Abstract. Endmember mixing analysis (EMMA) is often used by hydrogeochemists to interpret the sources of stream solutes, but variations in stream concentrations and discharges remain difficult to explain. We discovered that machine learning can be used to highlight patterns in stream chemistry that reveal information about sources of solutes and subsurface groundwater flowpaths. The investigation has implications, in turn, for the balance of CO₂ in the atmosphere. For example, CO₂-driven weathering of silicate minerals removes carbon from the atmosphere over ~10⁶-yr timescales. Weathering of another common mineral, pyrite, releases sulfuric acid that in turn causes dissolution of carbonates. In that process, however, CO₂ is released instead of sequestered from the atmosphere. Thus, to understand long-term global CO₂ sequestration by weathering requires quantification of CO₂- versus H₂SO₄-driven reactions. Most researchers estimate such weathering fluxes from stream chemistry but interpreting the reactant minerals and acids dissolved in streams has been fraught with difficulty. We apply a machine learning technique to EMMA in three watersheds to determine the extent of mineral dissolution by each acid, without pre-defining the endmembers. The results show that the watersheds continuously or intermittently sequester CO₂ but the extent of CO₂ drawdown is diminished in areas heavily affected by acid rain. Prior to applying the new algorithm, CO₂ drawdown was overestimated. The new technique, which elucidates the importance of different subsurface flowpaths and long-timescale changes in the watersheds, should have utility as a new EMMA for investigating water resources worldwide.

1 Introduction

We need to understand the long-term controls on atmospheric CO₂ because of the impact of this greenhouse gas on global climate. This is important because humans are increasingly burning fossil fuels and releasing long-sequestered carbon to the atmosphere (Kasting and Walker, 1992). This new C flux upsets the natural long-term balance in the atmosphere between volcanic degassing and weathering-induced drawdown of CO₂ over millennial timescales. Chemical weathering of the most common rock-forming minerals, silicates and carbonates, removes CO₂ from the atmosphere by forming dissolved inorganic carbon that is carried in rivers to the ocean (DIC; Fig. 1). Over 10⁵–10⁶ yr timescales, this DIC is precipitated as marine calcite, releasing half or all of the atmospherically derived CO₂ back to the atmosphere for silicates and carbonates, respectively (Fig. 1). Thus, over this timescale, CO₂-driven weathering (CO₂-weathering) of silicates sequesters CO₂ out of the atmosphere while CO₂-weathering of carbonates neither

55 removes nor releases CO₂ to the atmosphere (Fig. 1). ~~Some~~ researchers ~~also emphasize~~ that this simple picture ~~neglects weathering~~ of another ubiquitous mineral, pyrite (Lerman et al., 2007). When pyrite weathers, it produces sulfuric acid that also dissolves silicates and carbonates, i.e., H₂SO₄-weathering. When DIC generated through H₂SO₄-weathering of carbonates is carried to the ocean, marine calcite precipitates and releases CO₂, increasing atmosphere concentrations (Spence and Telmer, 2005; Calmels et al., 2011; Torres et al., 2014; Kölling et al., 2019).

60 Thus, determination of the weathering contributions of silicates, carbonates, and pyrite is essential toward understanding long-term dynamics of CO₂. In this paper we describe a powerful machine learning technique to interpret the sources of stream solutes to understand problems such as weathering. While we show the importance of applying this machine learning technique to the weathering question, we also emphasize how machine learning can teach hydrogeochemists about subsurface flow paths and other characteristics of stream systems.

65 The most common way hydrogeochemists interpret the fluxes of weathering are to investigate stream and river chemistry. Determining the endmembers for streams is important because streams integrate the byproducts of weathering reactions over drainage basins, allowing assessment of regional to global understanding of fluxes – but only if minerals weathered by different acid sources can be deconvoluted (Li et al., 2008; Calmels et al., 2011; Torres et al., 2016; Winnick et al., 2017; Burke et al., 2018; Killingsworth et al., 2018). In small-scale studies in the laboratory or soil profiles, mineral reactions can be documented, but this information cannot be scaled up easily (Navarre-Sitchler and Brantley 2007). Here we show that machine learning can decipher the balance of fluxes of CO₂- versus H₂SO₄-weathering as recorded in stream chemistry. We discovered that catchments partition water into subsurface flowpaths that can be i) deciphered with respect to the extent of pyrite, silicate, and carbonate weathering in different lithologies, and ii) interpreted with respect to whether weathering is driven by CO₂ or H₂SO₄. We emphasize the long-term effects (over 10⁵ -10⁶ yr) on the CO₂ balance in the atmosphere.

75 Although geochemists commonly use stream chemistry to determine mineral sources of solutes via weathering reactions over large aerial extents (Gaillardet et al., 1999) and hydrologists commonly use endmember mixing analysis (EMMA) to determine the sources of solutes in a stream (Christophersen et al., 1990), stream datasets remain difficult to interpret because of spatial and temporal variations in endmember composition. For example, sulfur isotopes in stream solutes can distinguish pyrite-derived from rain-derived sulfate because pyrite typically is depleted in ³⁴S (Burke et al., 2018; Killingsworth et al., 2018). But this attribution is difficult, more expensive, and often ambiguous because pyrite δ³⁴S varies between formations (Gautier, 1986) or within a single catchment (Bailey et al., 2004). Likewise, inputs of sulfate to watersheds, such as acid rain, can swamp out the signal from mineral reactions, and can change significantly over time (e.g., because of changing acid rain deposition) (Lynch et al., 2000; Lehmann et al., 2007). These factors make it difficult to determine sources releasing sulfate to varying stream chemistries over time.

85 Several so-called “inverse models” have been used successfully to partition sulfate into endmember sources for streams and rivers. These include the two prominent modeling approaches by Torres et al. (2016) and Burke et al. (2018). However, because the chemistry of acid rain has varied over the past decades, utilizing the full range of rain

chemistry in those models results in unrealistic contributions of acid rain (i.e., > 100%) or models that fail to converge. This is at least partly because the chemistry of acid rain has been so variable that it spans the entire measured range of stream samples. Additionally, utilizing the approach of Burke et al. (2018), based on the approach of Gaillardet et al. (1999), requires a priori assignment of accurate endmember chemistries. Often, the researcher must rely on a few samples to characterize endmembers, resulting in large uncertainties in endmember chemistry and in source apportioning. Since the inception of EMMA, many researchers have aimed to improve analysis through a more accurate determination of unknown or under-constrained endmember chemistries (Hooper, 2003; Carrera et al., 2004; Valder et al., 2012). But these efforts all use some a priori determination of endmembers. Our machine learning model adds to the growing effort to improve EMMA by applying blind source separation. The machine-learning approach we describe here de-convolves sources of stream chemistry without pre-defining the endmembers. We demonstrate this first with a synthetic dataset and then with data from three well-studied watersheds with different characteristics. The new method discovers the endmember chemistries and, as a result, documents new findings of importance previously undiscovered with the other methods.

