**Abstract.** NASA's Soil Moisture Active-Passive (SMAP) mission characterizes global spatiotemporal patterns in surface soil moisture using dual L-band microwave retrievals of horizontal,  $T_{Bh}$ , and vertical,  $T_{Bv}$ , polarized microwave brightness temperatures through a modeled mechanistic relationship between vegetation opacity, surface scattering albedo, and soil effective temperature ( $T_{eff}$ ). Although this model has been validated against *in situ* soil moisture, there is a lack of systematic characterization of where and why SMAP estimates deviate from the *in situ* observations. Here, we assess how the information content of *in situ* soil moisture observations from the US Climate Reference Network contrasts with (1) the information contained within raw SMAP observations (i.e. 'informational random uncertainty') derived from  $T_{Bh}$ ,  $T_{Bv}$  and  $T_{eff}$  themselves, and (2) with the information contained in SMAP's Dual Channel Algorithm (DCA) soil moisture estimates (i.e. 'informational model uncertainty') derived from the model's inherent structure and parameterizations. The results show that, on average, 82% of the information in the *in situ* soil moisture is unexplained by SMAP DCA soil moisture. 36% of the unexplained information is caused by the loss of information in the DCA modeling process while the remainder is induced by a lack of additional explanatory power beyond  $T_{Bh}$ ,  $T_{Bv}$  and  $T_{eff}$ . Overall, retrieval quality of SMAP DCA soil moisture is negatively correlated with the informational uncertainties, with slight differences across different landcovers. The informational model uncertainty (Pearson correlation of -0.51) was found to be more influential than the informational random uncertainty (Pearson correlation of -0.37). The DCA has a higher informational total uncertainty (88% of unexplained information of *in situ* soil moisture) in shrublands while the informational model uncertainty (31% of the informational total uncertainty) in shrublands is less dominant than other landcovers. A decomposition of mutual information between  $T_{Bh}$ ,  $T_{Bv}$  and DCA soil moisture shows that on average 57% of information provided by  $T_{Bh}$  and  $T_{Bv}$  is redundant. The amount of information redundantly provided by  $T_{Bh}$  and  $T_{Bv}$  was found to be tightly correlated (Pearson correlation of -0.83) to how well the DCA correlated to *in situ* soil moisture. Higher redundant information provided by  $T_{Bh}$  and  $T_{Bv}$  tends to be found in landcovers with less woody components. The DCA retrieval quality improves as  $T_{Bh}$  and  $T_{Bv}$  provide more redundant information for the DCA soil moisture. This suggests that the informational redundancy between these remotely sensed observations can be used as independent metric to assess the retrieval quality of algorithms using these data streams. This study provides a baseline approach that can also be applied to evaluate other remote sensing models and understand informational loss as satellite retrievals are translated to end user products.

# 1 Introduction

Accurate information on soil moisture is of great importance for understanding various biophysical processes in hydrology, agronomy, and ecosystem sciences (Bassiouni et al., 2020; Uber et al., 2018). The poor spatial representativeness of *in-situ* soil moisture sensors, combined with their labor-intensive installation and maintenance, impedes the application these sensors to understand large scale ecosystem phenomena (Babaeian et al., 2019; Petropoulos et al., 2015). Spaceborne passive microwave remote sensing has been developed as a reliable method to estimate surface soil moisture at large scales (Petropoulos et al., 2015). It leverages the large discrepancies in dielectric properties between liquid water and dry soil that result in a high dependency of soil dielectric constants on soil moisture (Njoku and Entekhabi, 1996). Various microwave frequencies have been available to date, amongst which the L-band (1.4-1.427 GHz) microwave frequencies were found to be desirable for soil moisture estimations because they can sense soil moisture at a relatively deeper layer (~5cm) and can provide greater vegetation penetration power (Njoku and Entekhabi, 1996). Though microwave remote sensing has been investigated for decades, significant uncertainties still exist in both microwave radiometry and in the algorithms used to translate microwave observations to soil moisture estimates.

L-band remote sensing soil moisture estimation uses a radiometer to measure surface emission intensity, which is a linear function of brightness temperature. The brightness temperature is linked with soil moisture and vegetation opacity through the '*tau-omega*' emission model and parameterized by soil and vegetation functions (Njoku and Entekhabi, 1996). The '*tau-omega*' model rationale has been adopted by NASA's Soil Moisture Active-Passive (SMAP) mission, which is one of the earth observation missions dedicated to estimate soil moisture at L-band microwave frequency. SMAP implemented two primary algorithms: (1) the single channel algorithm (SCA) that uses one polarized brightness temperature as primary input to retrieve soil moisture and (2) the dual channel algorithm (DCA) that retrieves soil moisture and vegetation opacity simultaneously by taking the polarized brightness temperature information in both horizontal and vertical directions (O'Neill et al., 2020). There is strong interest in the DCA approach because of its independent estimation of vegetation opacity in lieu of the specified vegetation climatology employed by the SCA. Additionally, it has been suggested that using a time-integrated vegetation opacity, as is employed in the multi-temporal dual channel algorithm (MT-DCA) for instance (Piles et al., 2016), improves the estimates of soil and vegetation state. These contrasting approaches, as well as other studies on SMAP's temporal polarized ratio algorithm (TPRA) (Gao et al., 2020) and regularized dual channel algorithm (RDCA) (Chaubell et al., 2019), suggested there is still uncertainty about how SMAP observations of horizontal and vertical brightness temperature can be best translated into estimates of surface properties. Although SMAP can provide spatially explicit soil moisture estimates that have been shown to be useful to understand a set of ecohydrological problems (Jadidoleslam et al., 2019), the soil moisture retrievals are still subject to significant amount of uncertainty due to the imperfection of the model and the forcing datasets. The success of retrieving soil moisture and vegetation opacity are interdependent (Konings et al., 2017) and it is important to consider the how the amount of duplicate information carried within a set of observations limits the number of parameters to be inferred (Konings et al., 2015). Therefore, it is critical to diagnosis and quantify the causality of the uncertainty caused by the SMAP algorithm in order to improve the soil moisture and vegetation opacity retrieval quality.

