Abstract.

The influence of the soil moisture initial conditions on climate extreme indices over West Africa is investigated using the fourth generation of Regional Climate Model version 4 (non-hydrostatic) coupled to the version 4.5 of the Community Land Model (RegCM4-CLM4.5) at 25 km spatial resolution. We initialized the control experiments with the reanalysis soil moisture of the European Centre Meteorological Weather Forecast's reanalysis of the 20th century data (ERA20C), while for the dry and wet experiments, we initialized the soil moisture at the maximum and minimum value over West Africa domain, respectively. For each experiment, an ensemble of five runs are performed for five years (2001- 2005), with soil moisture initial conditions prescribed on June 1 and simulations performed over four months (122 days) from June to September. The performance of RegCM4-CLM4.5 in simulating the ten extreme rainfall and temperature indices used in this study is presented. Then, the results are discussed for the two idealized simulations most sensitive to the dry and wet soil moisture initial conditions to highlight the impacts beyond the limits of soil moisture internal forcing in the model. Over the Central Sahel, dry (wet) experiments lead to a decrease (increase) of precipitation extreme indices related to the number of events, not for those related to the intensity of the events. Soil moisture initial conditions unequally affect the daily minimum and maximum temperatures. The strongest impact is found on the maximum temperature. Wet (dry)

32 experiments decrease (increase) maximum temperature in the whole region. Over the Central
33 Sahel, wet (dry) experiments lead to a decrease (increase) of the maximum values of minimum
34 temperature.

35

36 **1 Introduction**

37 West Africa experienced large rainfall variability during the late 1960s. This variability often
38 leads to flooding events, severe drought, and regional heatwaves, which have major economic,
39 environmental, and societal impacts (Easterling et al., 2000; Larsen, 2003). In recent years,
40 climate extremes have attracted much interest because they are expected to occur more
41 frequently (International Panel on Climate Change (IPCC), 2012) than changes in the mean
42 climate. Yan and Yang (2000) showed that for many cases, the extreme climate changes were
43 five to ten times greater than climate mean change. Many key factors or physical mechanisms
44 could be the cause of the increase in climate extremes (Nicholson, 1980; Le Barbé et al., 2002),
45 such as the effect of increasing greenhouse gases in the atmosphere on the intensification of hot
46 extremes (IPCC, 2007), sea surface temperature (SST) anomalies (Fontaine and Janicot 1996;
47 Folland et al., 1986), and land surface conditions (Philippon et al., 2005; Nicholson (2000)). In
48 addition, smaller-scale physical processes, including the interactions of land–atmosphere
49 coupling, can lead to changes in climate extremes. For the European summer, the influence of
50 soil moisture on land–atmosphere coupling using a regional climate model and focused on the
51 extremes and trends in precipitation and temperature have been studied by Jaeger and
52 Seneviratne (2011). For extreme temperatures, their studies have shown that interactions of soil
53 moisture and climate have a significant impact, while for extreme precipitation, they only
54 influence the frequency of wet days. Over Asia, Liu et al. (2014) studied the impact on
55 subsequent precipitation and temperature of soil moisture anomalies using a regional climate
56 model. They showed that wet (dry) experiences decrease (increase) the hot extremes, decrease
57 (increase) the drought extremes, and increase (decrease) the cold extremes in a zone with strong
58 soil moisture–atmospheric coupling. However, none of these studies examined the impacts of
59 the soil moisture initial conditions on subsequent climate extremes using a regional climate
60 model over West Africa. In part 1, the influence of initial soil moisture on the climate mean
61 was based on a performance assessment of the Regional Climate Model coupled with the
62 complex Community Land Model (RegCM4-CLM4.5) performed by Koné et al. (2018), where
63 the ability of the model to reproduce the climate mean has been validated. However, in Part 2,

64 before starting to study the influence of initial soil moisture on climate extremes, it was
65 necessary to assess the performance of RegCM4-CLM4.5 in simulating the ten temperature
66 indices and extreme rainfall events used in this study. This has never been done before in Africa;
67 therefore, we separated the work in two parts. The manuscript is organized as follows: Section
68 2 describes the RegCM4 model, experimental design, and methodology used in this study;
69 Section 3 presents the assessment of RegCM4-CLM4.5 in extreme climate simulation and the
70 impacts on climate extremes of the soil moisture initial conditions; and Section 4 documents
71 the conclusions.