For the target watersheds, we focus first on Shale Hills, an acid rain-impacted shale watershed in central Pennsylvania, USA with extensive data for water/rock chemistry (Jin et al., 2010; Brantley et al., 2013a; Sullivan et al., 2016). This watershed allows the most complete understanding of solute sources. Although we do not show this here, if we use either of the two previously used models for source attribution, stream chemistry data for Shale Hills either does not separate acid rain and pyrite as a sulfate source (if we use the model of Torres et al., 2016) or yields a proportion for acid rain which is larger than 100% (if we use the model of Burke et al., 2018). As shown below, the Non-negative Matrix Factorization (NMF) model easily defines endmembers and proportions.

We then show the utility of the machine learning method for watersheds where less water/rock chemistry has been published: we investigate East River and Hubbard Brook catchments. Like Shale Hills, East River is shale-hosted, but it receives little acid rain (Winnick et al., 2017). In contrast, Hubbard Brook has been extensively impacted by acid rain but is underlain by glacial till over schist (Likens et al., 2002). In both cases, NMF successfully determines endmembers and source proportions.

Figure 1. Schematic summarizing the reactions, timescales, and net CO₂ release to or uptake from the atmosphere accompanying weathering of silicate and carbonate minerals. Uptake or release depends upon timescale, as shown, and as discussed in text. CaSiO₃ is used as a generic silicate mineral.

2 Methods

2.1 Study Sites

Where previous deconvolutions of stream chemistry into endmembers were generally based on assumptions of the chemistry of dissolving minerals alone, data for watersheds show that the flowpath of the water also affects this chemistry (e.g., Brantley et al 2017). We demonstrate this with data from three well-studied watersheds with different characteristics. We focus first on Shale Hills, a small (0.08 km²), acid-rain impacted forested watershed underlain by Rose Hill shale located in central Pennsylvania, USA (Brantley et al., 2018). The Rose Hill Formation shale contains ~0.14 wt% S as pyrite (FeS₂) (Gu et al., 2020a).

We then show utility of the method in East River (shale-hosted but it receives little acid rain) and Hubbard Brook (extensively impacted by acid rain but is underlain by schist and glacial till) catchments. Specifically, East

River is a large (85 km²), mountainous watershed underlain by Mancos Shale that is located near Gothic, Colorado USA within the Gunnison River basin (Winnick et al., 2017). The Mancos is a black shale that contains ~1.6 wt% S as pyrite (Wan et al., 2019). Both of these shale-hosted watersheds contain carbonate minerals that vary in composition and abundance in the subsurface. Lastly, Hubbard Brook (Nezat et al., 2004), located in the White Mountains of New Hampshire USA, consists of a series of nine small (0.14-0.77 km²), forested watersheds underlain by Rangeley Formation metamorphosed shale and sandstone (schist) generally covered by glacial till derived mostly from the Kinsman granodiorite. The schist bedrock contains ~0.2-0.9 wt% S and till contains ~0.1-0.2 wt% S. Again, almost all S is present as iron sulfide (pyrite or pyrrhotite). Both bedrock and till are largely carbonate-free.

Deleted: (schist)

2.2 Data Acquisition

For Shale Hills, daily stream chemistry has been reported from 2008-2010 (Brantley et al., 2013b; Brantley et al., 2013c; Brantley et al., 2013d). Additional samples were measured in other time intervals for sulfur isotopes and alkalinity (Jin et al., 2014). All samples were filtered through a 0.45 μm Nylon filter and aliquots for cation analysis were acidified with nitric acid. Cations were measured on a Leeman Labs PS3000UV (Teledyne Leeman Labs, Hudson, NH) inductively coupled plasma-optical emission spectrometer (ICP-OES), and anions were measured on a Dionex Ion Chromatograph (Sunnyvale, CA). Alkalinity was measured by titration with 0.16 M H₂SO₄. Discharge data are available online (http://www.czo.psu.edu/data_time_series.html).

All published data from East River were used in analysis (Winnick et al., 2017), except for two samples with extremely high values of chloride (246 and 854 μM) because they differed significantly from the remaining sample chemistry (average Cl concentration = 21 μM). Hubbard Brook weekly chemistry from 2000-2017 was downloaded for the sub-catchments (3, 6, 7, 8, 9) that were not experimentally manipulated (Bernhardt et al., 2019). Stream discharge data for each sub-catchment are from USDA Forest Service (USDA, 2019).

2.3 Machine Learning Model

To assign the proportion of sulfate in streams to sources, we first bootstrapped measurements to increase data volume and then used a method of blind source separation (Alexandrov and Vesselinov, 2014; Vesselinov et al., 2018) called non-negative matrix factorization (NMF). NMF is unique from previously used methods in that it allows calculation of endmember compositions and mixing proportions simultaneously and does not rely on measurements or assumptions of endmembers a priori (Fig. 2A; see SM section 1). Specifically, NMF decomposes the $n \times m$ matrix, V , into two matrices W and H :

$$V = WH \quad (1)$$

Here, cell entries of V are molar solute concentration ratios, $[X]/[Y]$, for stream samples. Indicator n refers to the sampling date, m refers to different solutes (X = Ca²⁺, Mg²⁺, Na⁺, K⁺, Cl⁻), and brackets refer to concentrations. W is the $n \times p$ matrix whose cell entries are proportions, α , for each endmember in each stream sample. Again, n refers to sampling dates, but p is the number of sources of solutes (referred to as endmembers). The proportions refer to the

Deleted: →

Deleted: V is an $n \times m$ matrix whose

Deleted: SO_4^{2-} .