SMAP soil moisture products have been extensively validated against well-calibrated *in situ* soil moisture using unbiased root

mean square error (ubRMSE), bias, RMSE and Pearson correlation coefficients at ‘core’ and ‘sparse’ validation sites (Babaeian et al., 2019; Colliander et al., 2017). Additionally, the triple collocation method, which combines *in situ* measurements, SMAP observations, and model fields, has been used to characterize systematic biases and error variances (Chen et al., 2017, 2018). These validation investigations found that SMAP met the required accuracy target (ubRMSE, 0.04 m<sup>3</sup>/m<sup>3</sup>) on average, while there exist some locations where the performance of SMAP did not meet the expected performance. All these validation studies were focused on finding the general uncertainty of SMAP (which is the deviation of SMAP soil moisture from the *in situ* or reference soil moisture) and cannot diagnose and differentiate where the uncertainty arises. Indeed, the causality of uncertainty of SMAP soil moisture may arise from two aspects: (1) the uncertainty due to the inaccuracies from forcing the datasets and (2) the uncertainty due to poor model structure and parameterizations. In addition, the evaluation metrics used in these evaluation studies are either heavily dependent on *in situ* soil moisture or additional reference datasets, which does not allow for SMAP to be validated in some remote and inaccessible areas.

The challenges faced by previous SMAP evaluation investigations can be resolved by leveraging two information quantities (Shannon, 1948): (1) Shannon’s entropy, which is the amount of information required to fully describe a random variable and (2) mutual information, which represents the amount information of knowing one variable given the knowledge of another or a set of random variables. Gong et al. (2013) estimated these information quantities to partition overall uncertainty in the hydrological modeling process into two categories: (1) random uncertainty that arises by incompleteness of exploratory variable and/or inherent stochasticity of forcing datasets, and (2) model uncertainty that is contributed by poor model parameterization or formulation. The random uncertainty is not resolvable for the given system as it is only related to the probability distributions of the forcing data itself, while the model uncertainty is reduceable by a better model parameterization.

Given that both horizontal and vertical polarized brightness temperatures are measured by SMAP, it is unclear how each polarization contributes information to the overall performance of the DCA. Recent research on partial information decomposition has provided tremendous opportunities for understanding the nuanced interactions among different variables and model structure. Initially proposed by Williams and Beer (2010) and further advanced by Goodwell and Kumar (2017), this approach has been used to understand environmental processes that link two source variables with a target variable by partitioning multivariate mutual information into unique, redundant and synergistic components. The unique information represents the amount of information shared with the target variable from each individual source variable separately. Synergistic information is the information provided to the target while both source variables act jointly. Redundant information is the overlapping information that both source variables redundantly provide to a target. Information partitioning brings new insight by unambiguously characterizing the interdependencies between source variables and a target variable without any underlying modeling assumption. The partitioned components hold potential as a new model evaluation metrics that can be used to assess SMAP algorithm performance in remote and inaccessible regions.

In this study, we focus on (1) quantifying the random uncertainty and model uncertainty in SMAP’s Dual Channel Algorithm (DCA) and understand how model uncertainty is related to DCA retrieval quality; (2) developing an *in situ* and ancillary data independent SMAP DCA evaluation metric using partial information decomposition between SMAP DCA soil moisture and

110 horizontally polarized and vertically polarized brightness temperature.

## 2 Material and Methods

### 2.1 *In situ* soil moisture

115 The US Climate Reference Network (USCRN) is a systematic and sustained network that is operated and maintained by National Oceanic and Atmospheric Administration (NOAA) to support climate-impact research with continuous high-quality field observed soil moisture, soil temperature and windspeed at different temporal scales (Bell et al., 2013). The USCRN provides soil moisture observations at five different standard depth (5 cm, 10 cm 20 cm, 50 cm and 100 cm) in 114 locations of Contiguous U.S. (CONUS). The *in situ* datasets have been used for a wide variety of research such as drought monitoring and satellite soil moisture evaluations (Mishra et al., 2017). The hourly soil moisture datasets at the depth of 5 cm were collected from 51 (12 croplands, 30 grasslands, 5 shrublands, 4 mixed) selected USCRN stations (Fig. 1) based on the availability *in situ* soil moisture dataset and the data quality of SMAP pixels in the study period of 03/31/2015 – 10/01/2020.