72 **2. Model, experimental design and methodology**

73 **2.1 Model description and numerical experiments**

74 The fourth generation of the Regional Climate Model (RegCM4) of the International Centre for
75 Theoretical Physics (ICTP) is used in this study. Since this version, physical representations
76 have been subject to a continuous process of implementation and development. The release
77 used in this study was RegCM4.7. The non-hydrostatic dynamical core of the MM5 (Mesoscale
78 Model version 5, Grell et al., 1994) was ported to RegCM4 while maintaining the existing
79 hydrostatic core. RegCM4 is a limited-area model using a vertical grid sigma hydrostatic
80 pressure coordinate and a horizontal grid of the Arakawa B-grid (Giorgi et al., 2012). The
81 radiation scheme is from the NCAR-CCM3 (National Center for Atmospheric Research and
82 the Community Climate Model Version 3) (Kiehl et al., 1996), and the aerosol representation
83 is from Zakey et al. (2006) and Solmon et al. (2006). The large-scale precipitation scheme used
84 in this study is from Pal et al. (2000); the moisture scheme is called the SUBgrid EXplicit
85 moisture scheme (SUBEX), which considers the sub-grid variability in clouds. The accretion
86 and evaporation processes for stable precipitation are from Sundqvist et al. (1989). The sensible
87 heat and water vapour in the planetary boundary layer over land and ocean, as well as the
88 turbulent transport of momentum, is reported by Holtslag et al. (1990). The heat and moisture
89 and momentum of ocean surface fluxes are from Zeng et al. (1998). Convective precipitation
90 and land surface processes in RegCM4.7 are represented in several options. Based on Koné et
91 al. (2018), the convective scheme of Emanuel (1991) is used. The parameterization of land
92 surface processes is from CLM4.5 (Oleson et al., 2013). In each grid cell of CLM4.5, there are
93 sixteen different plant functional types and ten soil layers (Lawrence et al., 2011; Wang et al.,
94 2016). The integration of RegCM4 over the West African domain is shown in Fig. 1 with
95 eighteen vertical levels and 25 km of horizontal resolution (182×114 grid points; from 20°W

96 - 20°E and 5°S - 21°N). The European Centre for Medium-Range Weather Forecasts reanalysis
97 (EIN75; Uppala et al., 2008; Simmons et al., 2007) provides the initial and boundary conditions.
98 The sea surface temperatures (SSTs) are derived from the National Oceanic and Atmosphere
99 Administration optimal interpolation weekly (NOAA; OI_WK) (Reynolds et al., 1996). The
100 topography is derived from the United States Geological Survey (USGS) Global Multi-
101 resolution Terrain Elevation Data (GMTED; Danielson et al., 2011) at a spatial resolution of
102 30 arc-s, which is an update of the Global Land Cover Characterization (GTOPO; Loveland et
103 al., 2000) dataset.

104 We used the soil moisture from the reanalysis of the European Centre Meteorological Weather
105 Forecast's Reanalysis of the 20th century (ERA20C) to initialize the control runs. Wet and dry
106 experiments were initialized for the soil moisture at the maximum ($= 0.489 \text{ m}^3.\text{m}^{-3}$) and
107 minimum ($= 0.117.10^{-4} \text{ m}^3.\text{m}^{-3}$) soil moisture values over West Africa derived from the
108 ERA20C soil moisture dataset. We designed three experiments (reference, wet, and dry), each
109 with an ensemble of five (5) simulations (2001, 2002, 2003, 2004, and 2005) starting from June
110 1st to September 30th. The difference between these three experiments is the change in the
111 initial soil moisture condition (reference initial soil moisture condition, wet initial soil moisture
112 condition, and dry initial soil moisture condition) during the first day of the simulation over the
113 West African domain. Then, we selected the two years most affected by the wet and dry initial
114 soil moisture conditions (2003 and 2004) to estimate the limits of the impact of the internal soil
115 moisture forcing on the new non-hydrostatic dynamic core of RegCM4.

116 For these two years most sensitive to soil moisture initial conditions, the Student t-test is used
117 to compare the significance of changes in climate extreme indices between a wet or dry
118 sensitivity test (sample 1) and the control (sample 2) in assuming that this method performs
119 well for climate simulations (Damien et al., 2014) and knowing that it is extensively used for
120 climatological analysis (Menedez et al., 2019; Talahashi and Polcher, 2019). In this study, the t-test
121 at the 95% confidence level was used to consider statistically significant.

122

123 **2.2 Validation datasets and evaluation metrics**

124 Our investigation focused on the air temperature at 2 m and the precipitation over the West
125 African domain during JJAS for 2003 and 2004. The simulated precipitation fields are validated
126 with the Climate Hazards Group Infrared Precipitation Stations (CHIRPS) dataset from the
127 University of California at Santa Barbara, available from 1981 to 2020 with 0.05° high-

128 resolution data. We have chosen CHIRPS as reference in this study, mainly because this
129 product has been widely assessed and used for the study of extreme events in West Africa by
130 Bichet et al. (2018a, b) and Didi et al. (2020).

131 We validated the 2-m temperature using the The National Oceanic and Atmospheric
132 Administration (NOAA) Climate Prediction Center (CPC) daily maximum and minimum
133 global surface air temperature. The NOAA/CPC global daily surface 2-m air temperature (CPC-
134 T2m) is a land-only gridded global daily maximum (Tmax) and minimum (Tmin) temperature
135 analysis from 1979 to the present, available at two spatial of $10 \text{ min} \times 10 \text{ min}$ and $0.5^\circ \times 0.5^\circ$
136 (latitude \times longitude). This product provides an observational T2m estimate for climate
137 monitoring, model evaluation, and forecast verification (Fan Y. and Huug van den Dool, 2008;
138 Pan et al., 2019). In this study, the daily Tmax and Tmin are used at spatial resolution $0.5^\circ \times$
139 0.5° . To compare the model simulations with the observation datasets, we re-gridded all the
140 products to $0.22^\circ \times 0.22^\circ$ using a bilinear interpolation method (Nikulin et al., 2012).