Deleted: Here

Deleted: (=

fractions of sulfate in each sample that derive from an individual endmember, where the sum of proportions must equal 1 ± 0.05 for each sample. To derive the mixing proportions of sulfate specifically, we set up the NMF approach by normalizing each analyte concentration by sulfate concentration ($Y = SO_4^{2-}$), the target solute. After running the algorithm for each of the three watersheds, we then inferred by inspection (see discussion below) that the endmembers represent different flowpaths in the subsurface. Therefore, these proportions of sulfate are referred to here as shallow, moderately shallow, and deep flowpaths, i.e. α_{shallow} , α_{moderate} , and α_{deep} respectively (only one of our target watersheds revealed the moderate-depth flowpath). H is the $p \times m$ matrix whose cell entries are the concentration ratios that define the chemical signature of each of the p endmembers. The key to NMF is that these concentration ratios are not determined prior to apportionment but rather are determined from the data itself. In addition, the chemical signatures of each endmember can vary temporally around central tendencies. Because the solution to eq. 1 is non-unique, we run the model 20,000 times, apply a filter to the models, and then calculate the mean and standard deviation of the remaining models for trend and error analysis (see SM section 1; Eq. S1).

The only hyperparameter that must be defined to run NMF a priori is the number of endmembers, p . We used principal component analysis (PCA) to determine the minimum number of components needed to explain >90% of the variance in stream solute ratios, and trained NMF to the bootstrapped data while assuming that number of endmembers. Machine learning determined the compositions defining the endmembers and the mixing proportions of each endmember in each sample. After running NMF, we interpreted each endmember composition based on geological and watershed knowledge.

Based on the outputs of the NMF model, we calculated the weathering rates of sulfide, carbonate, and silicate minerals in the watersheds. Additionally, we calculated the relative contributions of sulfuric and carbonic acid driving those weathering reactions. For details on the weathering calculations see SM section 2.

2.4 Synthetic Dataset

NMF is an algorithm that has been used for many applications (e.g., spectral analysis, email surveillance, cluster analysis; Berry et al., 2007) but has only recently been applied to stream chemistry (e.g., Xu and Harman, 2020). To exemplify the validity of our modeling approach, we generated a dataset of synthetic stream chemistry versus time and ran it through our NMF model. First, we defined two known endmember compositions, which are shown in Table S1. Next, we randomly generated 300 synthetic stream samples that were each calculated as a mixture of the two endmembers. Lastly, we ran NMF on the synthetic stream chemistry to determine the mixing proportions (α) and endmember compositions ($[X]/[SO_4^{2-}]$), for all X .

3 Results and Discussion

3.1 Synthetic Data Model

After generating the synthetic dataset of stream samples, we utilized NMF to determine the mixing proportions and endmember compositions. We then filtered out the poor fitting models (see SM [eq. S1](#)). As described more fully in the SM, this left an average number of valid models of 62 (range: 42-77). The average variance between valid models was <10%. Without any prior information about the system, NMF accurately determined the correct mixing proportions (RMSE = 0.04; $R^2 = 0.98$; $p < 0.001$; Fig. 2B) and endmember compositions (RMSE = 0.21; $R^2 = 0.99$; p

Deleted: Eq. 4

265 < 0.001; Fig. 2C). In effect, the model was able to use patterns in the data to [deconvolve sample chemistry into](#)
270 [endmembers and proportions](#).

Deleted: accurately unmix the samples.

3.2 Application to Shale Hills

270 While clay minerals in shale-underlain watersheds in rainy climates are found at all depths [because of their low](#)
[chemical reactivity](#), pyrite and carbonate minerals are [often chemically removed from upper layers and](#) only found in
unweathered shale at depth (Fig. 3; Brantley et al., 2013a; Wan et al., 2019; Gu et al., 2020a). For example, at Shale
Hills, pyrite and carbonate minerals are only observed deeper than at least 15 meters below land surface (mbls) under
the ridges and 2 mbls under the valley. In these deeper zones, calcite (CaCO_3), ankerite
($\text{Ca}(\text{Fe}_{0.34}\text{Mg}_{0.62}\text{Mn}_{0.04})(\text{CO}_3)_2$), and pyrite (FeS_2) dissolve in regional groundwaters that flow to the stream (Brantley
275 et al., 2013a; Gu et al., 2020a). These groundwaters thus contribute DIC, Ca^{2+} , Mg^{2+} , and SO_4^{2-} into the stream.

Deleted: generally

Deleted: because they are depleted from upper layers

Deleted: 2020

Like many catchments, water also flows to the stream in Shale Hills along a much shallower near-surface
flowpath, [which we call](#) interflow (Fig. 3). Interflow [is thought to occur](#) along a transiently perched water table [that](#)
[lies](#) within the upper 5-8 mbls. The most abundant mineral, illite

Deleted: 2020

Deleted: referred to here as

Deleted: occurs

280 ($\text{K}_{0.69}(\text{Si}_{3.24}\text{Al}_{0.76})(\text{Al}_{1.69}\text{Fe}^{3+}_{0.10}\text{Fe}^{2+}_{0.16}\text{Mg}_{0.19})\text{O}_{10}(\text{OH})_2$), dissolves in interflow [where it flows through](#) the soil, [with](#)
[minimal illite dissolution in underlying](#) weathered rock. Illite dissolution releases DIC and Mg^{2+} and K^{+} to interflow
waters and causes precipitation of clays and iron oxides. Interflow derives ultimately from local precipitation that
also contains Na^{+} , Cl^{-} , and SO_4^{2-} . Interflow and deep groundwater flowlines converge under the catchment outlet
where the stream, on average, is 90% interflow and 10% deep groundwater (Sullivan et al., 2016; Li et al., 2017).