### 2.2 SMAP Level-2 datasets

125 In this study, we acquired horizontally polarized brightness temperature ( $T_{Bh}$ ), vertically polarized brightness temperature ( $T_{Bv}$ ), soil effective temperature ( $T_{eff}$ ), DCA soil moisture and the fraction of landcover at each selected USCRN station from SMAP Level-2 Radiometer Half-Orbit 36 km EASE-Grid Soil moisture, Version 7 data product (O'Neill et al., 2020) in the same period as the USCRN soil moisture at every station. The extracted data series were filter by the quality flags of  $T_{Bh}$ ,  $T_{Bv}$  and DCA soil moisture quality flags. We only kept the data points when they all simultaneous pass quality control. DCA retrieves soil moisture based on the '*tau-omega*' model (O'Neill et al., 2020), which is a well-known radiative transfer-based soil moisture retrieval algorithm in the passive microwave soil moisture community. It requires the brightness temperatures as the main inputs, soil effective temperature as an ancillary input, and is parameterized based on overlaying vegetation and soil surface information. The DCA iteratively feeds the '*tau-omega*' model with initial guesses of soil moisture and vegetation optical depth. The retrieved soil moisture is assumed to be close to the real value when the estimated brightness temperatures are similar to the satellite observed brightness temperature (Konings et al., 2015; O'Neill et al., 2020). Compared to the SCAs, 135 the DCA uses a different polarization mixing factor function and different values of vegetation single scattering albedo (Chaubell et al., 2020).

The SMAP fraction of landcover data field provides the fraction of top three dominate landcovers that were classified by International Geosphere – Biosphere Programme (IGBP) ecosystem surface classification scheme at each pixel (Seitzinger et al., 2015). The IGBP classified land surface into water, evergreen needleleaf forest, evergreen broadleaf forest, deciduous needleleaf forest, deciduous broadleaf forest, mixed forest, closed shrublands, open shrublands, woody savannas, savannas, grasslands, permanent wetlands, croplands, urban and built-up, croplands/natural vegetation mosaics, snow and ice, barren. In this study, the landcover of the study site was classified as the most dominate landcover if the fraction of the most dominate landcover was greater than 50%. Otherwise, the landcover of the study site is classified as the "mixed" landcover. Furthermore, 145 the study sites that are dominated by woody savanna were classified as savannas, by closed/open shrublands were classified as shrublands, by cropland/natural vegetation mosaics were classified as croplands.

### 2.3 Information – based uncertainty partitioning

The fundamental quantity of information theory is Shannon’s entropy, which represents the amount of information required to fully describe a random variable (Cover and Thomas, 2005). Shannon’s entropy is the basic building block of computing mutual information and the informational uncertainties. The entropy of a single random variable is defined as

$$H(X) = - \sum_{x \in X} p(x) \log_2 p(x), \quad (1)$$

where  $p(x)$  is the probability mass function of random variable X. The estimation of  $p(x)$  often involves discretizing the values of X into a set of bins and then the  $p(x)$  of a specific bin is computed by dividing the total number of datapoints within a specific bin by the total of number of data points of X. The number of bins in this study is estimated by Freedman-Diaconis binning method (Freedman and Diaconis, 1981). The entropy calculated by eq. (1) is in unit of bits.

Previous study has indicated that this method (eq. (1)) may underestimate the true entropy (Paninski, 2003). Therefore, we leveraged the simple Miller-Madow corrected entropy estimator (Zhang and Grabchak, 2013) and applied a normalization method to remove the bias that may cause by the heterogeneity in length of available datasets across all stations. We acknowledge that there exist several entropy correction and estimation methods. However, we select the Miller-Madow correction based on its simplicity and effectiveness. The corrected and normalized entropy is then expressed as

$$H_{CN}(X) = \frac{H(X) + \frac{K-1}{2n}}{\log_2 n}, \quad (2)$$

where  $H_{CN}(X)$  is the Miller-Madow corrected and normalized entropy of random variable X (hereafter entropy),  $H(X)$  is the uncorrected entropy from eq. (1),  $n$  is the number of data points of X,  $K$  is the number of non-zero probabilities (bins contains more than one data point) based on the fixed binned method (Freedman and Diaconis, 1981). In this study, all entropies of single random variables in the later equations (i.e.,  $H_{CN}(T_{Bh})$ ,  $H_{CN}(T_{Bv})$ ,  $H_{CN}(in\ situ)$  etc.) are computed using the combination of eq. (1) and eq. (2) with the replacement of  $p(\bullet)$  by their individual probability mass functions.

The joint entropy is a critical intermediate information quantity to calculate these informational uncertainties. It represents the amount of information required to describe a set of random variables. The joint entropy for two random variables is defined as

$$H(X, Y) = - \sum_{x \in X} \sum_{y \in Y} p(x, y) \log_2 p(x, y), \quad (3)$$

where  $p(x, y)$  is the joint probability mass function associated with X and Y that is estimated by the same method mentioned above. The same normalization and correction method of eq. (2) is applied to joint entropy of eq. (3). The entropy after the correction and normalization is formulated as

$$H_{CN}(X, Y) = \frac{H(X, Y) + \frac{K-1}{2n}}{\log_2 n}, \quad (4)$$

where  $H_{CN}(X, Y)$  is the corrected and normalized joint entropy of random variable associated with  $\{X, Y\}$ ,  $H(X, Y)$  is the

175 uncorrected entropy from eq. (3),  $n$  is the number of data points that were used to calculate the normalized joint entropy  
 (hereafter joint entropy),  $K$  is the number of non-zero joint probabilities based on the Freeman and Diaconis method (Freeman  
 and Diaconis, 1981). All the joint entropies that are associated with two or more random variables in the later equations (i.e.,  
 $H_{CN}(in\ situ, DCA)$ ,  $H_{CN}(T_{Bh}, T_{Bv}, DCA)$ ,  $H_{CN}(T_{Bh}, T_{Bv}, T_{eff}, in\ situ)$  etc.) are computed using the combination of eq. (3) and eq.  
 (4) with the replacement of  $p(\bullet)$  by their joint probability mass functions, respectively.

