R95pTOT). The dry and wet experiments accentuated the precipitation
622 percentage due to very heavy precipitation days and maximum one-day precipitation
623 accumulation (R95pTOT and RX1day indices, respectively) over most of the studied
624 domains.

625 The initial soil moisture conditions unequally affected the daily maximum and minimum
626 temperatures over the West African domain. There was a greater impact on daily maximum
627 temperature extremes than on the daily minimum temperature extremes. These results are
628 consistent with those of previous studies (Jaeger and Seneviratne, 2011; Zhang et al., 2009).

629 The wet (dry) experiments resulted in an increase (decrease) in the TXx and TXn indices over
630 most of the studied. The impact of initial soil moisture conditions on the indices related to the
631 minimum temperature (TNx and TNn indices) was linear only for TNx index over central
632 Sahel. The dry (wet) experiments cause an increase (a decrease) in the TNx.

633 This study helps to understand the impact of the initial soil moisture conditions on extreme
634 events of precipitation and temperature in terms of intensity, frequency and duration over
635 West Africa. This is a contribution to the improvement of extreme event forecasts in West
636 Africa in highlighting the crucial role of initial soil moisture. For a proper assessment of the
637 dependence of the model in our results, it would be appropriate to repeat the investigation
638 using different RCMs in a multi-model framework.

639

640

641 **Author contribution**

642 The authors declare to have no conflict of interest with this work. B. Koné and A. Diedhiou
643 fixed the analysis framework. B. Koné carried out all the simulations and figures production
644 according to the outline proposed by A. Diedhiou. B. Koné and A. Diedhiou, S. Anquetin and
645 A. Diawara worked on the analyses. All authors contributed to the drafting of this manuscript.

646

647 **Acknowledgements**

648 The research leading to this publication is co-funded by the NERC/DFID “Future Climate for
649 Africa” programme under the AMMA-2050 project, grant number NE/M019969/1 and by
650 IRD (Institut de Recherche pour le Développement; France) grant number UMR IGE
651 Imputation 252RA5.

860 **TABLES AND FIGURES.**

861

Extreme indices		Definition	Units
Extreme Rainfall Indices			
1	R1mm	Number of wet days (daily precipitation $\geq 1\text{mm}$)	day
2	SDII	The amount of precipitation mean on wet days (daily precipitation $\geq 1\text{mm}$)	$\text{mm}.\text{day}^{-1}$
3	CDD	Maximum number of consecutive dry days (daily precipitation $< 1\text{ mm}.\text{day}^{-1}$)	day
4	CWD	Maximum number of consecutive wet days (daily precipitation $\geq 1\text{ mm}.\text{day}^{-1}$)	day
5	RX1day	The maximum one-day precipitation accumulation	mm
6	R95pTOT	Precipitation percent due to very heavy precipitation days.	%
Extreme temperature indices			
7	TXn	Minimum value of daily maximum temperature	$^{\circ}\text{C}$
8	TXx	Maximum value of daily maximum temperature	$^{\circ}\text{C}$
9	TNn	Minimum value of daily minimum temperature	$^{\circ}\text{C}$
10	TNx	Maximum value of daily minimum temperature	$^{\circ}\text{C}$

862

863 **Table1:** The 10 extreme climate indices used in this study.