Deleted: along a flowpath confined largely to

Deleted: and upper

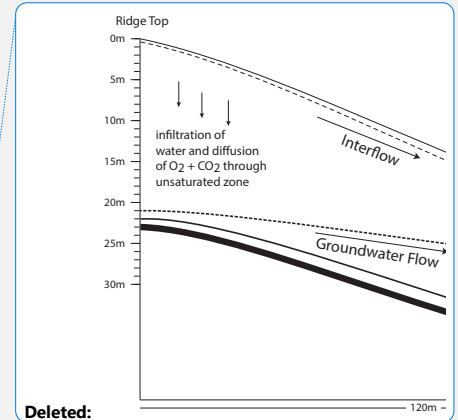

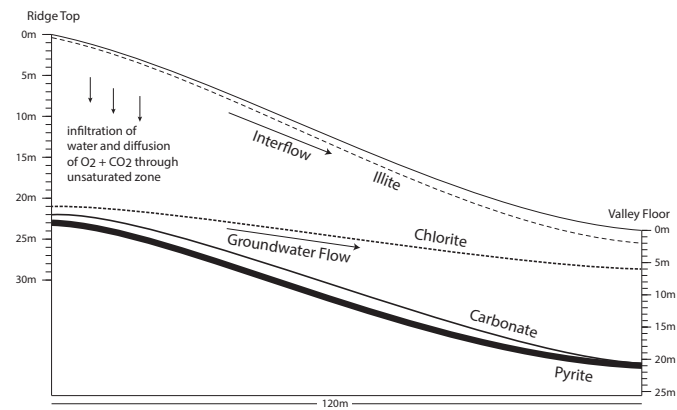

Deleted: zone

285 Only one mineral, chlorite ($(\text{Fe}^{2+}_{0.40}\text{Mg}_{0.15}\text{Al}_{0.35})_6(\text{Si}_{0.76}\text{Al}_{0.24})_4\text{O}_{10}(\text{OH})_8$), is observed to begin to weather in
the deep groundwater and continue weathering all the way to the surface (Fig. 3; Gu et al., 2020a). Chlorite thus
[dissolves](#) to release Mg^{2+} to both interflow and deep groundwater. While most water entering the catchment leaves as
interflow without entering deep groundwater, the wide reaction zone observed for chlorite is consistent with [a small](#)
[fraction](#) of water [infiltrating vertically](#) to the deeper zone (Brantley et al., 2017).

305 Figure 3. Schematic cross section of Shale Hills showing the depths (labelled lines) where [oxidation of pyrite, and dissolution of carbonate, chlorite, and illite](#), initiate (modified after Brantley et al., 2013a). Illite and chlorite dissolve at all depths above the labelled lines, but [reactions of carbonate minerals and pyrite only occur](#) in a narrow one-meter wide depth zone under the ridge that widens to [several meters](#) toward the valley. [Specifically, pyrite oxidation is complete under both ridge and valley at the depths where chlorite dissolution initiates. Carbonate dissolution is complete at the depth where pyrite oxidation is complete under the ridge but at ~4 m above the pyrite front under the valley.](#) These reaction [fronts are](#) estimated and extrapolated from bulk chemistry measured in samples from boreholes located at the ridge and valley (Jin et al., 2010; Brantley et al., 2013a; Gu et al., [2020b](#)).

PCA for stream chemistry (2008-2010) at Shale Hills revealed two sources of sulfate, and this was used to set up NMF, i.e., $p = 2$ (Table [S2](#)). By comparing the compositions from matrix H (Table [S2](#)) determined by NMF to our knowledge of the subsurface (Fig. 3), we interpreted the two endmembers as deep and shallow weathering along the two flowpaths, i.e. [groundwater and interflow](#) (Fig. 3), respectively (Jin et al., 2014; Sullivan et al., 2016). The endmember with high $[Ca^{2+}]/[SO_4^{2-}]$ and $[Mg^{2+}]/[SO_4^{2-}]$ was attributed to deep weathering because Ca- and Mg-containing minerals (i.e., calcite and ankerite) only dissolve at depth (Fig. 3; [Jin et al., 2014](#); Gu et al., [2020a](#)). The high $[Cl^-]/[SO_4^{2-}]$ endmember was attributed to shallow [interflow because it is](#) dominated by Cl-containing [acid rain](#). This attribution revealed, consistent with other studies of the acid rain-impacted northeastern United States, that precipitation accounts for the majority of sulfate flux (i.e., 77%) at Shale Hills [between 2008 and 2010](#).

Many lines of evidence back up these endmember attributions. The sulfate in the shallow endmember derives from [interflow](#) well above the pyrite oxidation front through pyrite-depleted rock and is thus attributed to acid rain, while the sulfate in the deep endmember is attributed mostly to pyrite oxidation. Some sulfate from acid rain may [infiltrate](#) to the regional groundwater, but the fraction is small. At Shale Hills, acid rain always contains Cl^- and pyrite oxidation always preferentially dissolves carbonate minerals, giving each flowpath endmember a unique signature.

To test the NMF deconvolution, we compared these attributions to isotopic data. [The value of \$\delta^{34}S\$ in dissolved sulfate](#) is observed to correlate with increasing concentrations of pyrite-derived sulfate [determined by NMF](#) (Fig. 4A), consistent with depleted $\delta^{34}S$ signatures in pyrite (e.g., -20‰; Killingsworth et al., 2018). In contrast, acid rain shows $\delta^{34}S$ values around +3-5‰ (Bailey et al., 2004), and low sulfate concentrations in stream samples are characterized by $\delta^{34}S$ values within this range. Also, as pyrite oxidizes, the concentration of sulfate increases and the $\delta^{34}S$ values decrease to reflect the inferred composition of pyrite, -9.5‰ to -7.2‰ (Fig. 4A). Finally, Gu et al. ([2020b](#)) showed that pyrite oxidation drives the [carbonate](#) dissolution at Shale Hills. NMF results [show that stream water was](#) near calcite equilibrium (i.e., $\Omega_{calcite} = 1$; $\log \Omega_{calcite} = 0$) and had the highest pyrite-derived sulfate concentrations [when the stream was fed by groundwater](#) (Fig. 4B).

However, the annual flux of acid rain-derived sulfate [from 2008-2010](#) in the shallow endmember determined from NMF at Shale Hills (Table 1) far exceeds the wet deposition of sulfate during the sampling period (Fig. 4C). [Such](#) inconsistencies have been noted elsewhere and attributed to travel-time delays over decades between acid rain input and stream output ([Cosby et al., 1985](#); Prechtel et al., 2001; Mörth et al., 2005; [Rice et al., 2014](#)). allows us to estimate a ~19-31-year lag time between input and export of sulfate from the temporally changing acid rain (see SM section 2.4).

Weathering profiles at Shale Hills, the chemistry of the composition (H) matrix, sulfur isotopes, calcite saturation, and lag in acid rain export all support our interpretation that the two components in the NMF model are shallow and deep flowpaths and that sulfate largely derives from acid rain and pyrite respectively. The dissolution of different minerals along these flowpaths lead to patterns in stream chemistry that our NMF model discerns and separates. If mineral reaction fronts are not separated in the subsurface, different flowpaths might not be separated by NMF; however, Brantley et al. (2017) and Gu et al. (2020a) have shown that separation of reaction fronts is common.

