**Abstract.** The ability of two downscaling experiments to correctly simulate the instability conditions that can trigger thunderstorms over the Iberian Peninsula is compared in this paper. To do so, three instability indices are evaluated: TT index, CAPE and CIN. The WRF model is used for the simulations. The N experiment is driven by ERA-Interim's initial and boundary conditions; The D experiment has the same configuration as N, but the 3DVAR data assimilation step is additionally run at 00, 06, 12 and 18 UTC. Eight radiosondes are available over the IP, and the values for these indices calculated from the University of Wyoming were chosen as reference in the validation of both simulations. Additionally, measured variables at different pressure levels from the radiosondes provided by Wyoming were used to calculate the three instability indices by our own methodology using the R package aiRthermo. According to the validation, the correlation, SD and RMSE obtained by the experiment D for all the indices in most of the stations are better than those for N. The different methodologies produce small discrepancies between the values for TT, but these are larger for CAPE and CIN due to the dependency of these indices on the initial conditions assumed for the calculation of an air parcel's vertical evolution. Similar results arise from the seasonal analysis concerning both WRF experiments: N tends to overestimate or underestimate (depending on the index) the variability of the reference values, but D is able to capture it in most of the seasons. The heterogeneity of the indices is highlighted in the mean maps over the Iberian Peninsula. According to those from D, the ingredients for the development of convective precipitation during winter are found along the entire Atlantic coast, but in summer they are located particularly in the Mediterranean coast. The chances of developing thunderstorms in those areas at 12 UTC is much higher than at 00 UTC; The convective inhibition is more extended towards inland at 00 UTC in those areas, which prevents storms from developing. However, high values are observed near Murcia also at 12 UTC.

## 20 1 Introduction

Precipitation is one of the most important variables involved in the water balance, and its variability determines the water resources in the planet. It can be separated in two categories: large-scale precipitation, associated with the frontal systems, and convective precipitation, triggered by convective instability of atmospheric layers. The latter is usually associated with extreme events due to their intensity and short duration. However, the simulation of these events is a well-known problem in the modelling community (Sillmann et al., 2013) due to restrictions in the resolution and the poor representation of complex topography in the numerical models. In order to avoid this problem, as previously done in the literature (Viceto et al., 2017), this paper focuses on the evaluation of the atmospheric conditions favourable for the development of convective extreme precipitation rather than the validation of the simulation of extreme events.

The evaluation of the atmospheric conditions is typically based on the calculation of some instability indices such as Convective Available Potential Energy (CAPE) (Moncrieff, 1981), Convective INhibition (CIN) (Moncrieff, 1981), Lifted Index (LI) (Galway, 1956), K-Index (George, 1960), Total Totals index (TT) (Miller, 1975) or Showalter Index (S) (Showalter, 1953). All of these indices are commonly used in the literature for this kind of studies (Ye et al., 1998; DeRubertis, 2006; Viceto et al., 2017). CAPE and CIN are based on the adiabatic lifting of a parcel, while the others are based on differences in the values of several variables at different pressure levels. The deep convection and thunderstorms are triggered by three ingredients: high levels of moisture in the planetary boundary layer (PBL), potential instability and forced lifting (Johns and Doswell, 1992; McNulty, 1995; Holley et al., 2014; Gascón et al., 2015). CAPE and CIN provide information about the first two ingredients (Holley et al., 2014), and both can provide information about the genesis and intensity of the convective precipitation (Riemann-Campe et al., 2009). However, previous studies (Angus et al., 1988; López et al., 2001) suggest that CAPE should not be used alone and it should be combined with other indices. The final ingredient (lifting) is provided by the orography (Doswell et al., 1998; Siedlecki, 2009), the convergence of horizontal moisture fluxes (McNulty, 1995) or the breezes in coastal regions (van Delden, 2001). Thus, the spatial and temporal resolution is important for these studies, and that is why regional simulations are needed (Siedlecki, 2009).

The probability of occurrence of precipitation extreme events is not the same along the day, and previous studies suggest that the maximum convection takes place in the afternoon and evening (Siedlecki, 2009). According to van Delden (2001), the preferred time in most of western Europe is between 18 and 24 UTC, with the exception of the island of Corsica where the sea breeze triggers convection usually between 6-12 UTC. A regional study focusing over the UK (Holley et al., 2014) suggests that the reduction overnight of CAPE is over 500 J/Kg.

In a global scale, CAPE follows the spatial pattern of specific humidity and surface air temperature, which means that it increases from pole to Equator (Riemann-Campe et al., 2009). The minimums are obtained in arid regions and over areas with cold water up-welling. Focusing on Europe, convective precipitation is developed with lower values than the U.S. (Kaltenböck et al., 2009), and several studies tried to determine the most active regions. Romero et al. (2007) found that the most unstable region is located along a zonal belt over the south-central Europe, particularly in the west Mediterranean sea and the surrounding areas. This agrees with Brooks et al. (2003), who found that the favourable environment for thunderstorms is developed

in the southern Europe, and that the highest number of days in such a regime is located in central Europe, south of the Alps,  
55 and southern Ukraine. However, van Delden (2001) found that the southwestern France and the Basque Country seem to be a  
preferred region for the formation of severe storms that drift towards the northeast.

Over the Iberian Peninsula (hereafter, IP), the seasonality of precipitation is determined by its heterogeneous topography and  
the different sources of moisture affecting the region. Northern and western IP are mainly affected by stratiform precipitation  
during winter, while eastern and southern IP receive great amounts of precipitation during autumn due to convective activity  
60 (Rodríguez-Puebla et al., 1998; Esteban-Parra et al., 1998; Romero et al., 1999; Iturrioz et al., 2007). Maximum precipitation  
amounts over central IP are measured in early spring (Tullot, 2000). Previous studies about instability indices over the IP  
(Viceto et al., 2017) suggest that CAPE presents high spatio temporal variability: the values in winter and spring over land are  
small due to the reduced surface temperature, and the differences between Atlantic and Mediterranean regions are remarkable  
during summer. According to Siedlecki (2009), they range from below 50 J/kg in the north to between 100 and 200 J/kg in  
65 the Mediterranean coast (some events can even reach 1000 J/kg). As Romero et al. (2007), Viceto et al. (2017) also stated  
that CAPE is low during autumn in the Atlantic and continental regions, but high in the areas surrounding the Mediterranean  
sea. This seasonality was also observed for other indices such as K-index or TT, which show maximum values during summer  
(Siedlecki, 2009). Observations proved that annual precipitation over eastern stations is mostly accumulated during autumn,  
as a result of the cumulative warming of the Mediterranean sea due to summer insolation (Romero et al., 2007; Iturrioz et al.,  
70 2007), and later entrance of very hot and humid air into the IP while cold air is present at higher levels (Dai, 1999; Eshel  
and Farrell, 2001; Correoso et al., 2006). Additionally, September and October are the months with highest frequency of  
waterspouts and tornadoes near the Balearic Islands (Gayà et al., 2001). Over the northwestern IP, the mean CAPE when a  
hailstorm occurs is 360 J/kg, while for a thunderstorm it is only 259 J/kg (López et al., 2001). The values are similar to those  
observed in Europe, but the dispersion of the values is really high (almost 350 J/kg over the whole sample) (Alexander and  
75 Young, 1992; Lucas et al., 1994).

Recent studies (Brooks, 2013; Rädler et al., 2019) suggest that due to global warming, the conditions necessary for the  
development of extreme precipitation events will be enhanced. The frequency and intensity of climate extremes will be magni-  
fied (Diffenbaugh et al., 2013). Marsh et al. (2009) projected higher values of CAPE in the Mediterranean during summer and  
autumn, which is in line with the projections from Viceto et al. (2017) for the IP and its surroundings. Thus, the probability of  
80 observing lower values of CAPE is expected to decrease in the future.

The main objective of this paper is to evaluate the performance of two simulations created by using the Weather and Research  
Forecasting (WRF) model (Skamarock et al., 2008) (including or not the extra 3DVAR data assimilation step) at reproducing  
the atmospheric conditions that can trigger convective precipitation over the IP. To do so, the comparison of pseudo-soundings  
extracted from the model against real observations will be carried out. Additionally, the seasonal patterns of different instability  
85 indices will be studied. The novelty of this study lies in the inclusion of data assimilation in the downscaling experiment used  
for the analysis of some instability indices.

This paper is organised as follows: The details of the configuration of the WRF model used in both experiments are presented  
in section 2, along with a brief outline of the methodologies used in the study. The main results are presented in section 3, while

they are compared against previous studies presented in the introduction. Finally, we conclude with some remarks about our  
90 research in section 4.

