10 **Abstract.** In this paper, we present a novel approach, enabling the measurement of nitrate concentrations in natural soil porewater containing natural soil dissolved organic carbon (DOC). The method is based on UV absorbance spectroscopy, combined with fluorescence spectroscopy, for simultaneous analysis of DOC and nitrate concentrations. The analytical procedure involves deduction of the absorption caused by the DOC from the total absorbance in the UV range that is attributed to both DOC and nitrate in the water solution. The analytical concept
15 has been successfully tested in soil water samples obtained from five agricultural sites, as well as in water samples obtained from a commercial hummus soil mixture. We believe that the new analytical concept can provide a scientific foundation for developing a sensor for real-time nitrate concentration measurements in agricultural soils. As such, it can play a significant role in reducing nitrate pollution in water resources, optimizing input application in agriculture, and decreasing food production costs.

20

1. Introduction

During the last half-century, clear trends of rising nitrate concentrations in groundwater have been observed in aquifers all around the globe (Jin et al., 2012; Kourakos et al., 2012; Liao et al., 2012). The World Health Organization (WHO) has determined that nitrate levels in drinking water should not exceed 50 ppm (WHO, 2011). At high concentrations, nitrate is especially harmful to infants, where it may cause “blue baby syndrome” (methemoglobinemia) and can lead to severe illness and even death (Lorna Fewtrell, 2004; Thompson et al., 2007). Unfortunately, nitrate contamination is the dominant factor responsible for severe degradation of groundwater and surface resources. On a global scale, the eutrophication and hypoxia of streams, rivers and lake, are mostly attributed to subsurface return flow from nitrate-contaminated groundwater from phreatic aquifers underlying agricultural fields. Moreover, nitrate-contaminated groundwater affects not only terrestrial water resources but marine ecosystems as well. Eutrophication and hypoxia on a large scale have been found in the Gulf of Mexico (Scavia et al., 2003) and the Black Sea (Tolmazin, 1985), as well as severely impacting the Great Barrier Reef, in Australia (Brodie et al., 2012). Overall, nitrate contamination has led to more groundwater disqualification and water well shutdowns than any other contaminant worldwide (Dahan et al., 2014; Osenbrück et al., 2006), with nitrate being considered the most common non-point source groundwater pollutant (Turkeltaub et al., 2016). Numerous studies have linked increased nitrate concentrations in groundwater to the excess use of agricultural fertilizers (Burow et al., 2010; Fisher and Healy, 2008; Kurtzman et al., 2013). As a result, a global regulatory effort to reduce excess fertilizer application to prevent nitrate pollution has recently been undertaken worldwide by environmental protection and water authorities (Bureau, 2018; EPA US and Office of Water, 1994).

Currently, agricultural fertilizer application relies primarily on farmers’ experience, expert recommendations, and sporadic soil testing. None of these provide information that is in line with the time scale of N-fertilizer mobilization, consumption, and transformation dynamics in the soil. As such, continuous in-situ nitrate measurement in the soil is essential for optimizing fertilizer application and reducing groundwater pollution potential (Šimůnek and Hopmans, 2009).

Presently, monitoring of soil chemical parameters is performed in water samples that may be obtained using suction cups installed in the soil or through water extraction of soil samples (Kabala et al., 2017; Reck et al., 2019). Water samples collected using these methods need to be transferred to a laboratory for further chemical analyses, or direct analysis on-site using analytical kits (Golicz et al., 2020). Nitrate in the soil is highly soluble, mobile, consumed by plants, and subject to various biochemical transformations. Accordingly, nitrate concentration in the soil may fluctuate dramatically in time scales of hours to days in response to irrigation and precipitation patterns, fertilization, root uptake, and different plant growth phases (Mmolawa and Or, 2000; Turkeltaub et al., 2015). Thus, monitoring nitrate concentrations with conventional tools often does not meet the required time resolution for optimizing fertilizer application and preventing groundwater pollution from excess use. The use of highly sophisticated soil sampling methods can be expected from a dedicated research team but not from farmers who are focused on food production in large scale agricultural setups (Thompson et al., 2007). Therefore, automated, real-time monitoring of soil nitrate concentrations may provide growers with vital information on nutrient availability. Such data is critical for maximized productivity, in addition to water resource protection from nitrate pollution.