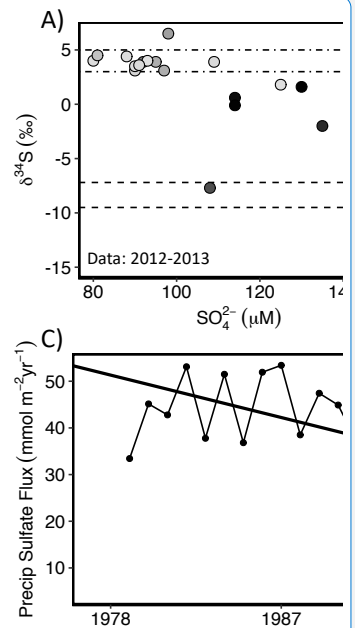

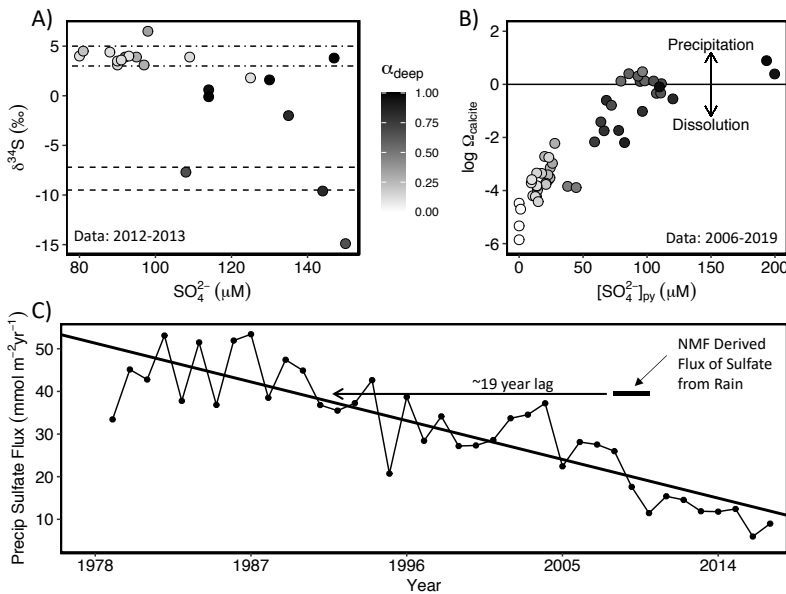

Figure 4. (A) Sulfur isotope composition plotted versus concentration for sulfate in the subset of stream or groundwater samples at Shale Hills where S isotopes were measured (symbols; Jin et al., 2014). Dot-dashed lines represent the average sulfur isotope range for acid rain in USA (3-5‰; Bailey et al., 2004) and dashed lines represent the average sulfur isotope range of pyrite calculated from NMF results (-9.5‰ to -7.2‰). Sulfur isotopes in pyrite at Shale Hills were previously constrained to lie in the range of -1‰ to -15‰ (Jin et al., 2014). (B) Plot showing the calcite saturation index ($\log \Omega_{\text{calcite}}$) vs. concentration of pyrite-derived sulfate (calculated through NMF) in surface and groundwater samples at Shale Hills where alkalinity was measured. Here Ω_{calcite} (= ion activity product / equilibrium constant for calcite dissolution) is <1 the water is undersaturated with respect to calcite, and when Ω_{calcite} is >1 , the water is oversaturated. Black line represents water-calcite equilibrium. Some samples in B differ from those in A because more samples were collected for alkalinity than sulfur isotopes. In both A and B, color shading represents the fraction of total sulfate derived from pyrite calculated by NMF (i.e., α_{deep}). Hills) from wet and dry deposition (see SM section 2.4). Black bar shows the NMF results for the export flux of sulfate derived from acid rain for Shale Hills during our sampling period, and the rationale for the inferred 19 y lag between input and output.

3.3 Rates of Weathering and CO₂ Sequestration at Shale Hills

With these calculations we can use NMF results to elucidate the effect of sequestration or release of CO₂ at Shale Hills. We emphasize fluxes of importance over 10⁵–10⁶ yr timescales. CO₂-driven weathering of the silicate minerals chlorite and illite removes carbon from the atmosphere and carries it as DIC in rivers to the ocean where it is buried as carbonate minerals (akin to reaction 2 in Figure 1, Table S3). In contrast, calcite and ankerite weathering coupled to pyrite oxidation instead releases CO₂ to the atmosphere over those timescales (reaction 7 in Figure 1) and carbonate mineral weathering is neutral over those timescales (reaction 4 in Figure 1). Additionally, acid rain can interact with silicate minerals but not carbonate minerals at Shale Hills (because these are not present in the shallow subsurface (Fig. 3)). Thus H₂SO₄-dissolution caused by acid rain competes with CO₂-dissolution for silicates. This competition lowers the CO₂ consumption from silicate weathering, which been observed in other watersheds (e.g., Suchet et al., 1995).

To summarize the effect of weathering on CO₂ considered at the timescale of 10⁵–10⁶ yr as shown in Figure 1, we propose a new parameter, the stream CO₂ sequestration coefficient, κ_{stream} (see SM section 2.2 for full derivation). This coefficient is defined as mol CO₂/[Σ^+]_{total} where [Σ^+]_{total} is the sum of the equivalents of base cations in a sample. Here, equivalents refer to molar concentration multiplied by charge for an ion. Positive κ_{stream} implies the stream acts as a source and negative implies it acts as net sink of CO₂ and the values are calculated for an individual sample or integrated over some time period of stream sampling. The product of κ_{stream} times [Σ^+]_{total} in a sample equals the moles of CO₂ sequestered or released during weathering as represented in that sample (but the accounting is calculated for the reactions considered for the 10⁵-10⁶ y timescale in Figure 1). Quantitatively this parameter reveals the moles of CO₂ sequestered or released during weathering per cation equivalent in a given stream sample:

$$\kappa_{stream} = \frac{1}{2}(-1 + \gamma_{stream} + \zeta_{stream}), \quad (2)$$

Here, γ_{stream} is the proportion of cation equivalents in the stream derived from carbonate weathering per [Σ^+]_{total}, and ζ_{stream} is the ratio of sulfate equivalents from sulfuric acid per total base cation equivalents. We calculate γ_{stream} for a sample by multiplying the pyrite-derived sulfate concentration (i.e., α_{deep} multiplied by total sulfate concentration) by the [Ca²⁺]/[SO₄²⁻] and [Mg²⁺]/[SO₄²⁻] ratios in the sample calculated by NMF to have derived from the deep weathering endmember and then dividing by [Σ^+]_{total}. Likewise, ζ_{stream} is calculated by multiplying the fraction of sulfate from pyrite + acid rain (e.g., $\alpha_{deep} + \alpha_{shallow}$) by the total sulfate concentration and dividing that by [Σ^+]_{total}. This calculation shows that seasonally, Shale Hills switches between net source and net sink of CO₂ (Fig. 5D). Using the weathering reactions described in SM section 2.2, we also calculated the actual associated CO₂ fluxes: annual CO₂ dynamics are net-neutral at Shale Hills when considered over timescales of 10⁵–10⁶ yr (Table 1; Fig. S4).