## 2 Data and Methodology

### 2.1 WRF model configuration

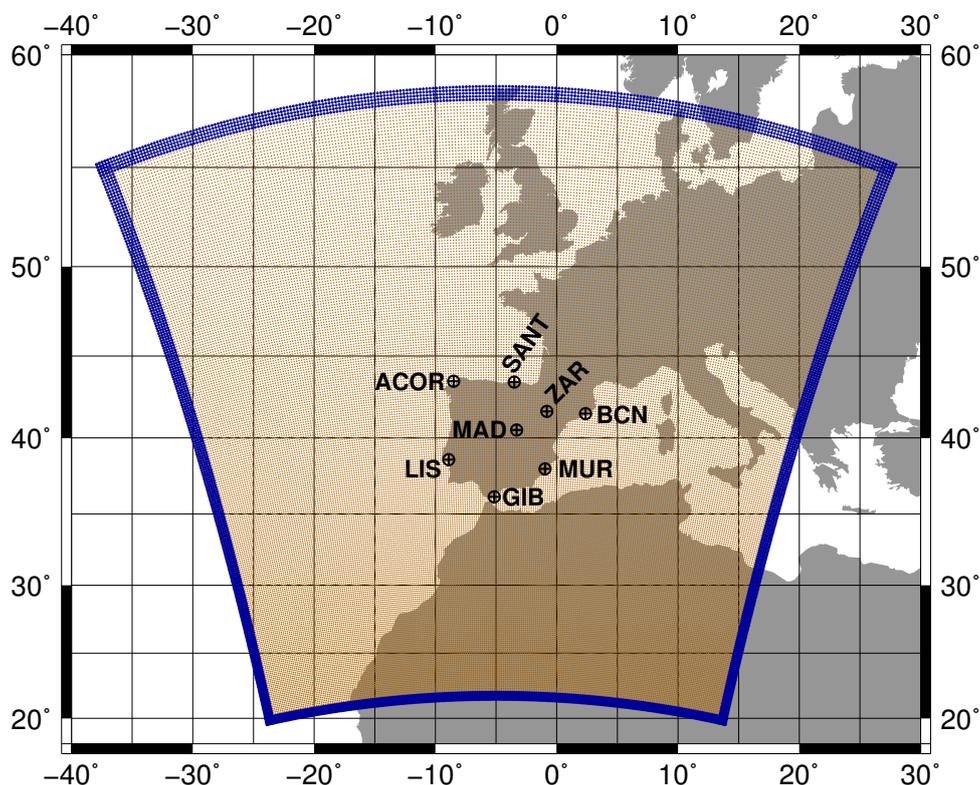

Two experiments were carried out using version 3.6.1 of the WRF model for the period 2010–2014. In both simulations, ERA-  
Interim provides the initial and boundary conditions (Dee et al., 2011). 6-hourly data were downloaded from the Meteorological  
95 Archival and Retrieval System (MARS) repository at European Centre for Medium-Range Weather Forecasts (ECMWF), and  
they present a 0.75 degrees resolution and 20 vertical levels. Both simulations were started on the 1st of January, 2009 from  
a cold start. Following similar methodologies to previous studies (Argüeso et al., 2011; Zheng et al., 2017), the entire year  
2009 was selected as the spin-up for the land surface model included in WRF, and consequently, it was omitted in the study  
presented here.

100 One of the experiments (hereafter, N) was nested inside ERA-Interim as usual in numerical downscaling exercises, which  
means that the model is driven by the boundary conditions after its initialization. The other experiment (D) presents the same  
configuration as N, but with the additional 3DVAR data assimilation step (Barker et al., 2004, 2012) that is run every 6 hours (at  
00, 06, 12 and 18 UTC). In this step, quality controlled temperature, moisture, pressure and wind observations in PREPBUFR  
format from the NCEP ADP Global Upper Air and Surface Weather Observations dataset (referenced as *ds337.0* at NCAR's  
105 Research Data Archive) were included. Only those observations included in a time-window of two-hours centered in the  
analysis times were assimilated.

As Figure 1 shows, the domain focuses over the IP, but it also includes parts of Europe, Africa and the Atlantic ocean. As  
stated by previous studies (Jones et al., 1995; Rummukainen, 2010), the set-up of the domain used in this study prevents border-  
effects affecting our results as mesoscale systems can develop freely. The spatial resolution of both experiments is 15 km, and  
110 they use 51 vertical levels. The recording frequency of the outputs is 3 hours in both experiments.

Apart from the ERA-Interim data, sea surface temperature (SST) of the model was updated on a daily basis using the high-  
resolution dataset *NOAA OI SST v2* (Reynolds et al., 2007). Additionally, the following parameterizations for the physics of  
the model were included in both simulations: five-class microphysics scheme (WSM5) (Hong et al., 2004), MYNN2 planetary  
boundary layer scheme (Nakanishi and Niino, 2006), Tiedtke cumulus convection scheme (Tiedtke, 1989; Zhang et al., 2011),  
115 RRTMG scheme for both long and shortwave radiation (Iacono et al., 2008), and NOAH land surface model (Tewari et al.,  
2004).

The background error covariance matrices were created before running the simulation with 3DVAR data assimilation. To  
do so, the CV5 method included in WRFDA (Parrish and Derber, 1992) was used. A separate simulation initialized at 00 and  
12 UTC and spanning 13 months (from January 2007 to February 2008) was necessary for the calculation of these matrices.  
120 Independent matrices were created for each month, and each of them was calculated taking into account a 90 days period  
centered on each month.

**Figure 1.** The domain used in both WRF simulations is presented with darkorange dots, while the darkblue region highlights the relaxation zone. The location of all the radiosondes available over the IP is also presented with quartered circles.

Both simulations were already presented and validated in previous studies by the authors. Precipitable water, precipitation and evaporation over the IP were validated against station measurements and gridded datasets in González-Rojí et al. (2018), and the outputs produced by D were always superior to N and the driving reanalysis ERA-Interim (for the latter, at least comparable for some variables). The closure of the water balance was also better for D. Additionally, the precipitation from D exhibited similar capabilities to the one downscaled with statistical methods (González-Rojí et al., 2019). Furthermore, the wind field from D showed also improvements compared to ERA-Interim, and consequently, that data were used for the calculation of the offshore wind energy potential in the west Mediterranean (Ulazia et al., 2017). Afterwards, that study was extended to every coast of the IP (Ulazia et al., 2019). The moisture recycling over the IP was also evaluated in González-Rojí et al. (2020), highlighting its importance in the Mediterranean coast during spring and summer.

## 2.2 Radiosonde data

Atmospheric radiosonde data were downloaded from the server of the University of Wyoming (freely accessible at <http://weather.uwyo.edu/upperair/sounding.html>). Only eight radiosondes are available over the IP: A Coruña (ACOR), Santander (SANT), Zaragoza (ZAR), Barcelona (BCN), Madrid (MAD), Lisbon (LIS), Gibraltar (GIB) and Murcia (MUR). The location

135 of each station is presented in Figure 1. Measurements are carried out every day at midday and midnight (00 and 12 UTC),  
with the exception of Lisbon where they only measure it at 12 UTC. Additionally, the amount of data available for Gibraltar is  
extremely scarce since August 2012.

Height, pressure, temperature, potential temperature and mixing ratio were retrieved at all the available pressure levels at  
each location. Moreover, the values of the TT, CAPE and CIN indices as calculated by the University of Wyoming were also  
140 downloaded. These values were assumed as the reference in our analysis.

Additionally, pressure, temperature and mixing ratio at different pressure levels obtained from the University of Wyoming  
were also used to calculate the TT, CAPE and CIN indices following our own methodology (further details can be found in the  
next subsection). The comparison between the original values of the indices retrieved from the University of Wyoming and our  
results can give us information about whether their discrepancies are only due to differences in the calculation procedure.

145 It must be said that all the radiosondes presented here were assimilated during the 3DVAR data assimilation step in WRF.  
As stated in González-Rojí et al. (2018), the analysis increments are stronger at 12 UTC, particularly in southeastern IP and  
both Guadalquivir and Ebro basins (see their Figure 13). This pattern is consistent along the seasons, but its intensity varies  
seasonally. Strong increments are observed during summer, but not during winter. Thus, the assimilation is useful to correct  
the well-known cold bias observed during summer over the IP (Fernández et al., 2007; Argüeso et al., 2011; Jerez et al., 2012)  
150 and the effect of the assimilation is not restricted only to the station location.

## 2.3 Methodology

### 2.3.1 Calculation of instability indices

For both simulations, the nearest grid point to the real latitude and longitude of each radiosonde was determined, and the  
corresponding pseudo-sounding (pressure, potential temperature and mixing ratio) at 00 and 12 UTC was obtained at model's  
155 original eta levels. This procedure was tested for reanalysis (Lee, 2002) and model data (Molina et al., 2020), and it showed  
that these pseudo-soundings are able to reproduce reasonably well the atmospheric conditions measured by the soundings.  
However, as highlighted by Holley et al. (2014), this procedure takes into account a stationary column at a fixed time, which  
can influence the comparison to real radiosonde data because they are made by balloons that take many minutes to measure the  
profile of the atmosphere and that deviate from a straight vertical line because of wind.