141 The performance of RegCM4-CLM4.5 to simulate the extreme indices is evaluated using four
142 selected sub-regions (Fig. 1) based on the previous work of Koné et al. (2018), which
143 correspond to different annual precipitation cycle features. We used the mean bias (MB), which
144 captures the small-scale differences between the simulation and observation. The pattern
145 correlation coefficient (PCC) is also used as a spatial correlation between model simulations
146 and observations to indicate the large-scale similarity degree.

147 To quantify the impact of soil moisture initial conditions on climate extremes over Asia, Liu et
148 al. (2014) used the MBs in five subregions. In our study, we used the MBs and the probability
149 density functions (PDF, Gao et al. (2016); Jaeger and Seneviratne (2011)) for this purpose to
150 better capture how many grid points are impacted by initial soil moisture and their highest value.

151

152 **2.3. Extreme rainfall and temperature indices**

153 In this study, we investigated the changes in precipitation and temperature in terms of duration,
154 occurrence, and intensity of six extreme rainfall and four extreme temperature indices using
155 daily rainfall and daily minimum and maximum temperature data (Table 1). These ten extreme
156 indices are recommended by the Expert Team on Climate Change Detection and Indices
157 (ETCCDI, Peterson et al., 2001).

158 **3. Results and discussion**

159 **3.1. Seasonal extreme rainfall**

160 In this section, we analyzed six extreme rainfall indices based on daily precipitation in RegCM4
161 simulations over West Africa. All precipitation indices were calculated for JJAS in 2003 and
162 2004. Table 2 summarizes the PCC and the MB of all precipitation indices studied in this
163 section for simulations obtained from control experiments with respect to CHIRPS
164 observations, calculated for the West Sahel, Central Sahel, Guinea Coast, and the entire West
165 African domain during the runs JJAS 2003 and JJAS 2004

166

167 **3.1.1 The number of the wet days (R1mm)**

168 Figure 2 shows the mean values of the number of wet days (R1mm, in days) from CHIRPS
169 (Fig. 2a, c) observation and the simulated control experiments (Fig. 2b, d) with the initial soil
170 moisture derived from ERA20C reanalysis. The R1mm index maximum values up to 100 days
171 in CHIRPS observation are found over mountainous regions such as the Cameroon Mountains,
172 Jos Plateau, and Guinea Highlands, while minimum values less than 50 days are found over the
173 Sahel and along the coastline from Liberia to Ghana with the number of wet days decreasing
174 gradually from south to north.

175 The control experiments (Fig. 2b, d) reproduce well the large-scale pattern of the observed
176 rainfall, with PCC values of 0.96 and 0.95 for runs JJAS 2003 and JJAS 2004, respectively
177 (Table 2) over the entire West African domain, but exhibit some spatial extent and magnitude
178 biases at local scale. The control experiments display a large and quite homogeneous area of
179 maximum values of R1mm index below 12 °N latitude and overestimate the number of wet
180 days over most of the studied domains (Table 2). The largest MBs are found over the Guinea
181 Coast with MB values more than 53.16 and 55.46 days for the runs JJAS 2003 and JJAS 2004,
182 respectively (Table 2). This overestimation of the number of wet days in RegCM4 is also found
183 by Thanh et al. (2017) with RegCM4 for Asia.

184 Figure 2 (second panel) displays additional changes in the R1mm index for JJAS 2003 and
185 JJAS 2004 from the dry (Fig. 2e and g) and wet experiments (Fig. 2f and h) compared to the
186 control experiments; the dotted area shows changes with statistical significance at the 95%
187 level. The dry experiments (Fig. 2e, g) decrease the R1mm index values, while the wet
188 experiments (Fig. 2h, j) increase them, especially over Central Sahel. However, over the Guinea
189 Coast sub-region, both wet and dry experiments show a significant increase in R1mm index
190 values.

191 For a better quantitative evaluation, Figure 3 displays the PDF distributions of changes in
192 R1mm over the sub-domains (Fig. 1), during the runs JJAS 2003 and JJAS 2004 while Table 3
193 summarizes the PDF maximum values. The results essentially confirm the linear impact found
194 over Central Sahel (Fig. 3a). Over West Sahel, the Guinea Coast, and the West African domain
195 (Fig. 3b, c, and d), both dry and wet experiments increase the R1mm index values. The strongest
196 R1mm increase is found in wet experiments over West Sahel, with a maximum change about
197 12 days in JJAS 2003 (Table 3) while the strongest R1mm decrease is found for dry experiments
198 over Central Sahel, with a maximum change about -5.19 days (Table 3).

199 .
200 Summarizing the results of this section, RegCM4 overestimated the number of wet days over
201 most of the studied domains. Over the Central Sahel, wet and dry experiments lead both to a
202 linear impact on the R1mm index with an increase and a decrease respectively of the number
203 of rainy days. These results are compatible with previous work that sustained a strong land–
204 atmosphere coupling in transition areas between wet and dry climate regimes (Zhang et al.,
205 2011; Koster et al., 2006).