60 Ultraviolet (UV) absorption spectroscopy is one of the most common methods for nitrate analysis in
aqueous solutions (Mayerstein and Treinin, 1961; Moorcroft, 2001). Light absorption by nitrate in an aqueous
solution takes place at two main wavelength bands on the UV spectrum: (1) the high absorbance band from 200–
240 nm and (2) the low absorbance band from 280–340 nm. Tuly et al. (2009) suggested a continuous soil solution
65 monitoring setup to measure nitrate concentration by applying absorbance spectroscopy techniques in a porous
cup installed in the soil. This setup consisted of a porous stainless-steel cup filled with deionized water that was
placed in a reservoir of a potassium nitrate solution. Once the solution inside the porous cup achieved chemical
equilibrium by diffusion between the cup and the surrounding medium, the absorption spectrum of the solution
was measured by a UV dip probe. The dip probe was connected to a spectrophotometer and a UV light source
through optical fibers, which enabled continuous measurement of the solution within the suction cup. However,
70 this method was limited by two main factors: (1) achieving chemical equilibrium between the porous cup and the
surrounding medium is a slow process, especially in unsaturated sediment that has limited water storage. The time
lag between the actual variation in soil nitrate concentration and its measurement in the porous cap precludes the
real-time measurement of the rapid changes in the soil nitrate concentration, and (2) the presence of natural soil
dissolved organic carbon (DOC) limits the UV absorption spectroscopy analysis since both nitrate and soil DOC
75 absorb UV light in a similar wavelength range (Causse et al., 2017; Ferree and Shannon, 2001; Shaw et al., 2014).

 Recently, a monitoring setup for real-time soil nitrate concentration measurement was developed, which
is based on continuous spectral analysis of soil porewater (Yeshno et al., 2019, and 11-158 PCT, 2018) in an
optical flow cell that is connected to a specially designed porous cup (suction lysimeter). This enables the creation
of a continuous low rate flux of soil porewater flowing from the soil through the cell. The absorption spectrum of
80 the soil porewater in the optical flow cell is continuously recorded and analyzed to achieve real-time nitrate
concentration measurements. The analysis involves an algorithm that scans the entire absorption spectrum of the
soil porewater to identify an optimal wavelength where DOC interference with nitrate measurement is minimal.
Use of the method showed that the optimal wavelength is site-specific, and the calibration equations for nitrate
concentration are consistent over a long-time duration. Measurements conducted for two years in four different
85 agricultural fields and through a series of column experiments offered detailed information on time variations in
soil nitrate concentrations (Yeshno et al., 2019). Despite this significant breakthrough in continuous soil nitrate
concentration measurement, the technology is still too cumbersome and impractical for commercial agricultural
applications since it is based on a wide-band UV spectrophotometer and a bulky deuterium lamp as a UV light
source.

90 Reducing the cost, size, and energy consumption of a spectroscopy-based apparatus for measuring soil
porewater nitrate concentrations requires a shift in applied technology from the commonly used UV deuterium
lamp to a less expensive LED-based UV light source. In addition, the commonly used wide spectrum
spectrophotometer can be replaced with a more affordable photodetector. However, currently, most affordable,
commercially available UV-LEDs do not possess the range of the high nitrate absorbance band (200–240 nm),
95 but only of the low nitrate absorbance band in the range of 300 ± 20 nm. Nevertheless, the 300-nm spectral band
can still be used for the nitrate absorption spectral analysis (Moo et al., 2016). However, this band is also sensitive
to DOC presence. Moreover, DOC's impact on the absorption at 300 nm is inconsistent and depends on the soil
water's specific chemical composition (Yeshno et al., 2019). Thus, directly analyzing nitrate concentration from

100 the absorbance in the wavelengths surrounding the 300-nm band in water samples originating from agricultural soils is challenging.