160 In order to calculate the instability indices TT, CAPE and CIN using the pseudo-sounding from the model, the R package  
*aiRthermo* was used (Sáenz et al., 2019). The most recent version was used (version 1.2.1), which is publicly available in the  
CRAN repository (<https://cran.r-project.org/package=aiRthermo>). Both CAPE and CIN are calculated by means of the vertical  
integrals using discrete slabs defined by the resolution of pressure in the soundings. The virtual temperature was used in every  
integral (Doswell and Rasmussen, 1994). The energy on each slab is calculated analytically, and the values are accumulated  
165 until the end of the sounding, which means that the final value of CAPE and CIN are obtained. Additionally, in order to calculate  
CAPE and CIN in the most similar way to the University of Wyoming with the aim of reducing the differences between the  
values due to different calculation procedures (Siedlecki, 2009), the average of the lower vertical levels was set as the initial

representative parcel (Craven et al., 2002; Letkewicz and Parker, 2010). As in Siedlecki (2009), the averaged values from the lowest 500 m were used in this study. Additionally, an isobaric precooling was applied to the initial parcel state.

170 The TT index was calculated following the definition from Miller (1975). It is defined as:

$$TT = (T_{850} - T_{500}) + (D_{850} - T_{500}) \quad (1)$$

where  $T_{850}$  and  $T_{500}$  are the temperatures in Celsius at 850 and 500 hPa, and  $D_{850}$  is the dewpoint temperature in Celsius at 850 hPa. According to the ECMWF (Owens and Hewson, 2018), thunderstorms are likely when the values for this index are above 44 °C. It can be seen that this index is not highly dependant on the initial conditions for its calculation as it only depends  
175 on temperature at different pressure levels. CAPE and CIN are very sensitive to the initial conditions used for the simulated ascent. TT avoids this problem, but the results can suffer from errors due to inversion layers (Siedlecki, 2009).

Further indices could be calculated from the pseudo-soundings obtained from the outputs of the model or real observations, but they were omitted because they can provide similar information to CAPE, CIN and TT. K-index is also based on temperature at different pressure levels, so it suffers from the same problems as TT. Additionally, previous studies reported a strong  
180 correlation between CAPE and LI (Blanchard, 1998; López et al., 2001). In order to avoid these connections between indices, we restricted this study to TT, CAPE and CIN indices.

### 2.3.2 Analysis

Once TT, CAPE and CIN are calculated at the nearest grid points to radiosonde locations of both simulations (N and D), and also those using the original sounding data (labelled as *aiRthermo* in the results), we obtain a time series with a 12-hourly  
185 temporal resolution for each index. These values can be compared against the reference values of the indices retrieved directly from the University of Wyoming (labelled as *Reference* in the next figures). The comparison of *Reference* vs *aiRthermo* aims to achieve an estimation of the error/differences due to the different methodologies used by both sources of results. This comparison was based on independent locations, so a Taylor diagram was chosen as the best option to show Pearson's correlation ( $r$ ), root mean squared error (RMSE) and standard deviation (SD) of each experiment in the same plot. Additionally, the boot-  
190 strap technique with resampling was applied to the results in order to represent an estimation of the sampling errors from each experiment. In this case, 1000 new time series were subsampled with replacement, and the variability of the correlations of these synthetic time series were shown by means of box and whiskers plots.

Then, the seasonal analysis of each index at each location was carried out. In this case, the variability of the results is showed by different box and whiskers plots. Each season was defined as follows: winter is defined from December to February (DJF),  
195 spring from March to May (MAM), summer from June to August (JJA) and autumn from September to November (SON).

Finally, the calculation of each index was extended to every point included in a mask defined for the land points of the IP over model's domain. The spatial distribution of the mean values of each index at 00 and 12 UTC during winter and summer was calculated. These maps show the regions over the IP where the convective precipitation can be developed and in which season.

### 200 3 Results

Taylor diagrams for the TT index calculated for each radiosonde of the IP are shown in Figure 2. The box and whiskers associated to the correlations obtained for each of the 1000 time-series created with the bootstrap technique are also included. According to the Taylor diagrams, as expected, the best experiment reproducing the reference values is aiRthermo (the real measurements of temperature, mixing ratio and pressure from the sounding were used to calculate TT with our methodology),  
205 followed by D and later by N. aiRthermo obtains the closest values to the observations in all the stations with the exception of Murcia, where D is the best one reproducing the observed data. The correlations are always above 0.98 for aiRthermo, 0.97 for D and 0.75 for N. The observed SD is really well simulated by aiRthermo and D, but N underestimates it in most of the stations as it is only able to reproduce the one in Santander. The RMSE is below 0.6 °C for aiRthermo, below 1 °C for D and below 2.5 °C for N.

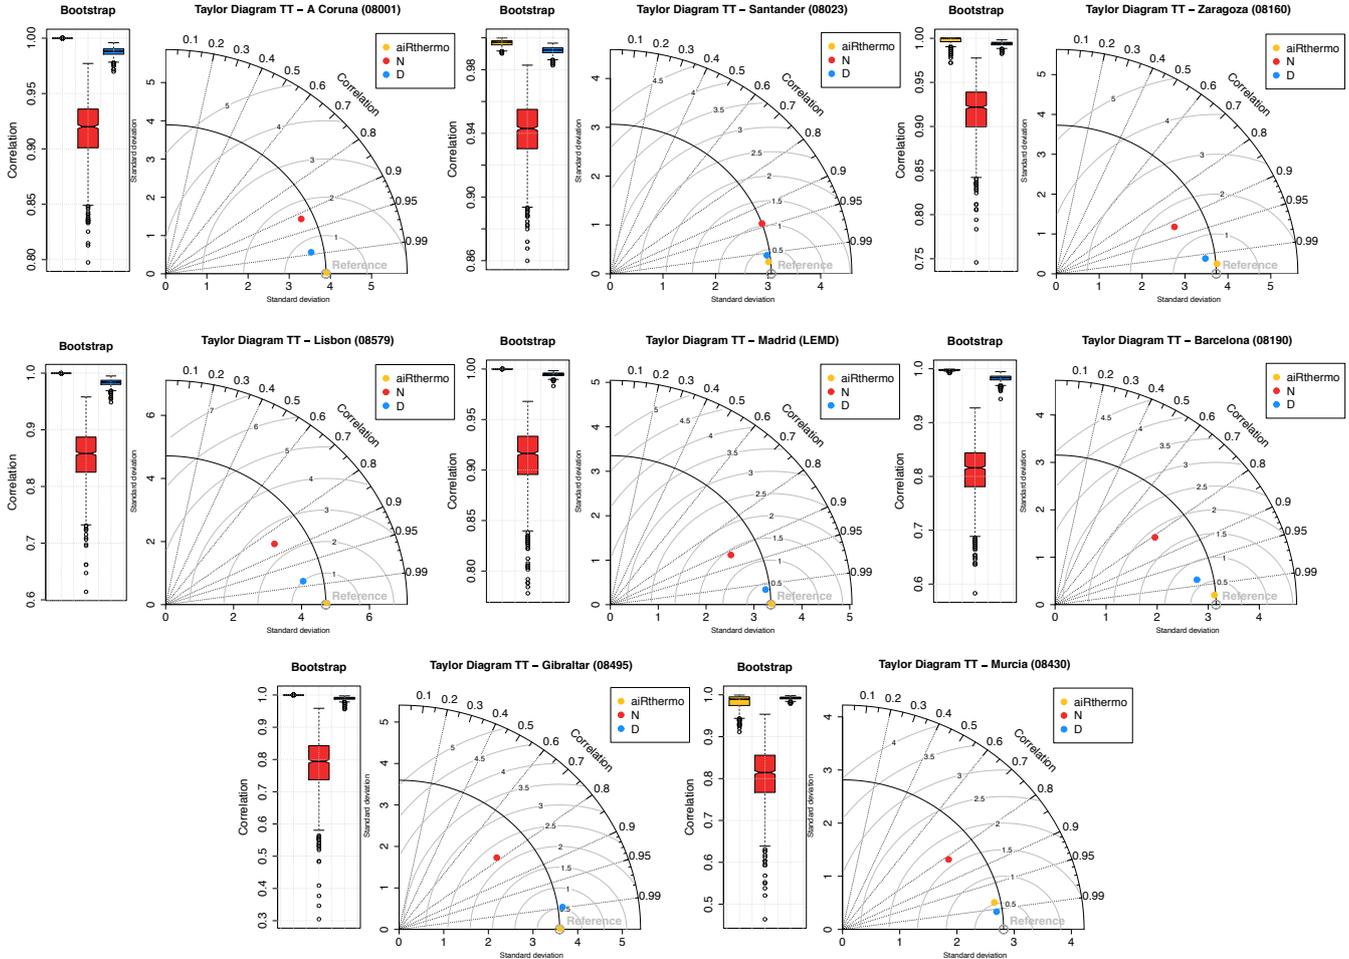

210 The bootstrap analysis is consistent with the results obtained in the Taylor diagrams, and it shows that the correlations are always above 0.98 for aiRthermo (again, with the exception of Murcia where they are above 0.9). The correlations are always above 0.95 for D. In the case of N, the spread of the values is much larger than for aiRthermo and D, and their mean values are obtained between 0.8 and 0.9.