206

207 **3.1.2 Simple daily intensity index (SDII).**

208 We analyzed in this section the SDII index (rainfall intensity in $\text{mm}\cdot\text{day}^{-1}$) which gives the
209 amount of precipitation mean on total wet days (daily precipitation $>1\text{mm}$). Figure 4 (first
210 panel) is the same as figure 2 (first panel) but for the rainfall intensity. Over the coastline of
211 Guinea Coast, CHIRPS observation (Fig.4a, c) depicted the highest values of SDII index, more
212 than $25\text{ mm}\cdot\text{day}^{-1}$. While, over the Sahel and Sahara, CHIRPS observation showed large extend
213 SDII index values not exceeding $12\text{ mm}\cdot\text{day}^{-1}$ in both runs JJAS 2003 and JJAS 2004.

214 The control experiments (Fig. 4 b, d) reproduced well the large-scale pattern of CHIRPS with
215 PCC values reaching 0.73 and 0.77 (in the runs JJAS 2003 and JJAS 2004, respectively; Table
216 2) over the West African domain. However, at the local scale, some biases are found. Over most
217 of the studied domains, the magnitude of the SDII is underestimated and not exceed $10\text{ mm}\cdot\text{day}^{-1}$,
218 excepted over the Cameroon Mountains (Fig. 4b, d). The largest MB values were located
219 over the Guinea Coast with MB values greater than -13.62 and $-14.65\text{ mm}\cdot\text{day}^{-1}$ for the runs
220 JJAS 2003 and JJAS 2004, respectively (Table 2).

221 Figure 4 (second panel) is the same as figure 2 (second panel) but for the rainfall intensity.
222 Unlike the R1mm index, changes in the SDII index due to soil moisture initial conditions are
223 not linear over most of studied domains. Fig. 4 (second panel) shows that generally, the impact

224 on rainfall intensity of dry and wet experiments presents areas of increase and decrease over
225 most of the studied sub-domains.

226 Figure 5 displays PDFs of changes in SDII, as in Fig. 3. The PDFs show a maximum change
227 value centered approximately on zero (Table 3), indicating that changes in the rainfall intensity
228 for wet and dry experiments are not significant.

229 In summary, RegCM4 underestimates the rainfall intensity over the studied domain compared
230 to the observation and the impact on SDII index in wet and dry experiments are not significant.

231

232 **3.1.3 Maximum number of consecutive dry days (CDD).**

233 The duration of consecutive dry days (CDD, in days), which represents the maximum number
234 of consecutive dry days with precipitation less than $1 \text{ mm}\cdot\text{day}^{-1}$ is analyzed in this subsection.

235 Figure 6 (first panel) is the same as figure 2 (first panel) but for CDD. CHIRPS observation
236 locates the highest CDD values over the Sahara, with length more than 50 days (Fig. 6a, c). The
237 lowest CDD values are found over the Guinea Coast, with length less than 8 days.

238 The control experiments (Fig. 6b, d) over the entire West African domain well reproduce the
239 large-scale pattern of the observed rainfall with a PCC values more than 0.85 and 0.89 for the
240 runs JJAS 2003 and JJAS 2004, respectively (Table 1). However, in terms of magnitude, some
241 differences are observed at local scale. In general, the control experiments overestimate the
242 CDD over most of studied subdomains, except over the Guinea Coast (Table 2). The strongest
243 overestimation is found over West Sahel with MB values reaching more than 14.49 and 17.51
244 days for runs JJAS 2003 and JJAS 2004, respectively (Table 2). The current model
245 parameterization increases the drought extreme over most of the studied domains, except over
246 the Guinea Coast (Table 2).

247 Figure 6 (second panel) is the same as figure 2 (second panel) but for CDD. The soil moisture
248 initial condition impact on CDD index is linear over the Central and West Sahel (Fig. 6, second
249 panel); Over the Sahel, dry (wet) experiments increase (decrease) the length of dry spells. Over
250 the Guinea Coast, the impacts on CDD are weak for both dry and wet experiments and in
251 average, soil moisture initial conditions seem to decrease the length of dry spells in a central
252 band between Côte d'Ivoire and Nigeria.

253 Figure 7 is the same as figure 3 but displays the PDF distribution of the changes in CDD. The
254 highest length of CDD increase are found over the Central Sahel in dry experiments with
255 maximum change in length reaching 3.80 days in JJAS 2004 (Table 3), while the highest CDD

256 decrease are found over West Sahel in wet experiments with maximum change in length
257 reaching -12.73 days in the run JJAS 2003 (Table 3).

258 In summary, RegCM4 overestimated the maximum number of consecutive dry days over most
259 studied subdomains, except over the Guinea Coast. However, the impact of soil moisture initial
260 condition is linear over the Central and West Sahel. Over the Guinea Coast, the dry and wet
261 experiments generally decrease the length of dry spells.

262

263 **3.1.4 Maximum number of consecutive wet days (CWD).**

264 The duration of wet spells (CWD) which represents the maximum number of consecutive wet
265 days with precipitation $\geq 1 \text{ mm.day}^{-1}$ is investigated in this subsection. Figure 8 (first panel) is
266 the same as figure 2 (first panel) but shows the CWD duration. In the CHIRPS observation, the
267 maximum length of CWD lasting longer than 20 days are found over the mountain regions such
268 as Cameroon Mountains, Jos plateau and Guinea highlands. While the minimum length of
269 CWD lasting less than 4 days are found over most of the area above the latitude 17°N (Fig.8a,
270 c).

