Section 1 NMF Model

To employ NMF on limited datasets of stream chemistry, a bootstrapped data set was generated using a multivariate normal distribution of log-transformed stream water chemistries, similar to the procedure outlined in Lautz et al. (2014). The bootstrapped dataset matches the measured means of the log-transformed stream water chemistries and maintains covariation between analytes. A comparison between the measured and bootstrapped data sets can be seen in Fig. S2. All of the input features were normalized to values between 0 and 1 to not bias the model training to any one input feature. Next, the model was trained to the bootstrapped dataset using NMF algorithms in the python library scikit-learn (Pedregosa et al., 2011). Lastly, the trained model was applied to measured stream water samples to delineate mixing proportions.

The model results are sensitive to the random initiation of the H matrix (i.e., endmember chemistries) used in the training. To produce a more robust decomposition, the starting H matrix was randomly initiated 20,000 times. For each stochastic iteration, we used NMF to calculate optimal W and H matrices (Eq 1) and then filtered out any models with proportions that did not add to 1 ± 0.05 . Additionally, the fit of the model was evaluated from SSE:

$$SSE = \sum_m \left(\left(\frac{[X_m]}{[SO_4^{2-}]} \right)_n - \sum_p \alpha_p \left(\frac{[X_m]}{[SO_4^{2-}]} \right)_p \right)^2, \quad (S1)$$

Here, SSE is the sum of square errors, α_p is the sulfate mixing proportion of endmember p derived from the model, X is the element “ m ” (i.e., Ca, Mg, Na, K, and Cl), and brackets denote concentration. The subscript “ n ” refers to measured concentrations at timepoint “ n ” in the stream. Using eq. S1, we filtered out additional models that yielded poor fitting solutions following the procedure outlined in Torres et al. (2016). Here we define a reference SSE that is equal to the 5th percentile SSE for all the models for that sample and filtered out any models where the SSE was larger than the reference SSE. In other words, we kept only the 5th percentile of best fitting models for each sample. The remaining models were averaged and reported as the final result. Additionally, we calculate the standard deviation for the remaining samples to represent uncertainty in our modeling results and we propagate these errors throughout our calculations. This average number of valid models per sample after all filters were applied was 44 for Shale Hills, 104 for East River, and 55 for Hubbard Brook.

Section 2 Calculations

S2.1 Solute Fluxes

The time-averaged flux of each species, $Flux$, was calculated using values for concentration and discharge following an equation adapted from Moatar et al. (2013):

$$40 \quad Flux = \beta \frac{\sum_n [X]_n Q_n}{\sum_n Q_n} \bar{q} A^{-1},$$

(S2)

Here, $Flux$ has the units of $\text{mmol m}^{-2} \text{yr}^{-1}$, $[X]_n$ is the concentration of a weathering product in the stream (e.g., $X = \text{SO}_4^{2-}$, Ca^{2+} , Mg^{2+}) at timepoint n , Q_n is the discharge measured at timepoint n , \bar{q} is the mean annual discharge (i.e., sum of daily discharge measurements/number of daily discharge measurements), A is the basin area (Shale Hills =
45 $8.0 \times 10^4 \text{ m}^2$; East River = $8.5 \times 10^7 \text{ m}^2$; Hubbard Brook = $4.0 \times 10^5 \text{ m}^2$ (W3), $1.5 \times 10^5 \text{ m}^2$ (W6), $7.7 \times 10^5 \text{ m}^2$ (W7),
 $6.1 \times 10^5 \text{ m}^2$ (W8), $7.0 \times 10^5 \text{ m}^2$ (W9)), and β is a coefficient for unit conversions to $\text{mmol m}^{-2} \text{yr}^{-1}$ (i.e., $3.15 \times 10^{10} \text{ l s m}^{-3} \text{yr}^{-1}$) or to $\text{meq m}^{-2} \text{yr}^{-1}$ (i.e., $3.15 \times 10^{10} \text{ l s m}^{-3} \text{yr}^{-1}$ multiplied by species charge (meq/mmol)).