In this paper, we present a novel approach, enabling nitrate estimation in porewater samples containing DOC with a variety of concentrations and chemical compositions. The analysis is based on UV absorbance spectroscopy in the vicinity of 300 nm combined with simultaneous fluorescence spectroscopy with excitation/emission at 350/451 nm for characterizing DOC impact on the absorption pattern. The independent DOC measurement allows subtracting DOC's contribution to the adsorption at 300 nm ((nitrate + DOC) – DOC = nitrate), thus enabling the estimation of nitrate concentration. The analytical procedure involves the spectral analysis of a matrix of soil porewater solutions containing variable combinations of DOC and nitrate concentrations from different agricultural soils. The resulting absorption and fluorescence database was used to develop a polynomial calibration equation that calculates nitrate concentration as a function of the absorbance at 300 nm and the DOC concentration (patent pending: PCT 62/860,273). The rationale behind the selection of these wavelengths for the analysis is related to the commercial availability of LED light sources in these wavelengths. Obviously, developing a robust soil nitrate sensor that is commercially affordable for widespread use in agricultural applications will lead to the optimization of fertilizer application and the reduction of water resource pollution.

115 2. Materials and methods

2.1 Study sites and soil samples

Soil samples from five different agricultural fields, located on the coastal plain of Israel, were collected and analyzed for this study. The samples were collected from organic and conventional greenhouses that grow vegetable crops, an open field that is used for rotating mixed crops, and a citrus orchard. These sites were chosen to represent a spectrum of typical agricultural practices in different soils. In addition, a commercial hummus soil mixture (Dovrat. LTD, Israel) was also examined to represent the potential impact of DOC originating from compost enrichment on a soil porewater spectral analysis. These sites have been intensively studied in the past, and additional information can be found in previous publications (Dahan et al., 2014; Turkeltaub et al., 2014, 2015, 2016) and in the Supporting Information section (Section S1).

125 2.2 Soil porewater samples

Soil solution samples were obtained by creating a mixture of the different soils with double distilled water (DDW). The soil extracts were left to stand for 24 h in order to achieve chemical equilibrium of the soil DOC. The soil and liquid phases were separated by a standard laboratory centrifuge, and the suspended solids were removed by a 0.22- μ m membrane filter. The samples were then diluted to obtain a series of replicates of different DOC concentrations. Each replicate was spiked with a variable volume of 10,000 ppm standard potassium nitrate solution, to achieve 4–6 different nitrate concentrations per DOC level. As a result, a matrix composed of 25–30 samples with variable combinations of DOC and nitrate concentrations, ranging from zero to ~1000 ppm nitrate and zero to ~100 ppm DOC was produced from each agricultural site (

Table 1). Table 1 shows a matrix of water samples obtained from the conventional greenhouse site. Additional databases for the remaining five soil type samples can be found under section S2 in the Supporting Information.

2.3 Chemical and spectral analyses

The initial values of DOC and total nitrogen (TN) in the sample were estimated by an Analytic Jena multi
140 N/C 2100s TOC/TN analyzer, while nitrate concentration was determined by a Dionex ICS 5000 Ion
chromatograph. The absorption of the samples at 300 nm was determined using a TECAN Spark 10M multimode
microplate reader spectrophotometer. The light absorbance was defined by the Lambert-Beer equation. (Equation
1):

$$Absorbance = -\log_{10} \frac{I}{I_0} \quad (1)$$

145 where I is the light intensity after passing through the examined solution, and I_0 is the light intensity after passing
through a reference water sample (DDW).