Thus, as expected, we obtain the most similar results to those calculated from the University of Wyoming (Reference) with  
215 the real measurements from the soundings (that is, aiRthermo). However, we can still measure small differences between the values due to the different procedure in the calculation of the TT index. These differences are remarkable in Murcia. Between both WRF experiments, it is clear that the experiment including the 3DVAR data assimilation is able to outperform the standard simulation only driven by the reanalysis data. The differences between both WRF simulations are highlighted particularly in those stations located in the Mediterranean coast (Barcelona, Murcia and Gibraltar) and in Lisbon.

220 In the case of CAPE, the validation results are presented in Figure 3. Similar results to what we obtained for TT index is observed for CAPE: the best experiment reproducing the results is aiRthermo, followed by D and finally by N. The correlations are in all the stations above 0.96 in aiRthermo, while for D they are above 0.9 and above 0.65 for N. A similar behaviour is observed for SD and RMSE. The largest RMSEs are obtained in Barcelona and Murcia (both in the Mediterranean region), where the RMSEs for N are 157.03 J/kg and 105.97 J/kg respectively (98.32 J/kg for D and 30.32 J/kg for aiRthermo in  
225 Barcelona, 55.62 J/kg for D and 8.23 J/kg for aiRthermo in Murcia).

The bootstrap analysis shows that the highest correlations are obtained by aiRthermo (as expected), but followed really closely by D. As for TT index, N presents the worst performance and the largest spread. The correlations can be even negative for some outliers in Santander (up to -0.2).

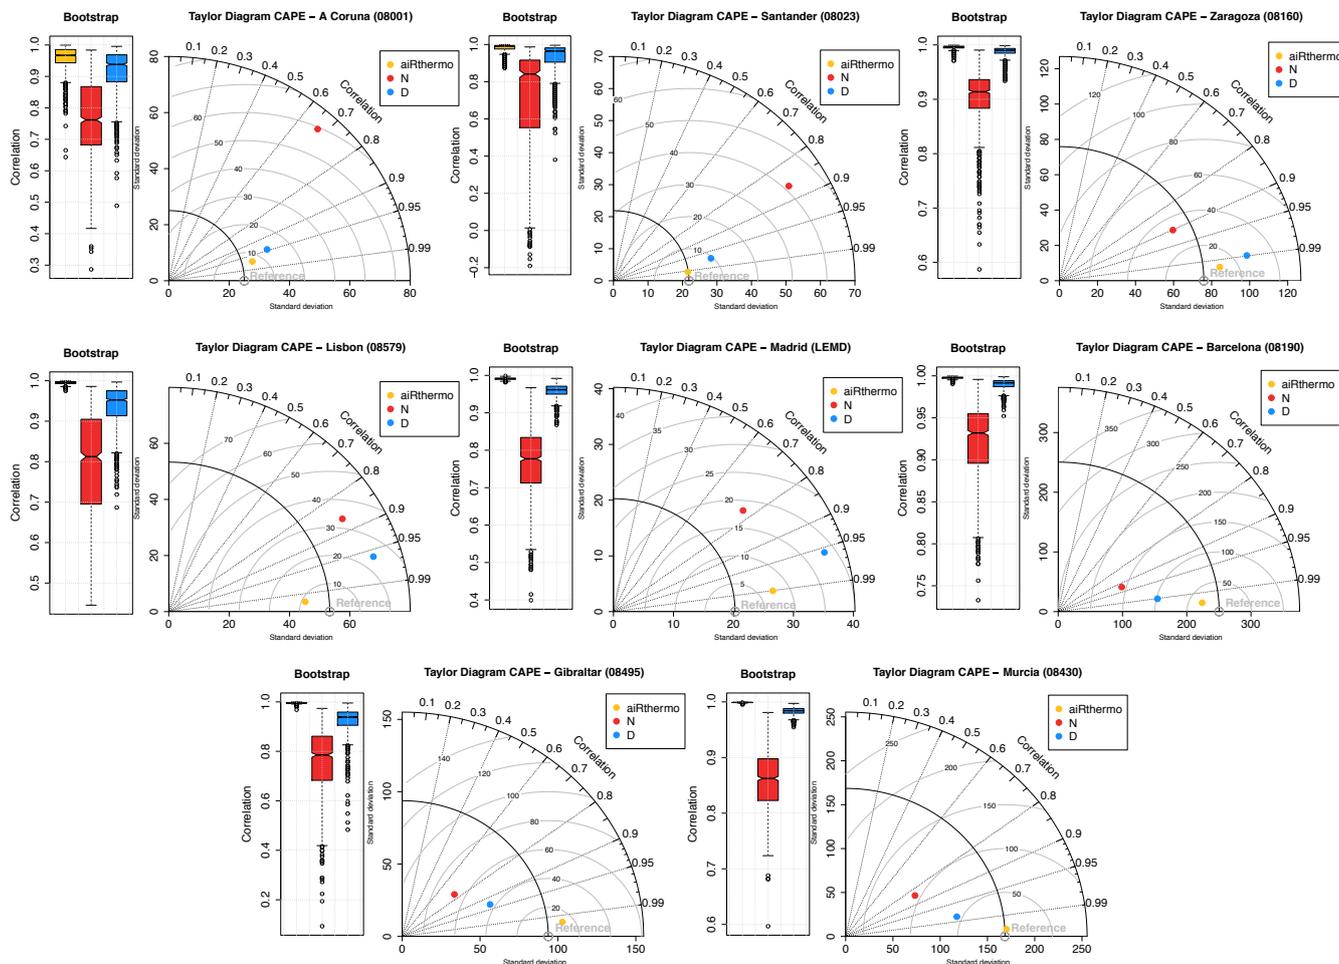

As stated before in section 2.3.1, the calculation of CAPE is much more difficult than TT index, and this is highlighted in the  
230 validation of these results. Even if the same data are used for the calculation of CAPE (Reference and aiRthermo used the same measurements), it is clear that small differences in the initial conditions can trigger serious discrepancies between both methods as stated by Siedlecki (2009). The largest RMSEs for aiRthermo can be found in Barcelona and Murcia (30.32 and 8.23 J/kg respectively). As for the TT index, two stations in the Mediterranean coast present the largest differences between experiments.

**Figure 2.** Taylor diagrams showing the  $r$ , RMSE and SD values for aiRthermo, N and D compared to TT values retrieved directly from the University of Wyoming (Reference). On the left side of each Taylor diagram, a box and whisker plot is added in order to show the correlations between each experiment and the reference data. The bootstrap technique with resampling was used to create 1000 synthetic time-series. aiRthermo, N and D are plotted in orange, red and blue respectively.

However, while the computation of TT from both WRF simulations produces standard deviations similar to the observed ones, the results for CAPE substantially overestimate the variance of Atlantic sites (A Coruña, Santander, Lisbon and Madrid) or overestimate it in the Mediterranean (Barcelona, Murcia and Gibraltar). Anyway, it can be seen that data assimilation improves the simulation of CAPE over the IP.

Finally, the validation of CIN is presented in Figure 4. As expected, the best results are obtained again by aiRthermo, followed by D and N (with the exception in Gibraltar where D and N are really similar). aiRthermo obtains in every station correlations above 0.95, followed by D and N (correlations above 0.85 and 0.65 respectively). aiRthermo tends to slightly