Deleted: flux and find that annually

The switch in systems from operating as a source or a sink is attributed to seasonality in the dominant flowpath: CO₂-weathering of silicates occurs year-round, but H₂SO₄-weathering is more important in the wet season and is dominated by acid from rain. Specifically, in the dry season when water tables are low, the stream water is often dominated by deeper groundwater flow that interacts with the deep pyrite reaction front and has little contribution of acid rain. However, even though this dry season is characterized by higher proportions of pyrite-derived sulfate, the watershed acts predominantly as a sink of CO₂ during this time of the year because the drawdown of CO₂ from CO₂-weathering of silicates is larger than the efflux of CO₂ from pyrite-driven H₂SO₄-weathering of carbonate (Fig. 5D). In the wet season when water tables are high, however, the stream is dominated by shallow interflow that does not interact with pyrite but has a large contribution of H₂SO₄ from rain. Kanzaki et al. (2020) also previously showed that the separation of reaction fronts (Fig. 3) can cause such important effects on CO₂ fluxes, although that previous treatment focused strictly on simple model systems unaffected by acid rain.

To test the accuracy of these inferences based on NMF, we compare to previous results for Shale Hills. Based on soil pore-water chemistry and rain fluxes at Shale Hills, Jin et al. (2014) estimated the CO₂ drawdown from silicate weathering to be 44 mmol m⁻² yr⁻¹. We find that if we assume all silicate weathering is CO₂-driven, then the silicate weathering drawdown is 38 mmol m⁻² yr⁻¹, which is consistent with the estimate of Jin et al (2014). But 44 mmol m⁻² yr⁻¹ is an overestimate because it does not consider H₂SO₄-weathering of silicates or carbonates.

3.4 East River

Shale Hills is unique in that it is a monolithologic catchment and the data volume to constrain endmember apportionment is large. But NMF also works well for watersheds in which the subsurface flow and reactions are less constrained partly due to the more complex subsurface geology. The weathering profile at East River (underlain by black shale) shows that pyrite and carbonate are depleted in upper layers but start dissolving at ~2-4mbls (Wan et al., 2019). PCA shows that the number of components is 2. The composition of the endmembers for East River are similar to Shale Hills (Table S2); however, the endmember composition indicates a higher proportion of H_2SO_4 -weathering of carbonates (see SM section 2).

Based on NMF for East River, pyrite contributes 62% of the annual sulfate flux (Table 1). Sulfuric acid drives 29% to 69% of carbonate dissolution depending on the season, and this compares well with previous estimates of 35-75% (Winnick et al., 2017). Unlike Shale Hills, pyrite oxidation at East River is the dominant source of sulfate because acid rain is less important, and the black shale is pyrite-rich (Fig. 5B).

Although East River is like Shale Hills in that it intermittently switches between acting as a source or sink of CO_2 (Fig. 5), the seasonality of the switch between Shale Hills and East River is reversed. During baseflow (i.e., between periods of precipitation), Shale Hills is predominantly a sink of CO_2 , and it sometimes switches to a source of CO_2 in the wet season because acid rain competes with CO_2 and reduces CO_2 consumption from silicate weathering. Without the large acid rain influx, East River instead acts as a sink of CO_2 during the wet season of snowmelt and then switches to a source during baseflow. Our results are consistent with previous interpretations (Winnick et al., 2017) suggesting CO_2 efflux rates are highest in baseflow-dominated and lowest in snowmelt-dominated flow regimes.

3.5. Hubbard Brook

Monolithologic shale watersheds are not the only target chemistries that can be deconvoluted with NMF; we now consider Hubbard Brook, a catchment on crystalline rock. Large variations in the $\delta^{34}S$ composition of the bedrock at Hubbard Brook (Bailey et al., 2004) mean that sulfur isotopes in stream water cannot be used to unambiguously apportion sulfate sources. Weathering fluxes from sulfide minerals are therefore difficult to constrain (Mitchell et al., 2001).

At Hubbard Brook, PCA shows three endmember sources of sulfate. As described below, we attribute these to three inferred flow lines, two in till and one at depth: waters flowing through i) shallow soil developed from till, ii) moderately-deep, less-weathered till, and iii) weathering bedrock. A three-layered weathering profile has been observed in other till-covered areas of New Hampshire as well (Goldthwait and Kruger, 1938). We used these ideas to identify endmembers as described below.

Concentrations of sulfate in acid rain have declined over time in northeastern USA (Lynch et al., 2000; Lehmann et al., 2007). Of the three NMF-determined endmembers at Hubbard Brook, two of them show declining sulfate concentrations with time. We therefore attributed the first and second endmembers to acid rain (Fig. S1).

Deleted: This reflects that most of the sulfate at East River is derived from the pyrite-rich shale (i.e., 65%) and that H_2SO_4 -weathering of carbonates is a more dominant reaction at East River than at Shale Hills.

Deleted: We agree with the interpretations of Winnick et al. (2017), but NMF adds the new insight that on an annual basis, the efflux of CO_2 from H_2SO_4 -weathering of carbonates is balanced by CO_2 -weathering of silicates making East River net neutral with respect to CO_2 .

Deleted: .

Deleted: are difficult

Deleted: pyrrhotite (FeS), the

Deleted: mineral known to be present, have

Deleted: never been fully

Only one endmember showed little to no decline in sulfate concentration over time, and we therefore attributed that endmember to deep weathering in water interacting with the underlying bedrock. The composition of the deep weathering endmember shows a strong correlation between $[Mg^{2+}]/[SO_4^{2-}]$ and $[K^+]/[SO_4^{2-}]$. [This chemical signature is](#) similar to previous observations of weathering of metasedimentary rock piles where silicates (biotite and chlorite) are the first minerals to dissolve when sulfides oxidize (Moncur et al., 2009). Specifically, biotite ($K(Si_3Al)Mg_2FeO_{10}(OH)_2$) is known to release Mg^{2+} and K^+ while chlorite releases Mg^{2+} upon weathering. Moreover, the metamorphic conditions that produce pyrrhotite also produce biotite and chlorite, and those three minerals tend to be located together in schist foliations (Carpenter, 1974). [We thus infer that pyrrhotite](#) oxidation at Hubbard Brook apparently causes dissolution of biotite \pm chlorite because these are the most susceptible minerals in close proximity to the sulfide. Thus, several lines of evidence underlie our interpretation that component 3 is the deep weathering source of sulfate.