A fluorescence spectroscopy technique was used to measure the DOC concentration in the examined
solution using a TECAN Infinite M200 spectrophotometer with excitation (EX)/emission (EM) at 350/451 nm
(Mostofa et al., 2007; Painter et al., 2018; Parlanti et al., 2000). An important advantage of DOC fluorescence
150 spectroscopy is that it is not affected by the presence of nitrate in the solution.

The chemical and optical data of the soil water solution was analyzed by the MATLAB 2019b curve
fitting tool to obtain the polynomial equation for nitrate estimation.

3. Results and discussion

155 3.1 Absorption spectroscopy for nitrate estimation in soil water containing DOC

The application of UV absorption techniques to aqueous nitrate solutions commonly results in a linear
correlation between the absorption rate and the nitrate concentration (Edwards et al., 2001). However, this
correlation is not straightforward in natural soil water containing DOC, as UV absorption by the organic matter,
in conjunction with the nitrate absorption, leads to an increase in the overall absorption in the examined solution.
160 For example, a series of solutions with variable nitrate concentrations and a relatively constant DOC concentration
shows a linear correlation with the absorption values (curve a in Figure 1). However, a similar series of nitrate
concentrations, with an increased DOC level, shows a linear correlation as well, yet with a greater absorbance
level (curve b in Figure 1). Nevertheless, the similarities between the trendline associated with the low DOC levels
and the trendline associated with the high DOC levels imply that the DOC contribution to the overall absorbance
165 is consistent and quantifiable.

However, examining the relation between nitrate and DOC concentrations and the UV absorption of a
large solution matrix may not be as intuitive as the 2D model presented in Figure 1. In order to assess the specific
contribution of nitrate and DOC to the total absorption at 300 nm, the data from the three variables was projected
on a 3D domain (Figure 2). The data distribution in space, which is geometrically defined as a plane, was
170 mathematically quantified by applying a multivariate regression model. From this model, the nitrate concentration
in the sample could be estimated as a function of the DOC concentration and absorbance at 300 nm (Equation 2):

$$Nitrate(DOC, Abs) = P_{00} + P_{01}xAbs + P_{10}xDOC \quad (2)$$

where DOC indicates the DOC concentration (in ppm), Abs indicates the absorbance as measured at 300 nm (a.u.), and P_{00} , P_{10} , and P_{01} are the coefficients as obtained from the regression model.

175 Yet, the contribution of the DOC to the overall absorbance can differ from site to site, due to variations
in DOC chemical and optical characteristics in the different soils. The composition of the organic matter that
constitutes the DOC is affected by site-specific characteristics such as: type of agricultural crop, biological activity
in the soil, and the type of compost and fertilizer used at the site (Kalbitz et al., 2000; Nelson et al., 1992; Tian et
al., 2010). Therefore, the polynomial calibration equation for nitrate must be site-specific. Nonetheless, it was
180 concluded that the impact of DOC on the absorption spectrum, due to its chemical composition, remained
relatively constant through time and is a site-specific feature (Yeshno et al., 2019). This implies that once an initial
calibration equation is obtained, it can be used for that particular site repeatedly in a long duration, making real-
time continuous measurement of soil nitrate concentration feasible.

Further validation of the concept was performed by reproducing similar multivariate calibration models
185 and their calibration coefficients for estimating nitrate in the soil water of five additional agricultural sites (Table
2). The polynomial calibration equations were obtained for matrices of water samples containing variable DOC
concentrations, ranging from 1.6 to about 200 ppm, and nitrate concentrations ranging from a few ppm to about
1000 ppm. Nitrate concentrations predicted by the multivariate model had a correlation of $R^2 > 0.93$ and an RMSE
ranging from 39.2 to 66.4 ppm nitrate with the observed nitrate concentration in the solution (Figure 3). Detailed
190 information on the range of concentrations and the 3D projected data can be found under section S2 in the
Supporting Information section.