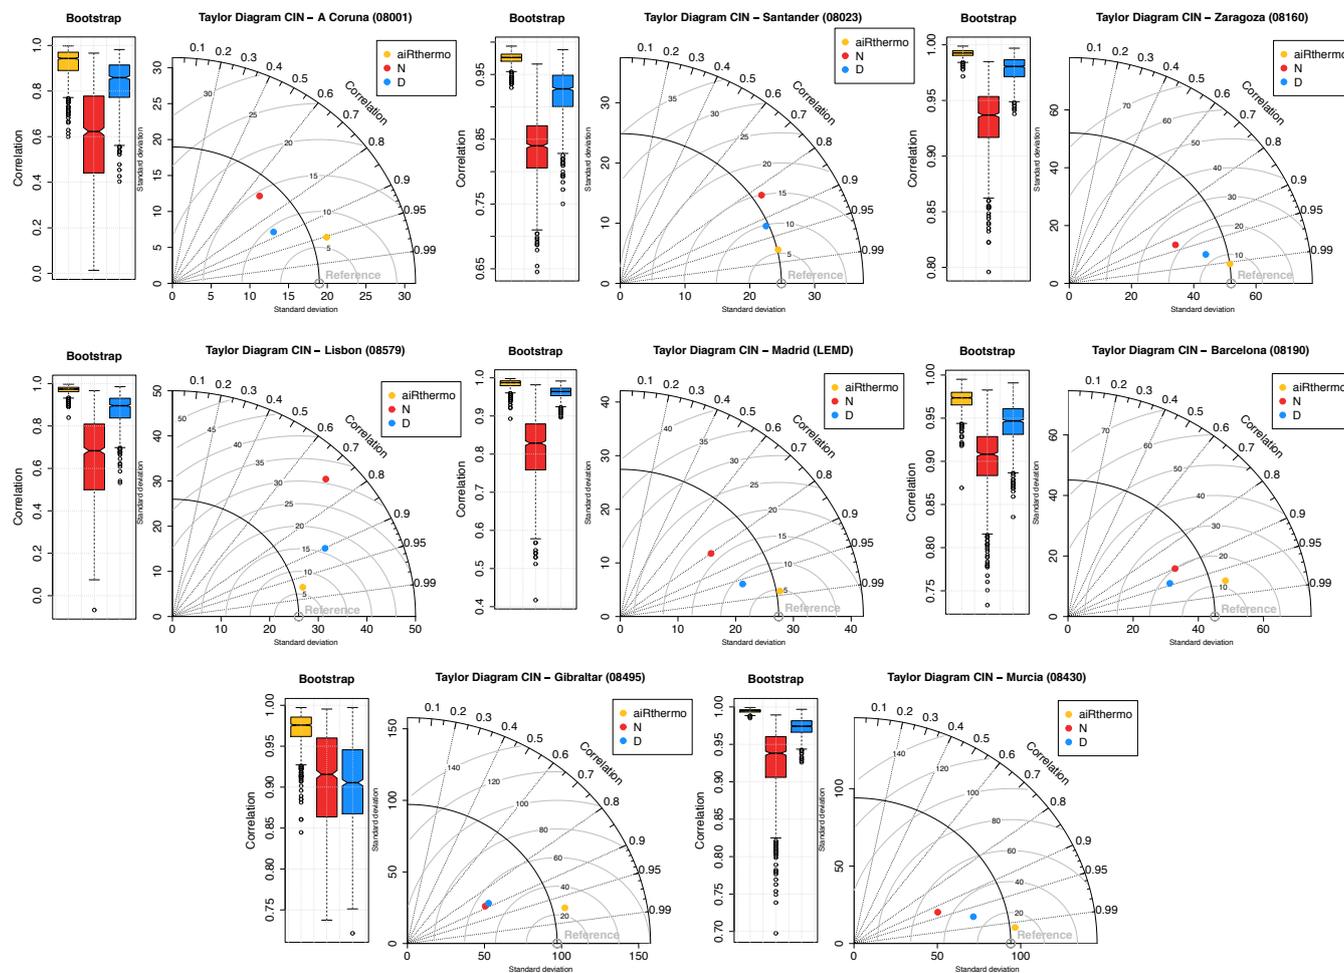

**Figure 3.** Same as Figure 2 but for CAPE.

overestimate the SD, but both WRF experiments overestimate or underestimate it depending on the station (particularly N in Lisbon, Madrid, Murcia and Zaragoza). The RMSE is always larger for N, and the values are remarkable in Murcia and Gibraltar for all the experiments (Gibraltar: aiRthermo 25.42 J/kg, D 52.67 J/kg, N 53.47 J/kg; Murcia: aiRthermo 10.71 J/kg, D 28.35 J/kg, N 48.24 J/kg).

245 The bootstrap analysis presents the same results as for TT and CAPE (Figures 2 and 3). However, for Gibraltar, as shown in the Taylor diagram, both WRF experiments produce similar correlation values during the bootstrap. In contrast to previous results, the poorest correlations for CIN are obtained in stations located in the Atlantic coast as Lisbon and A Coruña.

As for CAPE, the differences between aiRthermo and the reference data are highlighted here. This result supports the idea that small differences in the initial conditions can trigger large differences in the values of CIN even if the same values of

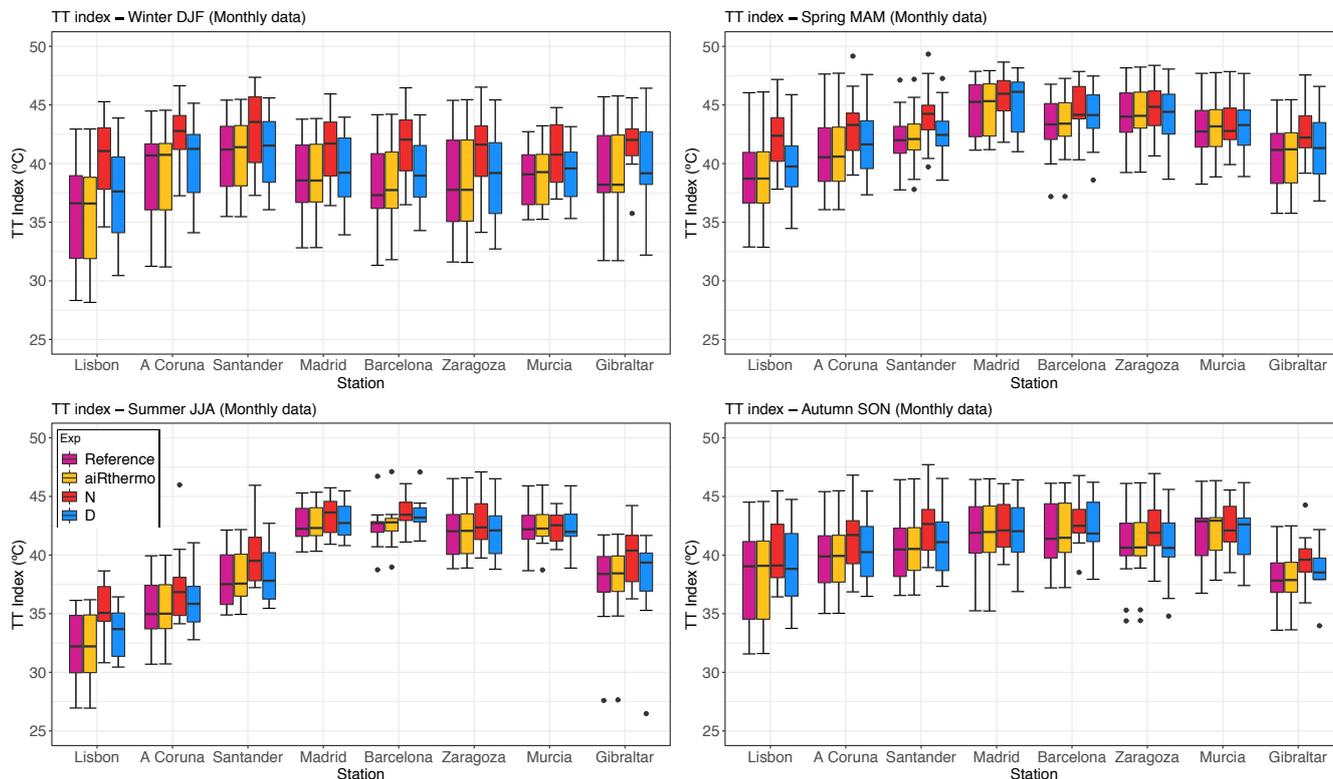

**Figure 4.** Same as Figures 2 and 3 but for CIN.

250 temperature, mixing ratio and pressure are used for its calculation. Again, the differences between both WRF experiments are important and the experiment including data assimilation (D) presents generally closer results to the observed ones.

The seasonal analysis of the four datasets (Reference, aiRthermo, N and D) for TT index is presented in Figure 5. In this case, aiRthermo and D are able to correctly simulate the reference seasonal variability of TT index in all the stations and all the seasons. However, N tends to overestimate the variability in every season and for most of the stations over the IP.