[From the NMF results](#) summarized in Table 1, pyrrhotite can account for 30% of the total sulfate flux at Hubbard Brook. The schist and till contain essentially no carbonate; therefore, weathering is always a net sink for CO_2 . In this watershed, however, the story is complicated by the [dissolution of silicate minerals by](#) sulfuric acid from pyrrhotite oxidation and acid rain. If we had assumed all of the base cations detected in Hubbard Brook were caused by CO_2 -weathering, we would have overestimated the net drawdown of CO_2 out of the atmosphere (Fig. 1).

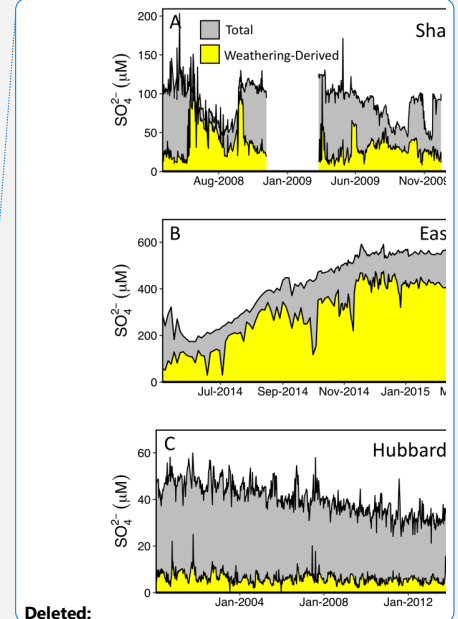

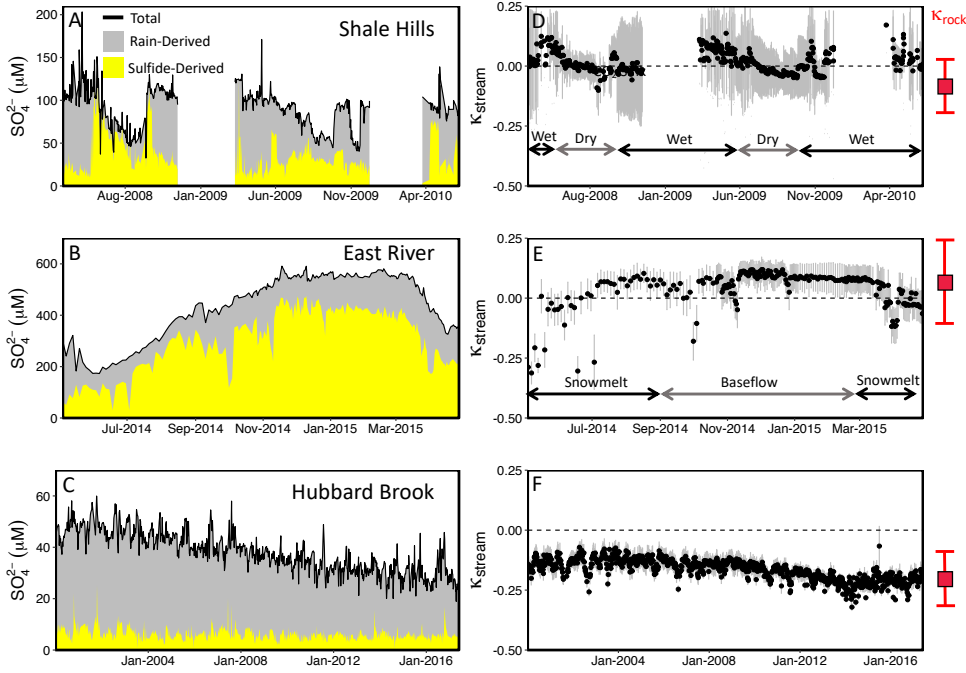

Figure 5. Concentration of total sulfate (black line), rain-derived sulfate (NMF-calculated; gray) and sulfide-derived sulfate (NMF-calculated; yellow) in stream water plotted versus time at Shale Hills (A), East River (B), and Hubbard Brook (W-3 sub-catchment) (C). Shale Hills and East River **temporally switch between being a source and sink of CO₂**, while Hubbard Brook is **always a sink** over the timescales studied, as shown by the CO₂ sequestration coefficient (κ_{stream}) for Shale Hills (D), East River, (E), and Hubbard Brook (F). **Gray error bars in D, E and F represent 1s.d. from the calculated κ_{stream} for that sample.** The range (mean + 1s.d.) indicated in red to the right of D, E, and F represent κ_{rock} , the time integrated CO₂ sequestration coefficient calculated from the rock chemistry (see text). **Here, $\kappa_{\text{stream}} > 0$ or < 0 indicates stream is a source or sink of CO₂, respectively when considering weathering reactions over 10⁵ to 10⁶ yr timescales (see Fig. 1).** The long record at Hubbard Brook shows that κ_{stream} is approaching κ_{rock} as the watershed recovers from acid rain. Gaps in the time series for Shale Hills occur when the autosampler tubing or stream froze.

3.6 Predicting CO₂ release or drawdown from rock chemistry

From the stream chemistry, we found that Shale Hills and East River are net neutral with respect to CO₂, and Hubbard Brook is a net sink (Table 1; Figure 5). In Table 1, the weathering fluxes are summarized as CO₂ fluxes (see SM section 2.2; Fig. S4), but the NMF results can also be used to calculate weathering losses for each mineral as described in SM 2.5 (Table S5). Although we do not explicitly discuss each of these **mineral-related** fluxes learned from NMF, **they have resulted in differences in composition of soil versus protolith**, and we can use soil chemistry therefore as an additional test of κ_{stream} : specifically, we compare κ_{stream} to the CO₂ flux recorded in the weathered

- Deleted: derived

profile as solid-phase chemistry. To do this, we calculate a CO₂ sequestration coefficient analogous to κ_{stream} but instead based on rock chemistry, κ_{rock} , by assessing soil and taking into account the fraction of base cations weathered, the fraction of base cations from carbonates, and the capacity of the bedrock to produce H₂SO₄:

$$\kappa_{\text{rock}} = \frac{1}{2}(\tau + \gamma_{\text{rock}} + \zeta_{\text{rock}}), \quad (3)$$