3.2 DOC analyses using fluorescence spectroscopy

In order to perform real-time analyses of nitrate in the water samples using the presented concept, the
DOC concentration in the examined solution needs to be continuously substituted in the polynomial calibration
195 equation (Equation 2), along with the absorption at 300 nm. Thus, an independent and simultaneous analysis of
DOC, along with the absorbance measurement, needs to be performed to determine the DOC concentration in the
examined solution.

One way of providing an independent, simultaneous measurement of DOC in the soil solution is by
fluorescence spectroscopy. Fluorescence emission values of the soil water samples at 451 nm, which had known
200 DOC concentrations, were used to develop a calibration curve for each site (Figure 4). The relation between DOC
concentration and fluorescence intensity in the water samples from the different fields shows that each field has
its own unique calibration equation due to the variation in the DOC chemical characteristics. As previously
mentioned, the composition of the organic matter that constitutes the DOC and its chemical characteristics are
site-specific properties. Therefore, similarly to the polynomial of the nitrate calibration equation, the calibration
205 curves for the DOC concentrations are also required to be site-specific.

3.3 Limitation in applications of UV-LEDs for nitrate analyses by absorption spectroscopy

As previously mentioned in this paper, UV absorption by aqueous nitrate can be divided into two distinct
sections: (1) a higher absorbance band around 220 nm and (2) a lower absorbance band at 300 nm. While both
absorbance bands are known to have direct correlations with nitrate concentration, the absorbance at 220 nm
210 absorbs light at two orders of magnitude higher than the absorbance at 300 nm. Consequently, the 300-nm

absorbance, which stretches at values from 0–1 (a.u.), corresponding to the relevant nitrate and DOC concentrations in this research, is characterized by a low signal (nitrate absorbance) to noise (DOC absorbance) ratio. Therefore, nitrate measurement at 300 nm is naturally more vulnerable to measurement errors, reducing the measurement accuracy, especially at the lower concentrations (< 100 ppm). Thus, future implementation of deep
215 UV LEDs in an LED-based nitrate monitoring sensor could improve the measurement accuracy. Estimating nitrate concentration in a hummus soil mixture water extract, using the combined absorbance-fluorescence concept when the absorbance data was measured at 235 nm, showed a great improvement in accuracy as compared to similar attempts to measure nitrate when the absorbance was measured at 300 nm (Figure 3e and Figure 5). However, with the currently limited availability of deep UV LEDs on the market, the 300-nm LEDs remain the most
220 affordable and attainable candidate for a UV light source for developing a nitrate monitoring sensor.

4. Summary and Conclusions

In the framework of this research, we have developed a new concept that enables nitrate estimation in soil water using UV absorption spectroscopy. The new concept allows the use of LEDs as a light source when performing spectral analyses, which are more affordable, compact, and power-efficient than the commonly used
225 deuterium UV light source. Moreover, the newly developed concept accounts for DOC measurement interference, which is a known issue when applying UV absorption spectroscopy techniques to nitrate analyses in soil water. Due to the currently limited availability of UV-LED light sources in the deep UV range, the concept was developed and validated at a wavelength of ~300 nm.

The simultaneous analytical procedure for DOC and nitrate was tested on soil water extracted from five
230 agricultural soils and from a soil mixture of commercial agricultural compost. The results indicate a reasonable correlation between the predicted and observed values of a series of samples obtained for each soil, with variable nitrate and DOC concentrations. Nevertheless, the non-ideal conditions when applying the new concept at 300 nm led to some measurement errors, which are not in line with a state-of-the-art standard laboratory apparatus. However, the concept is quite suitable for the practical demands of an onsite and real-time nitrate monitoring
235 sensor in agricultural and environmental applications. We hope that this work will establish the groundwork for the development of an affordable LED-based, electro-optical nitrate monitoring sensor. Such a system, which does not rely on the standard cumbersome light sources, is expected to be efficient in power consumption, size, and production costs and thus suitable for the requirements of both farmers and researchers. We believe that this nitrate and DOC monitoring concept may lead to a higher level of precision farming and the sustainable use of
240 associated water sources while optimizing yield and decreasing food production costs.