271 The control experiments well reproduce the large-scale pattern over the entire West African
272 domain, with PCC values around 0.81 and 0.87 (resp. for JJAS 2003 and JJAS 2004, Table 2).
273 However, at local scale, the control experiments exhibit some biases in the CWD minimum and
274 maximum values, both in terms of magnitude and spatial extent. Control experiments
275 overestimate the CWD length over most of subdomains studied (Fig. 8 b, d). We noted that,
276 areas of overestimation coincide with areas of excessive R1mm values (Fig.2b, d). The
277 strongest overestimation is found over the Guinea Coast, reaching 59.21 and 60.51 days (resp.
278 for JJAS 2003 and JJAS 2004, Table 2).

279 Figure 8 (second panel) is the same as figure 2 (second panel), but displays changes in CWD.
280 As for R1mm index, over the Central Sahel, the dry (wet) experiments decrease (increase) CWD
281 length for both JJAS 2003 and JJAS 2004. This result confirms the strong influence of soil
282 moisture initial conditions in the Sahel band, as found by Zhang et al. (201) and Koster et al.
283 (2006) over the transition zones with a climate between dry and wet regimes. However, over
284 Guinea and the West Sahel, the changes are not linear, both dry and wet experiments increase
285 the CWD length (Fig. 8e-h).

286 Figure 9, as in figure 3, but shows the PDF distribution of changes in CWD. The strongest
287 CWD increase is found over Central Sahel with maximum changes reaching 15.58 days in wet

288 experiments, while in dry experiments, the strongest CWD decrease is found in the same sub-
289 domain with maximum changes reaching -4.48 days.

290 Summarizing the results of this section, as for R1mm and CDD indices, the impact of wet and
291 dry experiment on CWD is linear over the Central Sahel meaning that dry (wet) experiments
292 decrease (increase) the CWD lengths. The model RegCM4 overestimates the duration of wet
293 consecutive days over most of studied subdomains. This overestimation is associated with the
294 excessive number of wet days in the model as documented by Diaconescu et al. (2014).

295

296 **3.1.5 Maximum one-day precipitation accumulation (RX1day).**

297 The maximum one-day precipitation accumulation (RX1day) during JJAS 2003 and JJAS 2004
298 is assessed in this section. Figure 10 (first panel) shows the spatial distribution of RX1day.
299 CHIRPS observation confines the spatial extent of RX1day maximum values greater than 80
300 mm over the coastline of the Guinea Coast. While, the large extent of RX1day minimum values
301 less than 50 mm are found over the Sahara, Sahel and part of Guinea Coast.

302 The control experiments capture the spatial pattern of RX1day with PCC values around 0.50
303 and 0.4 for JJAS 2003 and JJAS 2004, respectively (Table 2). This low coefficient of PCC is
304 also obtained by Thanh et al. (2017) over Asia with RegCM4 (correlation < 0.3). The model
305 simulations fail to capture the magnitude and spatial extent of the RX1day maxima. The control
306 experiments underestimate the RX1day over most of studied subdomains and this seems to be
307 associated with the excessive number of weak precipitation simulated by the model. The largest
308 underestimation is located over the Guinea Coast and the West Sahel. For instance, over the
309 West Sahel, the MB values are -38.07 and -36.67 mm for JJAS 2003 and JJAS 2004,
310 respectively (Table 2).

311 Figure 10 (second panel) is similar to Figure 2 (second panel), but displays changes in the
312 RX1day. As for the SDII, the impact of the soil moisture initial conditions on RX1day is not
313 linear (Fig. 10, second panel).

314 Figure 11 is similar to figure 3, but shows the PDF distribution of changes in the RX1day.
315 Increases of RX1day for both dry and wet experiments are found over most of studied
316 subdomains (Fig.11). The strongest increase in RX1day is found over Guinea Coast for wet
317 experiments, with values reaching 26.14 and 14.93 during JJAS 2003 and JJAS 2004,
318 respectively (Table 3).

319 In summary, RegCM4 underestimates the maximum one-day precipitation accumulation over
320 most of studied domain. Both wet and dry experiments lead to an increase of RX1day.

321

322 **3.1.6 Precipitation percent due to very heavy precipitation days (R95pTOT)**

323 In this section, we investigated the precipitation percentage due to very heavy precipitation days
324 during JJAS 2003 and JJAS 2004. Figure 12 (first panel) is the same as figure 2 (first panel),
325 but shows the spatial distribution of R95pTOT. CHIRPS observation confines the R95pTOT
326 maximum values greater than 40% over the Guinea Coast. While R95pTOT index minimum
327 values less than 30 % are found over the Central and West Sahel (Fig. 10 a, c). The control
328 experiments (Fig. 12b, d) capture the large spatial pattern with PCC values of 0.59 and 0.55 for
329 JJAS 2003 and JJAS 2004, respectively (Table 2). As with SDII and RX1day indices, the
330 control experiments underestimate the values of the R95pTOT index, while they overestimate
331 the R1mm index. This is also due to the current physical parameterization scheme of the
332 RegCM4 model, which results in a positive bias for the number of wet days with a low
333 precipitation amount (e.g., 1 mm.day⁻¹), and a negative bias in the number of wet days with a
334 higher precipitation threshold (e.g., 10 mm.day⁻¹, not showed here).