255 A Coruña and Santander present the largest values during winter, which agrees with the fact that the northern and northwestern IP receive great amounts of rain during that season (Rodríguez-Puebla et al., 1998; Esteban-Parra et al., 1998; Romero et al., 1999; Iturrioz et al., 2007). Higher values than in winter are observed during spring, but the maximum is recognizable in Madrid. This station is the only one located over central IP and it highlights the maximum in precipitation in that region during that season (Tullot, 2000). However, the other stations also present values above 38 °C. During summer, central, eastern and

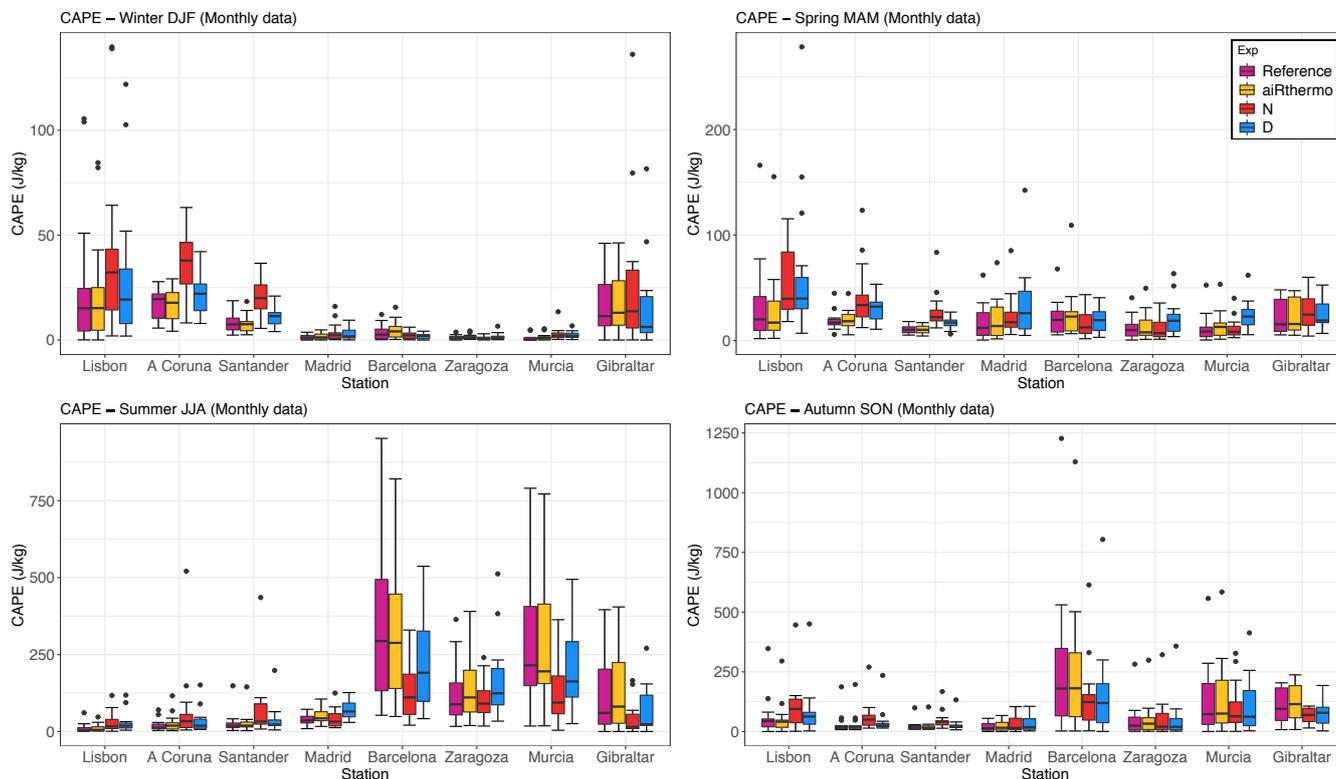

**Figure 5.** TT index for the reference data (magenta), aiRthermo (orange), N (red) and D (blue) computed at each station for every season: winter (top panel, left), spring (top panel, right), summer (bottom panel, left) and autumn (bottom panel, right).

260 southern stations (Madrid, Barcelona, Zaragoza and Murcia) are the ones presenting higher values. In that season, the Atlantic stations and Gibraltar present values below 40 °C. This feature is also in agreement with previous studies highlighting that precipitation is important in those regions during that season (Rodríguez-Puebla et al., 1998; Esteban-Parra et al., 1998; Romero et al., 1999; Iturrioz et al., 2007). Finally, all the stations show similar values in autumn, with the exception of Gibraltar where the values are smaller.

265 The seasonal analysis for CAPE is presented in Figure 6, and it highlights the spatial and temporal heterogeneity of the areas where convective precipitation can be triggered over the IP, as also shown by Holley et al. (2014). aiRthermo is able to reproduce (as expected) the variability of the reference values, and D is able to capture the spread of the values in most of the stations during winter, summer and autumn. However, it overestimates CAPE in most of the stations in spring. The other WRF experiment (N) tends to overestimate CAPE in winter and underestimate it in summer. During spring and autumn, its  
 270 underestimations or overestimations depend on the station and a clear pattern is not observed.

The lowest values of CAPE are obtained during winter (below 50 J/kg in all the stations), and the largest ones are observed in summer (reaching 500 J/kg in some stations). However, as stated before, the distribution of CAPE is not homogeneous

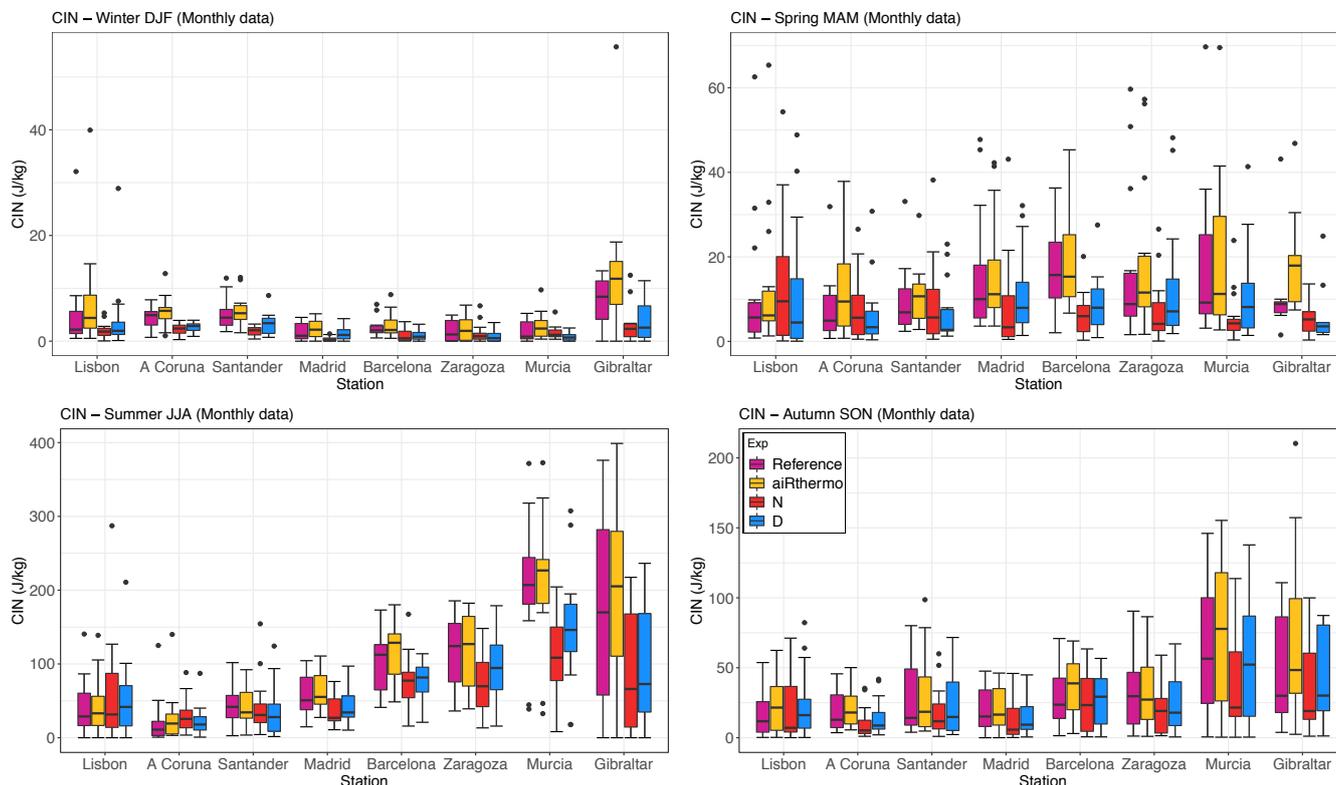

**Figure 6.** Same as Figure 5 but for CAPE.

and some regions are more important than others during each season. During winter, the three Atlantic stations (A Coruña, Santander and Lisbon) and Gibraltar present the highest values of CAPE over the IP. In general, the values are below 50 J/Kg, but some events can get CAPEs over 100 J/kg. During spring, the distribution of CAPE is quite homogeneous over the IP and only stations such as Lisbon, Madrid or Gibraltar present slightly higher values of CAPE than the other stations. In summer, only the stations located in the eastern and southern parts of the IP present remarkable values of CAPE. Particularly, the most active ones are those located in the Mediterranean coast (Barcelona and Murcia). Finally, during autumn, the regions with high CAPEs are extended towards the inland of the IP, such as Madrid and Zaragoza. During this season, some extreme events can reach values over 1000 J/kg over the Mediterranean coast. This feature was already observed by Siedlecki (2009).

Finally, the seasonal analysis for CIN is presented in Figure 7, and it highlights the stations where the inhibition is important. In general, aiRthermo tends to overestimate the observed variability of CIN in most of the stations and in every season. On the contrary, both WRF simulations (but particularly the experiment without data assimilation) tend to underestimate the observed variability.