Table 2: Calibration coefficients for the multivariate regression model of the study site's obtained water samples.

	p_{00}	p_{01}	p_{10}
Conventional greenhouse	-338	10800	-71.8
Hummus soil mixture	-375.3	11270	-124.2
Organic greenhouse	-229.8	8304	-68.47
Open crop field: coastal	-378.2	11620	-235.9
Citrus orchard	-328.8	9463	-20.71
Open crop field: inland	-395.1	12940	-46.96

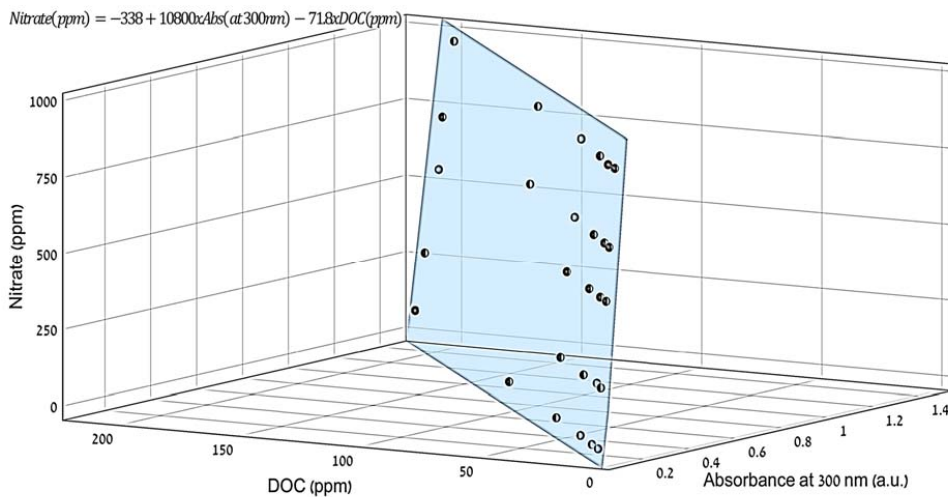

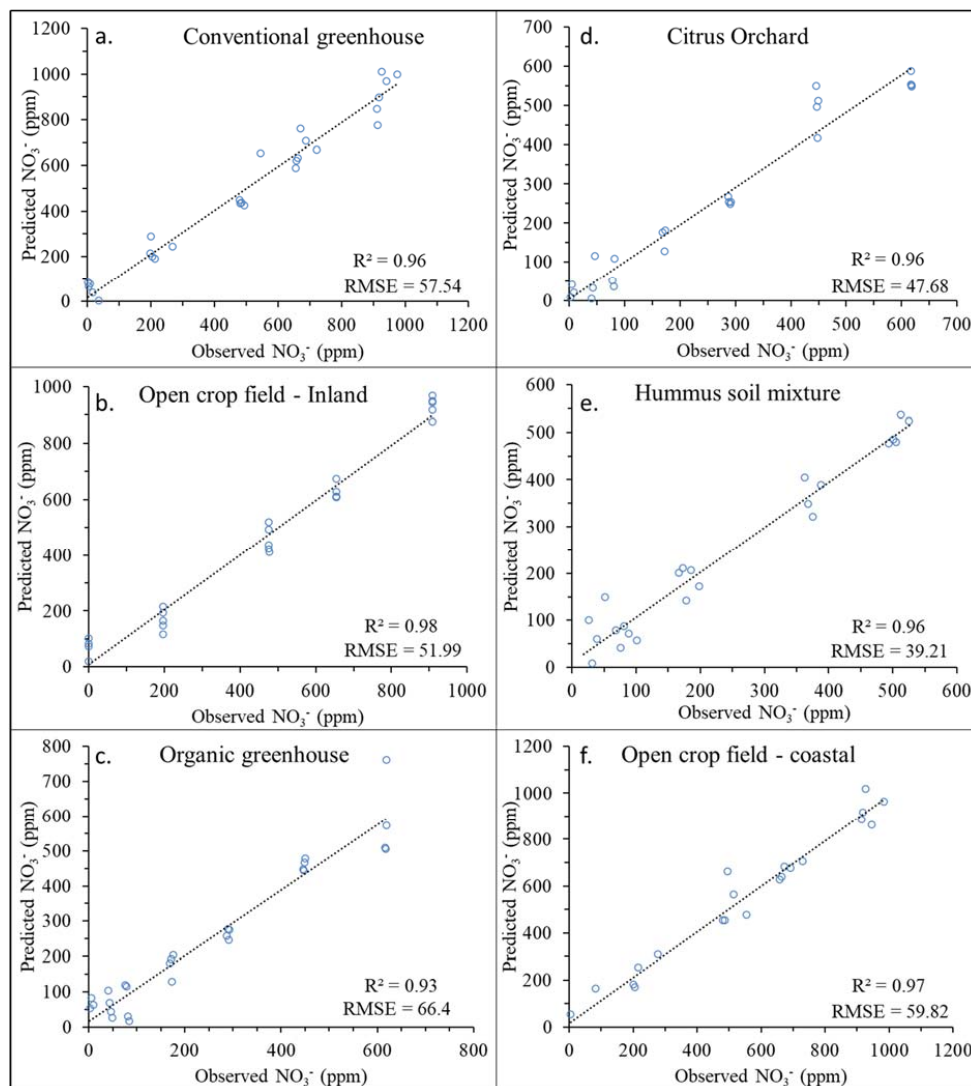

Figure 1 - Nitrate concentration vs. absorption at 300 nm of soil water samples from the conventional greenhouse.