S2.2 Using Stream Chemistry to Calculate CO₂ Drawdown or Release

50 To calculate the fluxes of CO₂ drawdown or release from weathering, we identify 4 weathering reactions: 1) CO₂-driven weathering (CO₂-weathering) of silicates, 2) H₂SO₄-driven weathering (H₂SO₄-weathering) of silicates, 3) CO₂-weathering of carbonates, and 4) H₂SO₄-weathering of carbonates. From the NMF decomposition described above and in the main body of the manuscript, all of these reactions are constrained.

For example, NMF yields proportions of sulfate derived from each endmember (deep flow, shallow flow,
55 and sometimes medium-depth flow) for each sample. We can easily constrain the total concentration of base cations derived from carbonate minerals as the Ca and Mg concentrations in the deep weathering endmember for either of the two shale watersheds. The total concentration of base cations minus the base cations derived from carbonate minerals is the concentration of silicate-derived base cations. Field observations tell us that that carbonate and pyrite reaction fronts are co-located. We constrain H₂SO₄-weathering of carbonates (i.e., coupling of pyrite oxidation to
60 carbonate dissolution) using the concentration of sulfate in the deep weathering endmember from the NMF decomposition. We assume that all of the sulfate in the deep weathering endmember dissolves carbonate minerals. Any carbonate-derived base cations that are in excess of what could have been produced by the sulfuric acid in the deep weathering endmember are associated with CO₂-weathering of carbonates. Similarly, because there are no carbonate minerals in the shallow subsurface, we assume that all of the sulfuric acid associated with acid rain
65 dissolves silicate minerals. Any cations not associated with H₂SO₄-weathering of silicates we assume to be associated with CO₂-weathering of silicates. For Hubbard Brook, because there are no carbonate minerals, all of the sulfate is associated with the dissolution of silicate minerals.

For long-term CO₂ dynamics, we consider H₂SO₄-weathering of silicates and CO₂-weathering of carbonates to be CO₂ neutral, while CO₂-weathering of silicates sequesters CO₂ and H₂SO₄-weathering of carbonates releases
70 CO₂ (Fig. 1). We calculate the potential sequestration or release of CO₂ in a sample as 0.5 times the base cation concentration from CO₂-weathering of silicates (on a charge equivalent basis) minus the product of 0.25 times the base cation concentration from H₂SO₄-weathering of carbonates (on a charge equivalent basis) (Fig. 1). Next, we calculate the flux of CO₂ following eq. S2 in section S2.1.

75 S2.3 Rock CO₂ Calculation

Here we compare the bulk elemental composition of parent rock to topsoil and calculate the difference to determine if the system acted on net as a source or a sink of CO₂ over the weathering duration. The three most important factors are 1) the ratio of base cations in carbonates relative to silicates, 2) the ratio of acid-generating units of pyrite relative to total base cations in carbonates+ silicate minerals, and 3) the ratio of base cations still retained in regolith at the
 80 land surface relative to total base cations. This latter ratio is related to the chemical depletion factor, i.e., the relative ratio of loss of a component in a rock to chemical weathering versus total loss by physical + chemical weathering (Riebe et al. 2003). We note that for this calculation we do not include organic carbon. For (1), we define the carbonate/silicate factor, γ_{rock} , which is the proportion of base cations in the rock derived from carbonate minerals divided by the total base cations:

$$85 \quad \gamma_{rock} = \frac{2C_{Ca,carb} + 2C_{Mg,carb}}{2C_{Ca,Total} + 2C_{Mg,Total} + C_{Na,Total} + C_{K,Total}}, \quad (S3)$$

Here $C_{X,k}$ is the molar concentration of base cation ($X = Ca, Mg, Na, \text{ or } K$) in carbonates ($k = carb$) or in carbonate + silicate minerals ($k = Total$). Eqn. (S3) expresses γ_{rock} as proton equivalents/kg rock. Often, rather than using quantitative X-Ray Diffraction (XRD), inorganic carbon (IC) in the rock is measured via acid titration to determine the amount of carbonate in the rock. Therefore, equation S3 can be re-written in terms of IC as:

$$90 \quad \gamma_{rock} = \frac{2C_{IC}}{2C_{Ca,Total} + 2C_{Mg,Total} + C_{Na,Total} + C_{K,Total}}, \quad (S4)$$

Here, C_{IC} refers to concentration of inorganic carbon. By definition, γ_{rock} ranges from 0 (where all cations derive from silicates) to 1 (where all cations derive from carbonates). Likewise, $1 - \gamma_{rock}$ is the proportion of cations derived from silicate minerals.