In effect, κ_{rock} is the time-integrated CO₂ sequestration coefficient recorded as the solid phase weathering products in units of mol CO₂/eq base cation. In eq. 3, τ is the mass transfer coefficient for base cations at the land surface (where $1-\tau$ equals the fraction of total base cations originally present in parent rock that remain in topsoil at land surface), γ_{rock} is the proportion of base cations in the bedrock associated with carbonate minerals, and ζ_{rock} is the acid generation capacity of the rock. The derivation of eq. 3 and description of each variable is more fully summarized in SM section 2.3. Briefly, γ_{rock} expresses the proportion of base cations in the parent rock that are associated with carbonate minerals (varies from 0 to 1 for 100% silicate protolith to 100% carbonate protolith). ζ_{rock} expresses the relative amount of (acid-generating) pyrite to base cations in the protolith (varies from 0 to 1.5 for catchments where 100% of weathering is CO₂-driven to catchments where 100% of weathering is H₂SO₄-driven, respectively). τ expresses the fraction of cations that have not dissolved away upon exposure at the land surface (varies from -1 to 0 for 0% cations remaining at land surface to 100% cations remaining, respectively). Negative κ_{rock} describes a lithology that has been net sequestering CO₂ over the duration of weathering, whereas positive κ_{rock} has been net releasing CO₂. Based on the chemistry of the bedrock and topsoil at each watershed, κ_{rock} is -0.08 ± 0.11 , 0.08 ± 0.17 , and -0.19 ± 0.11 for Shale Hills, East River, and Hubbard Brook, respectively (Tables 1, S4). Based on these values from observations of the solid weathering phases, Shale Hills and East River on net are CO₂ neutral (i.e., within error of 0), but Hubbard Brook has acted as a long-term CO₂ sink.

If the streams at each site today are acting just like the weathering recorded over the last tens of thousands of years in the solid-phase material and our assumptions about CO₂- versus H₂SO₄-weathering are correct, κ_{rock} should equal κ_{stream} . Here, we find that κ_{stream} (discharge-weighted average) for Shale Hills, East River, and Hubbard Brook are 0.01 ± 0.03 , -0.02 ± 0.02 , and -0.14 ± 0.01 respectively (Table 1, Fig. 5). For all sites, the stream chemistry shows similar values of CO₂ sequestration coefficient for the modern (stream timescale) compared to the time-integrated (soil timescale), i.e., $\kappa_{\text{stream}} \approx \kappa_{\text{rock}}$, consistent with Shale Hills and East River acting as CO₂ net neutral but Hubbard Brook as a CO₂ sink. In addition, at Hubbard Brook, it can be seen that acid rain has competed with CO₂ in weathering minerals, lowering the capacity of the rock to sequester atmospheric CO₂. Because our calculation of κ_{rock} does not include acid rain, we would expect acid rain would increase κ_{stream} relative to κ_{rock} , which is what we observe at Hubbard Brook. Hubbard Brook has only moved back to equivalency between the rock and stream record in recent years (2013-2016; Fig. 5F) as the system has recovered from acid rain. These comparisons also suggest that rock chemistry, which is much easier to analyze, can sometimes predict stream fluxes adequately.

By not requiring a priori assignments of endmembers, our machine learning model not only successfully reproduced source apportionments made in more traditional endmember analysis for streams, but also revealed new information about how watersheds work. At the same time, the method also solved some issues related to source apportionment for streams with time variations of large acid rain inputs. The approach documented that two carbonate-containing shale watersheds (Shale Hills, East River) are intermittent sources or sinks of CO₂ to the atmosphere but on net are neutral with respect to CO₂. In contrast, because it has no carbonate minerals, Hubbard Brook is a constant sink for CO₂ (Figs. 5 and S5). These observations were compared and confirmed by comparing stream chemistry to rock chemistry.

NMF also emphasized the importance of different water flowpaths in determining endmembers: the endmembers were not strictly defined by mineralogy but by patterns of subsurface flow that can be related to subsurface reaction zones. These flowpaths lead to patterns in stream water chemistry that were easily deciphered by our newly developed machine learning-based mixing model. In particular, for three streams, signals in the chemical variations were observed to reveal dissolution of the most reactive mineral in proximity to sulfide oxidation. Many watersheds have flowpaths distinguished by geochemical signatures from mineral reactions (Brantley et al., 2017) but we do not know these paths a priori when we investigate stream chemistry. Machine learning will be useful to model mineral reactions on broader spatial scales and will help constrain global weathering-related CO₂ dynamics because it can delineate endmembers without a priori assumptions.

Beyond these attributes, the machine learning approach also revealed other new attributes of weathering. In Shale Hills, we discovered that sulfate inputs from acid rain may not be exported completely for two decades, which impacts mass balance and weathering-related CO₂ dynamics. Although not discussed explicitly here, this decadal time-lag was also observed at Hubbard Brook. NMF also showed that Hubbard Brook, recovering from the impacts of acid rain, is only recently returning to its full potential as a CO₂-sequestering rock system. In other words, prior to acid rain, Hubbard Brook sequestered more CO₂ per mole of weathered bedrock than it does today. But acid rain dissolved some of the silicates with H₂SO₄, lowering the CO₂ sequestration capability of the watershed. NMF led us to discover this new attribute of acid rain, namely that it diminishes the capacity of a rock to sequester CO₂ at millennial timescales (Figure 1) by replacement of CO₂ by H₂SO₄ as a weathering agent. Regardless of the net CO₂ dynamic, we discovered that without considering sulfide oxidation or acid rain, the CO₂ weathering sink considered over 10⁵ to 10⁶ yr timescales is always overestimated.

Data Availability

Data used in analysis for this work can be found at the Susquehanna Shale Hills Critical Zone website

(http://www.czo.psu.edu/data_time_series.html), the Hubbard Brook data catalog

Deleted: (<https://criticalzone.org/shale-hills/data>),

900

(<https://hubbardbrook.org/d/hubbard-brook-data-catalog>), and in Wan et al. (2019) and in Winnick et al. (2017).

Codes used in the modeling are available upon request.

Author Contributions

SLB, TW, and ARS conceived the project. TW and ARS developed the codes for the model. SLB, XG, and ARS

905

interpreted the data and model outputs. All authors contributed in the preparation of the manuscript.

Competing Interests

The authors declare that they have no conflict of interest.