335 The control experiments underestimate R95pTOT over the different studied domains. The
336 highest R95pTOT underestimation is found over the Guinea Coast with MB values more than
337 -43.22 and -46.61 % for JJAS 2003 and JJAS 2004, respectively (Table 2).

338 Figure 12 (second panel) is similar to figure 2 (second panel), but displays changes in the
339 R95pTOT index. Both dry and wet experiments lead to R95pTOT index increase over the
340 orographic regions. Therefore, the soil moisture initial conditions, whether dry or wet extreme
341 reinforce occurrence of extreme floods events.

342 Figure 13 is the same as figure 3 but shows the PDF distribution of changes in the R95pTOT.
343 The highest R95pTOT increase is found over the West Sahel and Guinea Coast with maximum
344 change values around 4.03% and 4.33% for JJAS 2003 and JJAS 2004, respectively (Table 3).

345 In summary, RegCM4 underestimates R95pTOT while the soil moisture initial conditions,
346 whether dry or wet, increase the precipitation percent due to very heavy precipitation days. This
347 result is consistent with Liu et al. (2014) work over Asia using RegCM4.

348

349 **3.2. Temperature extreme indices**

350 In this section, using daily maximum and minimum temperatures, we analyzed four extreme
351 temperature indices (Table 1) in RegCM4 simulations over West Africa. All temperature
352 indices are calculated for JJAS 2003 and JJAS 2004. Table 4 summarizes the PCC and MB of

353 all temperature indices for the control experiments with initial soil moisture from ERA20C
354 reanalysis, with respect to CPC-T2m observation, calculated over the subdomains presented in
355 Fig. 1, during the JJAS 2003 and JJAS 2004.

356

357 **3.2.1. Maximum value of daily maximum temperature (TXx)**

358 In this section, we analyzed the TXx, which gives the hottest day's temperature during JJAS
359 2003 and JJAS 2004. Figure 14 (first panel) shows the TXx (in °C) from CPC-T2m observation
360 (Fig. 14a, c) for JJAS 2003 and JJAS 2004 and from the mean control experiments (Fig. 14b,
361 d). The CPC-T2m observation shows that the highest TXx values more than 46 °C are found
362 over the Sahara. The lowest TXx index values less than 32 °C are found over the Guinea Coast
363 (Fig. 14a, d). CPC-T2m observation (Fig. 14a, c) shows the lowest TXx values less than 28 °C
364 along the coastline of the Guinea Coast, while the TXx highest values more than 40 °C are
365 found over Sahara and the northern of Sahel (Fig.14a, c),

366 The control experiments (Fig. 14c, f) reasonably replicate the large-scale patterns of the TXx
367 values with PCCs up to 0.99 (Table 3) over the entire West African domain; however, they
368 exhibit some biases at local scale. The control experiments are closer to the maximum and
369 minimum values displayed in the CPC-T2m observation. The control simulations overestimate
370 the TXx values over the Central and West Sahel, and underestimate them over the Guinea Coast
371 (Table 4). The greatest overestimation is found over the West Sahel with MB values around
372 3.02 and 2.02 °C for JJAS 2003 and JJAS 2004, respectively (Table 4). However, the biases
373 obtained for TXx are much lower than those obtained by Thanh et al. (2017), who used
374 RegCM4 over Asia where they reached 8 °C.

375 Figure 14 (second panel) displays changes in TXx for JJAS 2003 and JJAS 2004 in dry (Fig.
376 14g, i) and wet experiments (Fig. 14h, j) with respect to the control experiments; the dotted area
377 showed significant changes with a statistical significance of 95%. Dry experiments lead to an
378 increase of TXx values, while the wet experiments decrease them.

379 The PDF distributions of TXx changes for JJAS 2003 and JJAS 2004 over (a) the Central Sahel,
380 (b) West Sahel, (c) Guinea Coast, and (d) West Africa derived from dry and wet experiments
381 compared to the control experiments are shown in Fig. 15. Table 5 summarizes the maximum
382 values of changes obtained on the PDF of TXx. The strongest decrease (increase) in the TXx
383 index are found over the Central Sahel with a maximum change around -2.57 °C (more than
384 1.69 °C) in wet (dry) experiments in JJAS 2004.

385 In summary, during JJAS 2003 and JJAS 2004, the RegCM4 model overestimates and
386 underestimates the hottest day's temperature over the Sahel and Guinea Coast, respectively.
387 Dry experiments result in an increase of TXx, while the wet experiments lead to a decrease of
388 TXx values.

389

390 **3.2.2. Minimum value of daily maximum temperature (TXn).**

391 In this section, we investigated the TXn index which gives the lowest day's temperature during
392 JJAS 2003 and JJAS 2004. Figure 16 (first panel) is the same as figure 14 (first panel) but
393 presents the spatial distribution of the TXn index. CPC-T2m observation displays maxima
394 (greater than 36°C) and minima (less than 24°C) of TXn over the Sahara and the Guinea Coast
395 respectively (Fig.16a, c).