365

Figure 2 - 3D projection of the nitrate concentration as a function of the DOC concentration and absorbance at 300 nm for water samples obtained from the conventional greenhouse.

370

Figure 3 - Observed vs. predicted nitrate concentrations.

Figure 4 - DOC concentration vs. fluorescence intensity at 451 nm.

375

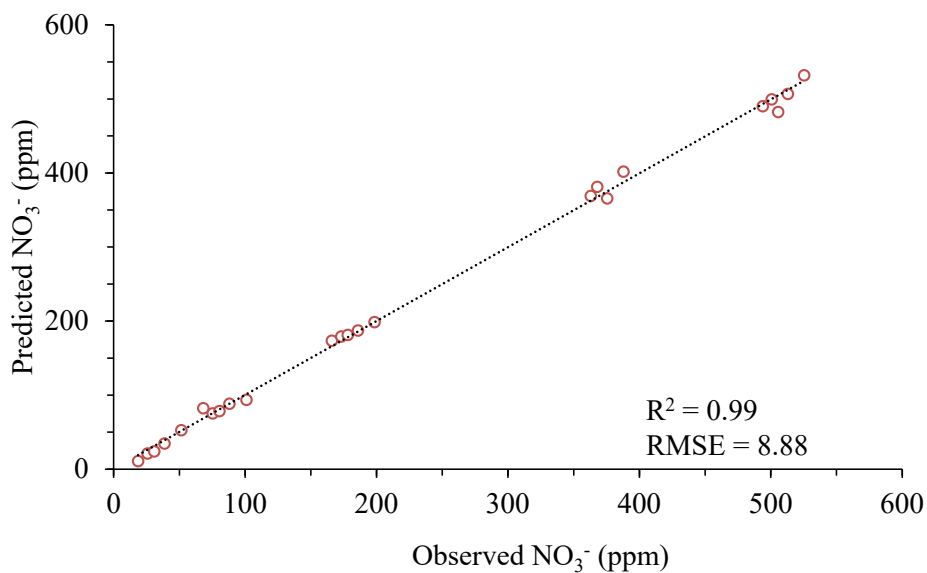

Figure 5 - Observed vs. predicted nitrate concentrations, for the hummus soil mixture water extract, when the calibration equation was obtained for absorption at 235 nm.