180

Commonly, modeling efforts are focused on capturing the information of a random variable of interest via other explanatory  
 variables through some physically- or empirically- based models. However, most of models being constructed of natural  
 processes are not perfect, and the model outputs are often not capable of capturing the exact relationship between the available  
 input variables and the variable of interest (Gupta et al., 1998). In theory, there exists a maximum achievable performance of  
 a model that describes the variable of interest the best for a particular system given the available datasets (Gong et al., 2013);  
 yet the detailed structure of this model is often unknown. Mutual information (Cover and Thomas, 2005), for instance  $I(A; B)$ ,  
 is a measure of the amount information due to the knowledge of knowing either random variable A or B in the function  $I(\bullet; \bullet)$ .  
 Mutual information between model inputs and *in situ* observations of model output (hereafter *in situ* observations) can be used  
 as a useful and effective measure of best achievable performance model because it links the model inputs and *in situ*  
 observations only through the joint and marginal probability mass functions that do not involve any priori model assumptions  
 (Gong et al., 2013).

190

The mutual information is defined based on entropy and joint entropy. The mutual information between  $T_{Bh}$  and DCA, and the  
 mutual information between  $T_{Bv}$  and DCA, are computed as

$$I(T_{Bh}; DCA) = H_{CN}(T_{Bh}) + H_{CN}(DCA) - H_{CN}(T_{Bh}, DCA) \quad (5)$$

195 and

$$I(T_{Bv}; DCA) = H_{CN}(T_{Bv}) + H_{CN}(DCA) - H_{CN}(T_{Bv}, DCA). \quad (6)$$

The mutual information between *in situ* and DCA soil moisture is computed as

$$I(DCA; in\ situ) = H_{CN}(DCA) + H_{CN}(in\ situ) - H_{CN}(DCA, in\ situ). \quad (7)$$

The mutual information between DCA and *in situ* soil moisture is calculated as

$$I(T_{Bh}, T_{Bv}; DCA) = H_{CN}(T_{Bh}, T_{Bv}) + H_{CN}(DCA) - H_{CN}(T_{Bh}, T_{Bv}, DCA). \quad (8)$$

The mutual information between  $T_{Bh}$ ,  $T_{Bv}$ ,  $T_{eff}$  and *in situ* soil moisture is computed as:

$$I(T_{Bh}, T_{Bv}, T_{eff}; in\ situ) = H_{CN}(T_{Bh}, T_{Bv}, T_{eff}) + H_{CN}(in\ situ) - H_{CN}(T_{Bh}, T_{Bv}, T_{eff}, in\ situ). \quad (9)$$

200 For a given system in which the inputs and output are linked via mathematical functions, the mutual information between  
 model outputs and *in situ* observation can never exceed the entropy of the *in situ* observations. This information gap is defined  
 as informational total uncertainty ( $I_{Tot}$ ). The mutual information between the *in situ* observations and the available explanatory  
 variables is also always smaller than the entropy of *in situ* observations. This information gap, defined as informational random  
 205 explanatory variables to fully capture the information in the *in situ* observations. Furthermore, the mutual information between  
 model inputs and *in situ* observations should equal to the mutual information between *in situ* observations and model output if  
 the model hypothesis completely captures or correctly expresses the true relationship between model inputs and *in situ*  
 observations. However, it's commonly known that "All models are wrong, but some are useful" (Peters and Kok, 2016) and  
 model assumptions typically cannot fully express the true relationship between the explanatory variables and *in situ*  
 210 observations. Hence, the mutual information between model output and *in situ* observation is expected to be smaller than the  
 mutual information between model inputs and *in situ* observations. This information gap, defined as informational model  
 uncertainty ( $I_{Mod}$ ) is induced by poor model assumption, formulations, and/or inappropriate model parameterizations. Therefore,  
 the informational total uncertainty ( $I_{Tot}$ ) is the sum of the informational random uncertainty and informational model  
 215 variables of DCA are  $T_{Bh}$ ,  $T_{Bv}$  and the  $T_{eff}$ . The *in situ* observation and model output are *in situ* USCRN soil moisture and DCA  
 soil moisture, respectively.

Leveraging eq. (7) and eq. (9), the DCA informational random uncertainty ( $I_{Rnd}$ ), DCA informational model uncertainty ( $I_{Mod}$ ),  
 and DCA total informational uncertainty ( $I_{Tot}$ ) calculated are calculated as:

$$I_{Rnd} = H_{CN}(in\ situ) - I(T_{Bh}, T_{Bv}, T_{eff}; in\ situ), \quad (10)$$

$$I_{Mod} = I(T_{Bh}, T_{Bv}, T_{eff}; in\ situ) - I(DCA; in\ situ), \quad (11)$$

220 and

$$I_{Tot} = H_{CN}(in\ situ) - I(DCA; in\ situ) = I_{Rnd} + I_{Mod}. \quad (12)$$

## 2.4 Partial information decomposition

The distinct informational contributions of  $T_{Bh}$  and  $T_{Bv}$  to the DCA outputs are be assessed through a decomposition of the  
 information. This method partitions multivariate mutual information to unique, redundant and synergistic components  
 225 (Williams and Beer, 2010). The decomposed information components on the DCA model inputs and outputs are expected to  
 indicative of informational flow as model inputs are translated to end user products, and these components may have potential  
 for evaluating model performance. The partial information decomposition of  $I(T_{Bh}, T_{Bv}; DCA)$  can be expressed as

$$I(T_{Bh}, T_{Bv}; DCA) = U_1(T_{Bh}; DCA) + U_2(T_{Bv}; DCA) + R(T_{Bh}, T_{Bv}; DCA) + S(T_{Bh}, T_{Bv}; DCA), \quad (13)$$

where  $U_1$  and  $U_2$  are unique information of  $T_{Bh}$  and  $T_{Bv}$  shared with DCA, respectively.  $S$  and  $R$  are the synergistic information and redundant information that  $T_{Bh}$  and  $T_{Bv}$  shared with DCA estimates, respectively. All the decomposed components are non-negative real values.