396 The control experiments (Fig.16b, d) show a good agreement with the CPC-T2m datasets in the
397 large scale patterns with PCC of approximately 0.99, however, the magnitude of the TXn index
398 over most of studied domain is overestimated. The strongest positive bias was observed over
399 West Sahel domain with MB about 6.56 and 5.44 °C for JJAS 2003 and JJAS 2004, respectively
400 (Table 4). The TXn biases of our study are lower than those obtained by Thanh et al. (2017) in
401 their work over Asia using RegCM4. As for Fig.14 (second panel), the Figure 16 (second panel)
402 displays changes in TXn index. Dry experiments increase TXn index values while the wet
403 experiments decrease them.

404

405 Figure 16 (second panel) is similar to figure 14 (second panel) but displays the PDF distribution
406 of changes in TXn. The impact on TXn is rather weak compared to the TXx. The strongest
407 increase of TXn index are found over the Central Sahel reaching 1.03 °C in dry experiments
408 during JJAS 2004 (Table 5). While the strongest decrease is found over the West Sahel about -
409 1.67°C for wet experiments during JJAS 2004 (Table 5).

410 In summary, RegCM4 overestimates the lowest day's temperature during JJAS 2003 and JJAS
411 2004 over the whole West African domain. As for TXx index, dry (wet) experiments increase
412 (decrease) the TXn values.

413

414 **3.2.3. Minimum value of daily minimum temperature (TNn index).**

415 In this section, we examined the TNn index, which gives the lowest temperature at night during
416 JJAS 2003 and JJAS 2004. Figure 18 (first panel) is the same as figure 14 (first panel) but
417 displays the spatial distribution of the TNn index. CPC-T2m observations (Fig. 18 a, c) shows

418 TNn maxima with values not exceeding 27 °C, above 15 °N latitude, while the minima values
419 (less than 17 °C) are found over the mountainous regions such as the Cameroon Mountains, Jos
420 Plateau, and Guinea Highlands.

421 The control experiments (Fig. 18 b, d) show good agreement with CPC-T2m observations with
422 PCC of approximately 0.99; however, they exhibit some biases at the local scale. The control
423 experiments overestimate the magnitude of the TNn index over most of studied domains.

424 The strongest positive biases are found over the West Sahel with MB reaching 3.30 °C and 2.55
425 °C for JJAS 2003 and JJAS 2004, respectively (Table 4). These positive biases obtained for the
426 TXx, TXn, and TNn indices are opposite to the cold bias known from RegCM4 in mean climate
427 simulation (Koné et al., 2018, Klutse et al., 2016). It is difficult to determine the origin of
428 RegCM4 temperature biases, as they can depend on several factors, such as surface energy
429 fluxes and water, cloudiness, and surface albedo (Sylla et al., 2012; Tadross et al., 2006).

430 Figure 18 (second panel) is the same as figure 14 (second panel), but displays changes in the
431 TNn. Over the Central and West Sahel, both dry and wet experiments decrease the TNn values.
432 Conversely, over the Guinea Coast, they increase the TNn values.

433 Figure 19 is the same as Figure 15 but shows the PDF distribution of changes in the TNn. Wet
434 (dry) experiments increase (decrease) the TNN values, especially over the Central Sahel. Table
435 5 shows that the strongest increase in TNn index in wet experiments is found over Guinea Coast,
436 with maximum change around 0.11 °C in JJAS 2004, while the strongest decrease in TNn is
437 found in dry experiments over the West Sahel, with maximum change around -1.15 °C in JJAS
438 2003.

439

440 In summary, RegCM4 overestimates the lowest temperature at night during JJAS 2003 and
441 JJAS 2004. Wet (dry) experiments lead to an increase (a decrease) of the TNN index.

442

443 **3.2.4. Maximum value of daily minimum temperature (TNx)**

444 In this section, the index TNx which gives the warmest night temperature during JJAS 2003
445 and JJAS 2004 is analyzed. Figure 20 (first panel) is the same as figure 14 (first panel), but for
446 the TNx index. CPC-T2m observation (Fig. 20a, c) shows the maxima of the TNx index over
447 the Sahara with values reaching 40 °C, while the minima around 24 °C are located over the
448 Guinea Coast.

449 The control experiments (Fig. 20b, d) well reproduced the general features of the TNx index
450 with a PCC value reached 0.99, but some differences exist at local scale. Unlike the TNn index,

451 control experiments underestimate the TNx over most of the studied domain. The strongest
452 negative biases are found over the Central Sahel, with MB values up to $-3.35\text{ }^{\circ}\text{C}$ and $-3.32\text{ }^{\circ}\text{C}$
453 for JJAS 2003 and JJAS 2004, respectively (Table 4). The TNx index underestimation seems
454 to be systematically related to the cold bias in RegCM4 over West Africa, which has been
455 reported in several papers (Koné et al., 2018, Klutse et al., 2016).

456 Figure 20 (second panel) is the same as figure 14 (second panel) but displays changes in the
457 TNx. Like for TNn index, over the Central Sahel, dry experiments increase the TNx values,
458 while the wet experiments decrease them. However, over the West Sahel, both wet and dry
459 experiments led to a dominant decrease. Conversely, over the Guinea Coast, although the signal
460 is weak, both dry and wet experiments led to a dominant increase.

461 Figure 21 is the same as figure 15 but displays the PDF distributions of the changes in the TNx.
462 The highest TNx increase (decrease) is found over the Central Sahel in dry (wet) experiments
463 with maximum changes up to 0.25 ($-1.67\text{ }^{\circ}\text{C}$) for JJAS 2003 (JJAS 2004) (Table 5). In
464 summary, RegCM4 underestimates the warmest night temperature and dry (wet) experiments
465 lead to an increase (decrease) of TNx magnitude.