The values of CIN are smaller in winter and spring, and the maximum is observed in summer. During winter, CIN is higher in Gibraltar and in the Atlantic stations (Lisbon, A Coruña and Santander) than in the other stations from the IP. However, these

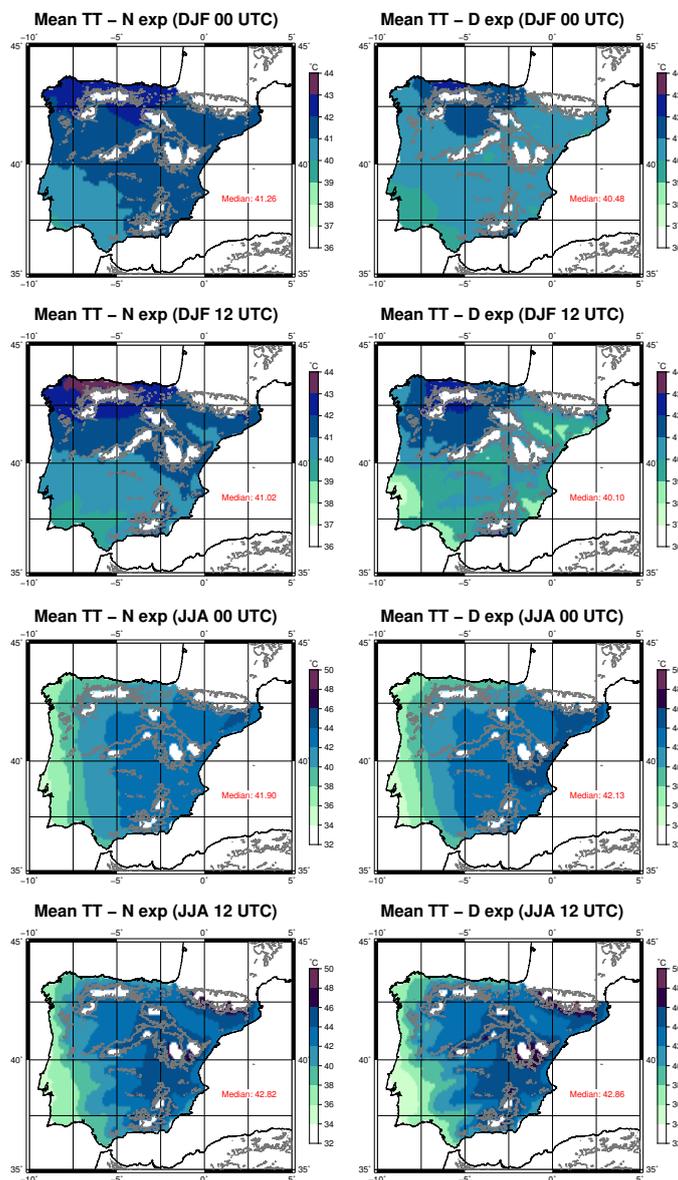

**Figure 7.** Same as Figures 5 and 6 but for CIN.

values are small compared to those from other seasons. During spring, the values are higher than in winter, and similar values are observed in most of the stations (around 10 J/kg), with the exception of Barcelona where the CIN reaches values of 20 J/kg. In summer, the values are higher in all the stations, but particularly in those from the eastern and southern IP (Barcelona, Zaragoza, Murcia and Gibraltar). The same regime is observed for autumn, but the values are smaller than in summer. These values during summer and autumn are in agreement with Siedlecki (2009), who found CIN means above 100 J/Kg in the west Mediterranean sea and surrounding countries.

As stated before, in the final phase of this study, the same procedure for the calculation of the instability indices at each station was extended to each grid point included in the IP. The mean winter and summer spatial patterns at 00 and 12 UTC were calculated for both WRF experiments. Figure 8 shows the results for TT. The heterogeneity of the results is highlighted in those results. The differences between both simulations are remarkable, but also those between day and night. Additionally, it can be seen that TT cannot be calculated in most of the mountain regions of the IP because the 850 hPa layer is near the surface or below ground.

During winter, the TT maps show that N yields higher values than D, which is in agreement with the overestimation observed in Figure 5. At 00 UTC, according to D, the regions where thunderstorms are likely to happen are those in the Cantabrian coast

**Figure 8.** Spatial distribution of mean TT for period 2010–2014 over the IP as computed from N (first column) and D (second column) for winter (rows 1 and 2) and summer (rows 3 and 4) at 00 (rows 1 and 3) and 12 UTC (rows 2 and 4). The median value (°C) of each map is presented in the bottom right corner of the plots.

and in the southeastern IP. Both regions are surrounded by important mountainous systems such as the Cantabrian Range and the Baetic system. For N, the possibility of thunderstorms is also extended to the rest of the IP, with the exception of the southwestern corner where the values are small. At 12 UTC, after solar irradiance has started heating up the land, the areas with high chance for thunderstorms extend towards inland areas. In the experiment with data assimilation (D), most of the

305 northern plateau presents high values of TT, and the lowest values are observed near the coastal valleys of the southwestern corner and the Mediterranean coast (like the Ebro basin or Murcia). In the case of N, the lowest values are observed mainly in the southwestern IP near the Guadalquivir valley.

As in Figure 5, much higher TT values are obtained during summer over the IP, particularly at 12 UTC. At 00 UTC, a west-east gradient is observed in both WRF simulations. However, the values depicted in the Mediterranean coast are higher for the  
310 experiment including data assimilation (D). At 12 UTC, the areas with higher chance to develop thunderstorms extend towards the central area. In this case, the regions are located near the mountains of the IP. Particularly, in the southern slope of the Pyrenees and in the proximities of the Iberian, central and Baetic systems. The minimum TTs are observed in the western part of the IP, but particularly near Lisbon. The intensity of the most extreme values of TT is higher in D (with data assimilation).

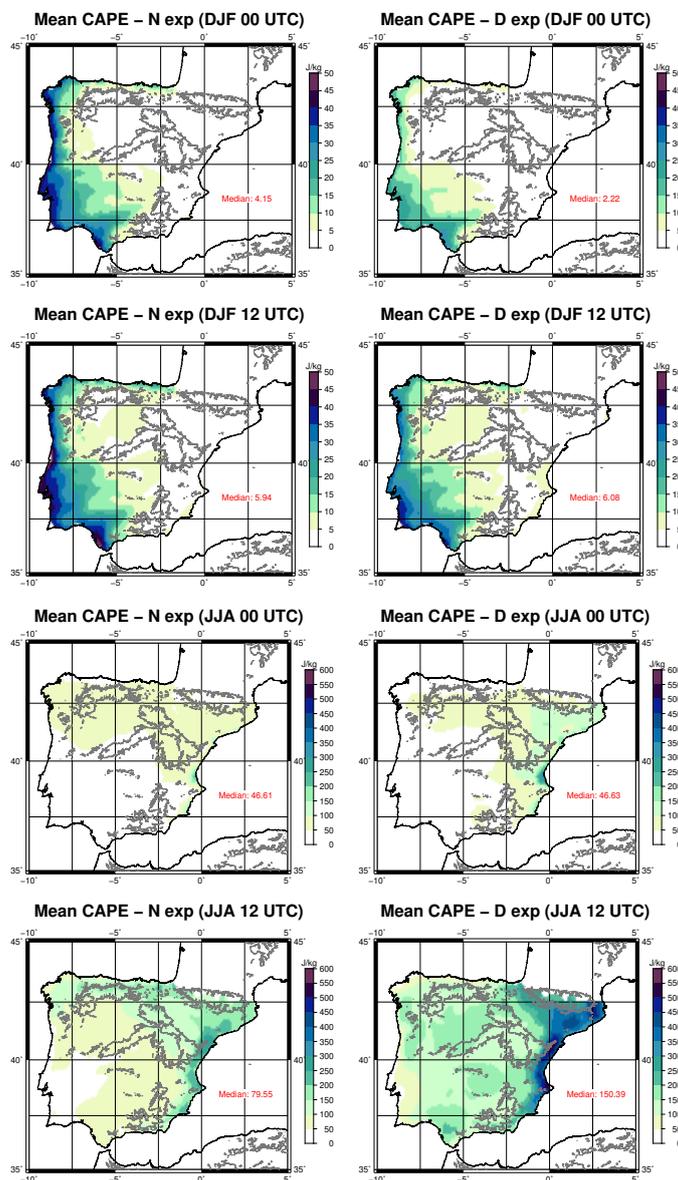

The maps for CAPE at 00 and 12 UTC during winter and summer are presented in Figure 9. During winter, as shown in  
315 Figure 6, the N experiment presents higher values than D. At 00 UTC, the patterns are really similar for both WRF experiments. The main difference between them is observed in the western Atlantic coast of the IP, where higher CAPE values are obtained for D. At 12 UTC, the unstable area is found in the western coast of the IP in both simulations, and it is extended further inland that at 00 UTC, particularly near the Tagus and Guadalquivir rivers. Again, the values are higher for N, but the pattern is similar in both experiments.