The mutual information between  $T_{Bh}$  and DCA and mutual information between  $T_{Bv}$  and DCA were defined as

$$I(T_{Bh}; DCA) = U_1(T_{Bh}; DCA) + R(T_{Bh}, T_{Bv}; DCA) \quad (14)$$

and

$$I(T_{Bv}; DCA) = U_2(T_{Bv}; DCA) + R(T_{Bh}, T_{Bv}; DCA), \quad (15)$$

where  $U_1$ ,  $U_2$ ,  $S$  and  $R$  are unknowns in the systems of equations (13) - (15). Goodwell and Kumar (2017) showed that the  $R$  can be formulated as

$$R = R_{\min} + I_s * (R_{MMI} - R_{\min}), \quad (16)$$

where

$$I_s = \frac{I(T_{Bh}; T_{Bv})}{\min \{H_{CN}(T_{Bh}); H_{CN}(T_{Bv})\}}, \quad (17)$$

$$R_{MMI} = \min(I(T_{Bh}; DCA), I(T_{Bv}; DCA)) \quad (18)$$

and

$$R_{\min} = \max(0, -II) \quad (19)$$

The  $II$  is the interaction information of  $T_{Bh}$ ,  $T_{Bv}$ , DCA and can be computed as:

$$II = I(T_{Bh}; DCA | T_{Bv}) - I(T_{Bh}; DCA) = H_{CN}(T_{Bh}, DCA) + H_{CN}(T_{Bv}, DCA) + H_{CN}(T_{Bh}, T_{Bv}) - H_{CN}(T_{Bh}) - H_{CN}(T_{Bv}) - H_{CN}(DCA) - H_{CN}(T_{Bh}, T_{Bv}, DCA) \quad (20)$$

It is important to acknowledge that we used the point based *in situ* soil moisture as the ground truth in this analysis. Due to coarse spatial resolution of SMAP products, we acknowledge that *in situ* soil moisture may not be able to represent the spatial averaged soil moisture well. Although the nominal sensing depth of L-band SMAP soil moisture is 5 cm, the penetration depth was found to be even shallower in wetter regions (Shellito et al., 2016). In fact, the L-band sensing depth was found to as little as ~1cm (Jackson et al., 2012) and can be more sensitive to surface meteorological conditions and more random than the actual *in situ* soil moisture. The heterogeneity in each pixel relative to the *in situ* observations together with the sensing depth disparity may negatively influence the results of this study and result in an overestimate the actual informational uncertainties. We also acknowledge the existence of upscaling methods for matching the *in situ* soil moisture to satellite footprint (Crow et al., 2012).

However, most of upscaling methods are achieved under the assistance of additional reference soil moisture datasets. This process introduces additional pieces of information in the DCA system making the separation of the uncertainty induced by the upscaling algorithm or additional dataset from other informational uncertainties much harder. Additionally, we used the hourly *in situ* data to best match the SMAP DCA soil moisture retrievals in time (within an hour). Therefore, it is hard to find a reference dataset at with high frequency in time domain and good spatial coverage. Here we consider the informational uncertainty caused by the spatial mismatch and sensing depth mismatch between *in situ* and DCA soil moisture as part of the informational random uncertainty ( $I_{Rnd}$ ). Because the DCA essential is a mathematical function and does not inherently require the inputs to be at a specific resolution. The spatial resolution is often the inherent attribute of the data. The sensing depth is more of imperfection L-band sensor. The reader should also keep these in mind while interpreting and adopting the results in this study.

### 3 Results

#### 3.1 Information quantities and system informational uncertainties

Figure 2 shows the estimated entropies across all the study sites while Figure 3 shows the mutual information quantities. The  $H_{CN}(T_{Bh})$  and  $H_{CN}(T_{Bv})$  general follow the same pattern with both having an average value of  $\sim 0.37$ . Although the patterns of  $H_{CN}(T_{Bh})$  and  $H_{CN}(T_{Bv})$  are similar, the  $H_{CN}(T_{Bh})$  is slightly more variable than  $H_{CN}(T_{Bv})$  with the coefficients of variation (CV) being 0.05 and 0.04, respectively.  $H_{CN}(T_{eff})$  shares the same average with  $H_{CN}(T_{Bh})$  and  $H_{CN}(T_{Bv})$ , whereas the patterns of  $H_{CN}(T_{eff})$  is quite different (Fig. 2). On average, the  $H_{CN}(in\ situ)$  is 0.35, while  $H_{CN}(DCA)$  and 0.38. In general,  $H_{CN}(DCA)$  follows the pattern of  $H_{CN}(in\ situ)$  with the CV of  $H_{CN}(DCA)$  (0.05) being smaller than the CV of  $H_{CN}(in\ situ)$  (0.08). As shown in Figure 4a,  $H_{CN}(T_{Bh})$ ,  $H_{CN}(T_{Bv})$  and  $H_{CN}(DCA)$  are significantly correlated with  $H_{CN}(in\ situ)$ , while no significant correlation is found between  $H_{CN}(in\ situ)$  and  $H_{CN}(T_{eff})$ . The  $H_{CN}(DCA)$  has the strongest correlation strength with  $H_{CN}(in\ situ)$  compared with other entropy quantities (Fig. 4a).