466

467 **4. Conclusions**

468 The impact of the soil moisture initial conditions on six precipitation extreme indices and four
469 temperature extreme indices over West Africa was investigated using the RegCM4-CLM4.5.
470 We first evaluated the performance of RegCM4-CLM4.5 in representing these climate extreme
471 indices over West Africa. We then performed sensitivity studies over the West African domain,
472 with a spatial resolution of 25 km. We initialized the control runs using ERA20C reanalysis soil
473 moisture and for dry and wet experiments, we used the maximum and minimum values of
474 ERA20C over the whole domain, respectively. Results have been presented for JJAS 2003 and
475 JJAS 2004 which are the two contrasted runs most sensitive to the effects of dry and wet soil
476 moisture initial conditions.

477 Compared to CHIRPS observation, the model overestimates and underestimates the number of
478 wet days. RegCM4 also underestimates the simple daily precipitation intensity index (SDII),
479 the maximum 1-day precipitation (Rx1day), and the precipitation percentage due to very heavy
480 precipitation days (R95pTOT). The current physical parameterization scheme of the RegCM4
481 model used in our study results in a positive bias of the number of wet days with a low
482 precipitation threshold (e. g. $1\text{ mm}\cdot\text{day}^{-1}$), and in a negative bias for a higher precipitation

483 threshold (e.g. 10 mm.day⁻¹, not shown here). RegCM4 generally overestimates the CWD and
484 CDD indices over West Africa. Most of the temperature extreme indices used in this study
485 (TXx, TXn, and TNn) are also overestimated, except the TNx index, which is underestimated
486 over the West Africa domain.

487 The impact on extreme precipitation indices of the soil moisture initial conditions is linear over
488 the Sahel central, only for indices related to the number of precipitation events (R1mm, CDD,
489 and CWD indices) meaning that wet (dry) experiments lead to an increase (decrease) of the
490 number of days, and not for those related to the amount or intensity of precipitation (SDII,
491 RX1day, and R95pTOT). However, the dry and wet experiments increase the precipitation
492 percentage due to very heavy precipitation days and the maximum one-day precipitation
493 accumulation (R95pTOT and RX1day indices, respectively) over most of the studied domain.

494 The soil moisture initial conditions unequally influence the daily maximum and minimum
495 temperatures over the West African domain. The impact on daily maximum temperature
496 extremes are greater than those on the daily minimum temperature extremes. These results are
497 consistent with previous studies (Jaeger and Seneviratne, 2011; Zhang et al., 2009). The wet
498 (dry) experiments lead to TXx and TXn increase (decrease) over West Africa. However,
499 regarding the minimum temperature we showed that dry (wet) experiments lead to a TNx
500 increase (decrease).

501 This study helped to quantify the impact of the soil moisture initial conditions on precipitation
502 and temperature extreme events in terms of intensity, frequency and duration over West Africa.
503 This study is the first to investigate the impact of soil moisture initial conditions on climate
504 extreme indices over West Africa. These experiments were done in a highly-idealized framework
505 and were intended to show the potential impact of very strong soil moisture initial conditions on
506 climate extremes. Consequently, it should be considered as a first overview of the influence of
507 initial soil moisture on climate extremes with a RCM (RegCM4). This study will benefit from
508 being performed in a multi-model framework with several RCMs within CORDEX-Africa
509 initiative (Coordinated Regional Downscaling Experiment).

510 **Author contribution**

511 The authors declare to have no conflict of interest with this work. B. Koné and A. Diedhiou
512 fixed the analysis framework. B. Koné carried out all the simulations and figures production

513 according to the outline proposed by A. Diedhiou. B. Koné and A. Diedhiou, S. Anquetin and
514 A. Diawara worked on the analyses. All authors contributed to the drafting of this manuscript.

515

516 **Acknowledgements**

517 The research leading to this publication is co-funded by the NERC/DFID “Future Climate for
518 Africa” programme under the AMMA-2050 project, grant number NE/M019969/1 and by
519 IRD (Institut de Recherche pour le Développement; France) grant number UMR IGE

733 **TABLES AND FIGURES.**

734

Extreme indices		Definition	Units
Extreme Rainfall Indices			
1	R1mm	Number of wet days (daily precipitation ≥ 1 mm)	day
2	SDII	The amount of precipitation mean on wet days (daily precipitation ≥ 1 mm)	mm.day ⁻¹
3	CDD	Maximum number of consecutive dry days (daily precipitation < 1 mm.day ⁻¹)	day
4	CWD	Maximum number of consecutive wet days (daily precipitation ≥ 1 mm.day ⁻¹)	day
5	RX1day	The maximum one-day precipitation accumulation	mm
6	R95pTOT	Precipitation percent due to very heavy precipitation days.	%
Extreme temperature indices			
7	TXn	Minimum value of daily maximum temperature	°C
8	TXx	Maximum value of daily maximum temperature	°C
9	TNn	Minimum value of daily minimum temperature	°C
10	TNx	Maximum value of daily minimum temperature	°C

735

736 **Table1:** The 10 extreme climate indices used in this study.