320 On the contrary to what is observed during winter, CAPE is higher during summer for the experiment including data assimilation. This is in agreement with the station analysis from previous Figure 6. At 00 UTC, the area where thunderstorms can be developed is observed in the northern and eastern IP, but particularly near the Mediterranean coast. However, at 12 UTC, this area with high values (over 250 J/kg) extends towards the interior and in the experiment including data assimilation it also covers the southern part of the Pyrenees. Additionally, high values are observed in most of the IP (except the southwestern  
325 corner for N), but particularly in the simulation including data assimilation.

Finally, regarding CIN, the maps for the mean values at 00 and 12 UTC during winter and summer are presented in Figure 10. In reverse to what we found for CAPE, CIN is usually higher at 00 UTC than at 12 UTC (with the exception of Murcia in summer at 12 UTC). During winter, at 00 UTC, both simulations show small values over the IP, and only some high values are observed in the western and southwestern corner of the IP (and particularly for N). At 12 UTC, the areas are confined to those  
330 coastal regions, but they also extend to the Mediterranean coast in the D experiment.

During summer, at 00 UTC, the most remarkable values are obtained in both simulations along the Ebro basin and near the Mediterranean coast. However, the CIN inland is higher for D. At 12 UTC, less inhibition is observed in the eastern valleys of the IP (with the exception of Murcia, which presents extremely high values of CIN). In the same time, an increase in the convective inhibition over the Guadalquivir basin is shown. The extension towards the interior is again higher for D (including  
335 data assimilation).

Thus, some clear dynamics arise from these results. During winter, the areas where thunderstorms can be developed are located in the Atlantic coast of the IP, and they are more active during the afternoon as CIN is really high in those region until 12 UTC. However, during summer, the unstable areas are located to the north of the Mediterranean coast. Thunderstorms will tend to occur during the afternoon in those regions, but they can also develop before 12 UTC even if the inhibition is high

**Figure 9.** Same as Figure 8 but for CAPE.

340 during that period (CAPE is also high). These features are in agreement with the precipitation dynamics observed in previous  
studies over the IP (Rodríguez-Puebla et al., 1998; Esteban-Parra et al., 1998; Romero et al., 1999; Iturrioz et al., 2007). The  
patterns for CAPE observed during winter and summer are similar to those obtained by the regional analysis performed by  
Viceto et al. (2017). However, their values are comparable to those obtained by our experiment without data assimilation (N).  
In this case, the data assimilation produces higher values, but much more realistic than the ones from those simulations without  
345 it (according to Figure 6).

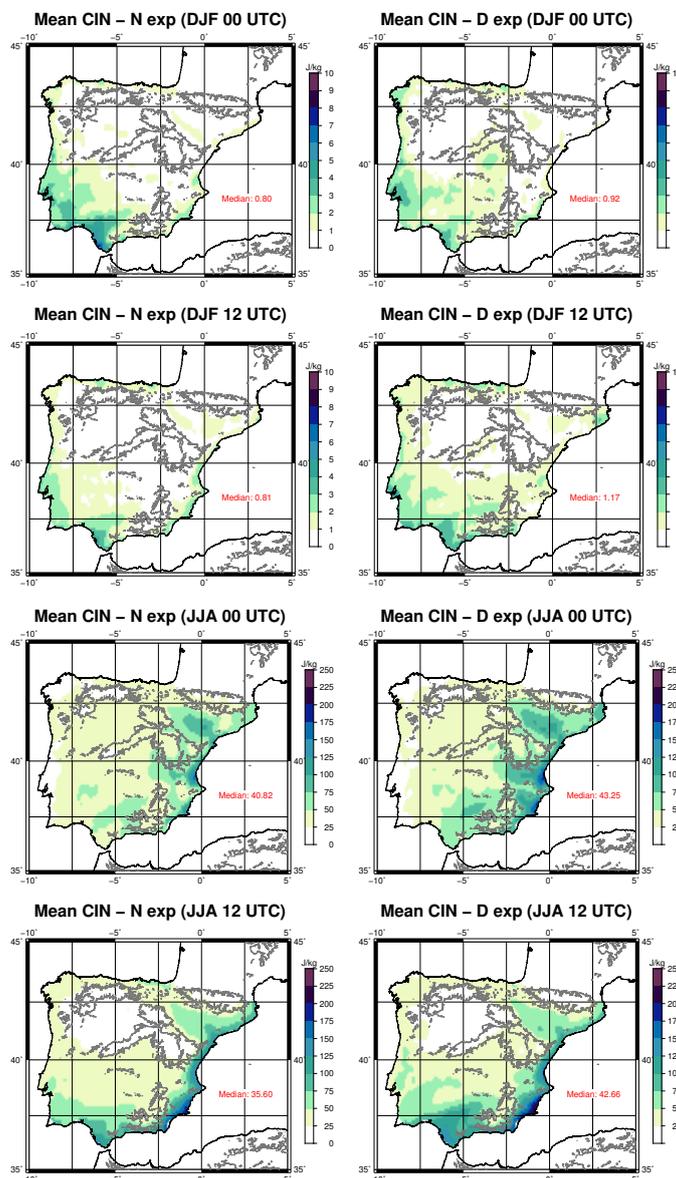

Figure 10. Same as Figures 8 and 10 but for CIN.

#### 4 Conclusions

The main purpose of this paper is to evaluate the ability to simulate the instability conditions that can trigger thunderstorms over the IP with two high-resolution simulations created with the state-of-the-art model WRF. One of these simulations is driven by the boundary conditions provided by ERA-Interim reanalysis (N experiment), while the second one presents the same configuration but including the additional 3DVAR data assimilation step every 6 hours (D experiment). Three instability

350

indices were evaluated: TT index, CAPE and CIN. All of them were calculated from the outputs of the model using the publicly available R package *aiRthermo*, also developed by the authors.

In order to validate these indices, their values were downloaded from the University of Wyoming server for the eight radiosondes available over the IP. Additionally, pressure, temperature, potential temperature, mixing ratio and height at all the available pressure levels from the radiosondes were also retrieved from the server. These variables were used to calculate with *aiRthermo* again these three indices. Comparing these new values with the ones retrieved directly from the University of Wyoming, the small differences which can only be attributed to different methodologies can be obtained.

First, the correlation, SD and RMSE were computed for each of the indices for both simulations and for the ones calculated with the data at pressure levels from the University of Wyoming following our own methodology. The three of them were compared against the reference values (the ones downloaded from the University of Wyoming) by means of Taylor diagrams. According to these results, small differences can be observed due to the different methodologies used for the calculation of the indices. However, these differences are more important for CAPE and CIN than for TT because they are highly dependant on the initial conditions for the calculation of the vertical integrations, while TT index is not. Between both WRF simulations, the most accurate results are produced by the experiment with data assimilation (D). The bootstrap analysis with resampling also supports this result.

Then, the seasonal analysis was carried out for each index. For TT, the differences between methods are really small in every season. Between both WRF experiments, N tends to overestimate the reference variability, while D is able to capture it. In the case of CAPE and CIN, the differences between methods are larger, but not as those within both WRF experiments. However, D is able to produce closer values to the reference values than N. During winter, the unstable areas where thunderstorms can be triggered are located mainly in the stations from the Atlantic coast of the IP. All the stations are quite active during spring. However, the regime changes to the Mediterranean coast during summer, and also autumn but with less intensity.

Finally, the calculation of the indices was also carried out for every grid point over the IP in both WRF simulations, particularly for winter and summer and at 00 and 12 UTC. All the three indices agree highlighting the heterogeneity of the patterns observed. The D experiment, which is the most accurate one according to the previous analysis, shows that during winter the convective activity is found along the entire Atlantic coast, but particularly in the southwestern corner of the IP when the instability is extended towards inland regions. During summer, this feature is reversed, and the region most prone to intense convection is located in the Ebro basin and the Mediterranean coast. The possibility of a storm developing at 00 UTC is rather small because of the high values of CIN in those regions, but that is highly reduced at 12 UTC.

*Data availability.* These results can be reproduced using the postprocessed outputs from the model available in <https://doi.org/10.5281/zenodo.3611343>.

*Author contributions.* The methodology and the software was developed by S.J.G.-R., S.C.-M. and J.S.; The conceptualization, preparation of datasets and analysis was carried out by all the authors; The original draft of the paper was written by S.J.G.-R., but all the authors took part in the edition and revision of it.

*Competing interests.* The authors declare no conflict of interest.

385 *Acknowledgements.* S.J.G.R. is now funded by the Oeschger Centre for Climate Change Research (OCCR), but during his PhD he was supported by a FPI Predoctoral Research grant (MINECO, BES-2014-069977). This study was also supported through MINECO project CGL2016-76561-R from the Spanish Government (MINECO/ERDF, UE) and the grant GIU 17/002 from the University of the Basque Country. The computational resources were provided by I2BASQUE, and the authors thank the creators of WRF/ARW and WRFDA systems. Finally, most of the calculations were carried out with R, and the authors want to thank all the authors of the packages used for it.