The mutual information quantities (Fig. 3) are shown to be generally smaller than the entropy quantities (Fig. 2). On average,  $I(T_{Bh}, T_{Bv}; DCA)$  is 0.14, while the  $I(DCA; in\ situ)$  and  $I(T_{Bh}, T_{Bv}, T_{eff}; in\ situ)$  are 0.06 and 0.17 (Fig. 3), respectively.  $I(T_{Bh}, T_{Bv}, T_{eff}; in\ situ)$  is significantly correlated (0.58) with  $H_{CN}(in\ situ)$ , while no significant correlation is found for other two mutual information quantities (Fig. 4b). It is noticeable that there exists a large information gap (Fig. 2 and Fig. 3) between  $H_{CN}(in\ situ)$  and  $I(T_{Bh}, T_{Bv}, T_{eff}; in\ situ)$  and  $I(DCA; in\ situ)$ . These information gaps confirm the existence of informational random uncertainty ( $I_{Rnd}$ ) and informational model uncertainty ( $I_{Mod}$ ) in the SMAP DCA system. On average, the SMAP DCA explains 18% of the  $H_{CN}(in\ situ)$  leaving 82% of the  $H_{CN}(in\ situ)$  that is unexplained (Table 1) as informational total uncertainty ( $I_{Tot}$ ). 36% (Table 1) of the  $I_{Tot}$  is caused by  $I_{Mod}$ , while the rest is induced by  $I_{Rnd}$ . The information uncertainties vary slightly across different landcovers. On average, the SMAP DCA system is capable of capturing more information of  $H_{CN}(in\ situ)$  at croplands (Table 1). Grasslands and Mixed landcover have largest absolute  $I_{Rnd}$  (0.20) than other landcovers, while shrublands has the largest proportion of  $I_{Rnd}$  to  $I_{Tot}$  (Table 1). The shrublands have the largest  $I_{Mod}$  in absolute value, while grasslands have the largest proportion of  $I_{Mod}$  to  $I_{Tot}$  (Table 1).

## 285 3.2 Informational uncertainties and retrieval quality

The relationship between different informational uncertainties and the Pearson correlation coefficients between *in situ* and SMAP DCA output, a commonly adopted relative model evaluation metric in SMAP studies (Chen et al., 2019; Colliander et al., 2017), was evaluated. The  $I_{Tot}$ ,  $I_{Mod}$  and  $I_{Rnd}$  are shown to be related how well the SMAP DCA soil moisture is correlated with *in situ* soil moisture (Fig. 5).  $I_{Tot}$  is found to be negatively correlated ( $r = -0.66$ , Fig. 5a) with the Pearson correlation between *in situ* soil moisture and SMAP DCA soil moisture. Similarly,  $I_{Mod}$  and  $I_{Rnd}$  are also shown to be negatively (-0.51 and -0.37 respectively) related to the Pearson correlation between *in situ* soil moisture and SMAP DCA soil moisture with  $I_{Mod}$  being more influential than  $I_{Rnd}$  (Fig. 5b - 5c). The negative relationship between SMAP DCA informational uncertainties are in line with general expectations since SMAP tends to capture more information about the *in situ* soil moisture when it retrieves high quality datasets.

## 295 3.3 Partial information decomposition of DCA

The partial information decompositions were assessed on a site basis and are shown in Figure 6. The fractional contribution of each component to that site's mutual information between brightness temperatures and DCA estimates,  $I(T_{Bh}, T_{Bv}; DCA)$ , was also calculated and are given in Table 2. Generally, the majority of  $I(T_{Bh}, T_{Bv}; DCA)$  is redundantly ( $R$ ) shared by  $T_{Bh}$  and  $T_{Bv}$ , which is about 0.08 (57% of  $I(T_{Bh}, T_{Bv}; DCA)$ ) on average (Table 2). The mean values of unique information of  $T_{Bh}$  ( $U_h$ ) and synergistic information ( $S$ ) of  $T_{Bh}$  and  $T_{Bv}$  are 0.026 (19% of  $I(T_{Bh}, T_{Bv}; DCA)$ ) and 0.019 (14% of  $I(T_{Bh}, T_{Bv}; DCA)$ ), respectively (Table 2). Compared to other decomposed information components,  $U_v$  is the smallest, but is of similar magnitude with  $S$ , with its mean being 0.013 (10% of  $I(T_{Bh}, T_{Bv}; DCA)$ ). Croplands have the highest  $R$  in absolute value 0.095 (68% of  $I(T_{Bh}, T_{Bv}; DCA)$ ), while mixed landcover has the highest fraction of  $R$  (74% of  $I(T_{Bh}, T_{Bv}; DCA)$ ) (Table 2). In general, the DCA system is mainly dominated by  $R$ . This indicates that both  $T_{Bh}$  and  $T_{Bv}$  provide similar information within the DCA.

## 305 3.4 Partial information decomposition and retrieval quality

Through this analysis, it is shown (Fig. 7) that there are strong relationships between SMAP retrieval quality and decomposed information components. In general, the DCA tends to retrieve high quality soil moisture when  $U_h$ ,  $U_v$  and  $S$  are low (Fig. 7a – Fig. 7c). This is demonstrated by a negative correlation of these component with the Pearson correlation between *in situ* and DCA soil moisture (Fig. 7a – Fig. 7c). In contrast,  $R$  shows the strongest positive correlation (Fig. 7d) with the relative model evaluation metric ( $r = 0.83$ ). This indicates that  $R$  could potentially be a reference metric for DCA evaluation that does not require *in situ* and ancillary datasets.

## 315 4 Discussion

### 4.1 DCA informational uncertainties

The first objective of this study is to leverage information theory to quantitatively decompose the informational total uncertainty into informational random uncertainty and informational model uncertainty in the DCA as an approach to understand where retrieval errors arise. This information theory approach can add considerable power to SMAP modeling diagnosis. Mutual information can provide a way to unambiguously define the best achievement performance of a model that is able to completely transform the available information to the desired target given a set of the input data.

Any model based on the DCA model structure is a hypothesis that relates the input datasets to soil moisture based on prior physical knowledge. The essence of the model is a procedure of processing the input dataset in order to estimate soil moisture. Thus, models, even the one performs the best, can only reduce the available information in its inputs and are not capable of adding new information about the “true” soil moisture. Hence, there is no chance of building a model that is better than the one with the best achievable performance of the input data themselves (yet even achieving this theoretically limit is nearly impossible). If, however, more freedom on available datasets to incorporate is given, it is possible to build models that outperform the aforementioned best achievable model performance by adding new explanatory variables which may lead to a family of models that have completely different model structure. Based on Table 1, we found that the DCA has more informational uncertainty in shrublands than grasslands and croplands which is consistent with previous study (Zhang et al., 2017). This might be due to stronger variability in vegetation types for shrublands while grasslands and croplands tend to be more uniform and homogeneous. Furthermore, shrublands tend to be relatively less sensitive to changes in water availability while grasslands are more sensitive to the soil moisture dynamics in the condition of drought (Geruo et al., 2017). It is worth to noting that these finding are based on lumping our studied sites into different landcover categories, and results may be different while comparing two specific sites from different landcovers.

The fraction that informational random uncertainty contributes to the informational total uncertainty is quite significant (64% on average) in this study. The informational random uncertainty in the system may arises from the inherent error due to calibration of  $T_{Bh}$  and  $T_{Bv}$  in the locations, the mismatch in the scale of observations, and the presence water bodies. If poorly calibrated, the soil moisture estimations can be exacerbated due to the error propagation that hinders the correct information being expressed. Furthermore, SMAP attempts to use the  $T_{eff}$  to capture both soil and canopy temperature because the differences between canopy and soil temperature are minimized in the morning and dawn. The  $T_{eff}$  is computed based on a model that uses the information from average soil temperature of first layer (5cm -15cm) and second layer (15cm - 35cm) and interpolated in time in order to match SMAP morning and dawn observations (O’Neill et al., 2020). These interpolation and modeling processes may produce erroneous  $T_{eff}$  dataset and hence contribute the informational random uncertainty of DCA. Therefore, a better and robust calibration strategy of  $T_{Bh}$  and  $T_{Bv}$  to the presence of water bodies and a comprehensive assessment of  $T_{eff}$  may be needed to reduce some of the information random uncertainty.

Informational model uncertainty contributes an unneglectable portion to the informational total uncertainty (36% on average). This model uncertainty may arise from poor model parameterizations. It’s known that DCA is parameterized with a set of surface and vegetation parameters such as vegetation single scattering albedo ( $\omega$ ), surface height standard deviation  $s$ , etc. These parameter values are landcover dependent are derived from past studies as well as prior experience and some information discussions with experts, all of which could be biased and inaccurate (O’Neill et al., 2020). These parameter values also are differentiated by landcover microwave polarization directions (Wigneron et al., 2004) and were assumed to be constant in time. It is possible that these parameters (such as  $\omega$ ) vary in time and shift during senescence or harvesting seasons (Konings et al., 2017). It is observed that the proportion of the informational model uncertainty is slightly smaller in shrublands (Table 1), while these proportions are larger in croplands and grasslands (Table 1). This might because the model parameterizations are

more reasonable in shrublands than other landcovers. In addition, croplands and grasslands may have seasonal harvesting and therefore may more subject to changes in these values, while shrublands may not.

To summarize, this is the first attempt of leveraging mutual information approach to quantitatively analyze the uncertainty components in microwave remote sensing models. The results of this study can be further used as a foundation guidance of SMAP algorithm assessing approach that can quantitatively identify where information lost in the process of SMAP soil moisture modeling. This analysis, though focused on DCA soil moisture, can be transferred and extended to analyze other remote sensing algorithms.

#### 4.2 Model evaluation from another perspective

The second objective of this study was to demonstrate that the partitioned information components can be used as a new DCA model evaluation metric that does not depend on *in situ* soil moisture and other ancillary datasets. We found a strong linear relationship between redundant information ( $R$ ) of the polarized brightness temperatures and Pearson correlation between DCA and *in situ* soil moisture, which indicated that  $T_{Bh}$  and  $T_{Bv}$  are highly dependent.  $R$  is also the dominant component relative to others quantified here. In general, it is more likely to observe higher  $R$  in the less woody landcovers (croplands and grasslands) where the range of brightness temperature may possible be greater. From an information perspective, higher or complete  $R$  indicates that one variable is a function of the other, or they share the same source.  $T_{Bv}$  and  $T_{Bh}$  are known to be highly correlated. It's important to note that the decomposed information component  $R$  is dependent on the DCA parameterizations that determines how strong the  $T_{Bh}$  and  $T_{Bv}$  are linked with the DCA. This stronger linkage is indicated by a higher value of  $R$  relative to other components.

We found that DCA model performance, as characterized by the correlation between Person correlation between DCA and *in situ* soil moisture, improves with larger values of  $R$  that  $T_{Bh}$  and  $T_{Bv}$  share with DCA estimates. Given the strength of this relationship, the  $R$  could be potentially used as a DCA evaluation metric that doesn't depend on *in situ* measurement and ancillary dataset. It is also useful for SMAP DCA soil moisture users to have a rough estimation of how high the quality of the obtained DCA soil moisture without actually knowing the *in situ* soil moisture. However, this depends on specific user requirements for data quality. In general, the DCA soil moisture tends to be in high end in term retrieval quality ( $\sim 0.75$  in Pearson correlation) when the  $R$  is greater 0.1.

#### 4.3 Approach Limitations

While we expect that this approach can be generalized to analyze other remote sensing models, it may be difficult to compute the joint probability density functions for models with high-dimensional inputs. Difficulty in determining the joint probability density functions hinders the estimation of high dimensional joint entropy and mutual information components. Although there exist several data dimension reduction techniques, these dimension reduction techniques are mostly based some assumptions (Xu et al., 2019). In practice, most of the systems with high dimension inputs tend to be complex. Therefore, there is a strong risk of introducing additional uncertainty if one chooses an inappropriate technique.

This study was conducted only at locations where *in situ* soil moisture is readily available. The problem of how to leverage information theory to evaluate the error components in the locations without *in situ* soil moisture measurements is challenging and could be an interesting topic for future works. Finally, we would expect the informational uncertainty analysis to provide asymptotic estimation of random and model uncertainties. The best performance we can expect from this current uncertainty analysis is to use all of the available datasets we have; yet we believe that uncertainty estimations of this approach should be stabilized given adequate representative locations and data records.

## 5 Conclusions

This study differentiates and quantifies the uncertainty sources in the SMAP DCA using information theory. We found that on average DCA soil moisture explains 18% of the information in the *in situ* soil moisture leaving 82% unexplained. Among the unexplained information, 64% is informational random uncertainty that is caused by the inherent stochasticity of the explanatory variables of SMAP DCA and a lack of additional explanatory variables in the system, while the rest of the informational uncertainty is caused by inappropriateness of the assumption of DCA model structure and parameterizations. We showed that the shrublands have smaller informational model uncertainty compared with other landcovers. The performance of SMAP DCA is negatively correlated to all the information uncertainties, with the informational uncertainty being more influential than the informational random uncertainty.

The decomposition of the mutual information has shown that all decomposed components are correlated with the Pearson correlation between *in situ* and DCA soil moisture, with the redundant information being the tightest. Good DCA model performance (as measured by Pearson correlation between *in situ* and DCA soil moisture) is more likely to be found in locations where the redundant information of brightness temperatures shared with DCA soil moisture is high and is more dominant relative to other components. The informational uncertainty decomposition analysis opens a new window for SMAP algorithm uncertainty diagnosis. The result of mutual information decomposition analysis can be adopted as a new *in situ* independent SMAP soil moisture evaluation reference metric especially in locations where *in situ* soil moisture is not readily available.

### Code availability

The code regarding the SMAP dataset time series, mutual information and partial information decomposition calculation can be obtained from [https://github.com/libonancaesar/HESS\\_Information\\_Uncertainty](https://github.com/libonancaesar/HESS_Information_Uncertainty)

### Data availability

SMAP L2 Radiometer Half-Orbit 36 km EASE-Grid Soil Moisture, Version 7 is acquired from US National Snow and Ice Data Center (<https://nsidc.org/data/smap>). The *in situ* soil moisture is accessible through U.S. Climate Reference Network (<https://www.ncdc.noaa.gov/crn/>).

625

Landcover	Informational random uncertainty, $I_{Rnd}$ (and its % of $I_{Tot}$ )	Informational model Uncertainty, $I_{Mod}$ (and its % of $I_{Tot}$ )	Informational total uncertainty, $I_{Tot}$ (and its % of $H_{CN}(in situ)$ )
Shrublands	0.22 (69%)	0.10 (31%)	0.32 (88%)
Grasslands	0.20 (62%)	0.09 (38%)	0.29 (83%)
Croplands	0.18 (65%)	0.10 (35%)	0.28 (79%)
Mixed	0.20 (68%)	0.09 (32%)	0.29 (81%)
Overall	0.18 (64%)	0.11 (36%)	0.29 (82%)

**Table 1** The amount of informational uncertainties in percentage. The values in the table are the average of each landcover. The values in “Overall” is the average of all the sites.

Landcover	Unique information of $T_{Bh}$ ( $U_h$ ) (and its % $I(T_{Bh}, T_{Bv}; DCA)$ )	Unique information of $T_{Bv}$ ( $U_v$ ) (and its % $I(T_{Bh}, T_{Bv}; DCA)$ )	Synergistic information of $T_{Bh}$ and $T_{Bv}$ ( $S$ ) (and its % $I(T_{Bh}, T_{Bv}; DCA)$ )	Redundant information of $T_{Bh}$ and $T_{Bv}$ ( $R$ ) (and its % $I(T_{Bh}, T_{Bv}; DCA)$ )	Mutual information ( $I(T_{Bh}, T_{Bv}; DCA)$ )
Shrublands	0.03 (27%)	0.017(15%)	0.03 (26%)	0.036 (32%)	0.113
Grasslands	0.029 (21%)	0.014 (10%)	0.02 (14%)	0.077 (55%)	0.14
Croplands	0.017 (12%)	0.013 (9%)	0.016 (12%)	0.095 (67%)	0.141
Mixed	0.014 (12%)	0.007 (6%)	0.01 (8%)	0.091(74%)	0.122
Overall	0.026 (19%)	0.013 (10%)	0.019 (14%)	0.08 (57%)	0.137

655 **Table 2** The partial information decomposition components. The values in the table are the average of each landcover. The values in “Overall” is the average of all the sites.