95 When pyrite oxidizes it produces sulfuric acid that can dissolve carbonate and silicate minerals. This impacts CO₂ dynamics by either releasing CO₂ (H₂SO₄-weathering of carbonates) or by diminishing the silicate content of the rock (H₂SO₄-weathering of silicates), thereby diminishing the rock's capacity to sequester CO₂. Here, we define a new variable, ζ_{rock} , which is the acid generation capacity relative to the base cations in the rock expressed on a proton equivalents basis:

$$100 \quad \zeta_{rock} = \frac{4C_{py}}{2C_{Ca,Total} + 2C_{Mg,Total} + C_{Na,Total} + C_{K,Total}}, \quad (S5)$$

Here, the subscript *py* refers to pyrite (proton equivalents/kg rock). We multiply the concentration of pyrite (i.e., C_{py} ; mol/kg) by 4 (eq/mol) because 4 moles of acid are produced (as H₂SO₄) per mole of pyrite as shown in reaction S6.

105 Lastly, in many catchments, the bulk chemistry of parent rock is not indicative of the CO₂ sequestration because silicate minerals are kinetically slow to dissolve and they do not completely dissolve before the rock physically erodes. (Here we assume all carbonate minerals chemically weather away before exposure at land surface,

i.e. wet climates and non-karst terrains). The relative depletion of an element in a weathered rock with respect to the parent rock is easily calculated from the mass transfer coefficient, τ .

$$\tau_{i,j} = \frac{C_{j,weathered}C_{i,parent}}{C_{j,parent}C_{i,weathered}} - 1, \quad (S7)$$

110 Here, C is the concentration of a base cation (j) or an immobile element (i) in the parent or weathered rock. When τ at the top of the weathering profile is 0, the composition of the weathering material is the same with respect to base cations and immobile element i as the parent and none of the element has been lost to solution before being eroded away. When τ is -1, all of the element has been lost to solution and none is left to erode away.

115 Using the variables γ_{rock} , ζ_{rock} , and τ , we now define κ_{rock} , the long-term CO₂ sequestration coefficient of the rock.

$$\kappa_{rock} = \frac{1}{2}\tau_{silicate\ cations}(1 - \gamma_{rock}) - \frac{1}{2}\zeta_{rock}, \quad (S8)$$

Here, $(1 - \gamma_{rock})$ is the proportion of base cations associated with silicate minerals. We multiply this by 0.5 because 1 eq of CO₂ is sequestered per 2 eq of base cations weathered. If pyrite oxidation is coupled to carbonate dissolution, 2 eq of CO₂ are released per mole of pyrite in the rock. Based on our definition of ζ_{rock} , this is equivalent to $\frac{1}{2}\zeta_{rock}$. If 120 pyrite oxidation is coupled to silicate dissolution, then CO₂ sequestration is reduced by 2 eq of CO₂ per mole pyrite in the rock. Again, based on eq 8, this is equivalent to $\frac{1}{2}\zeta_{rock}$. Lastly, $\tau_{silicate\ cations}$ is the mass transfer coefficient for silicate cations at the land surface. It ranges from 0 (no silicate minerals dissolve) to -1 (all the silicate minerals dissolve).

125 Finally, noting that $\tau_{silicate\ cations}$ is generally not reported just for silicate mineral base cations, we must instead calculate it from τ , the mass transfer coefficient for total base cations in the bulk rock:

$$\tau = \tau_{silicate\ cations}(1 - \gamma_{rock}) + \tau_{carbonate\ cations}\gamma_{rock}, \quad (S9)$$

Again, we emphasize wet climates and non karst terrain and implicitly assume that all carbonates are fully dissolved at the land surface (i.e., $\tau_{carbonate\ cations} = -1$) to solve for τ :

$$130 \quad \tau_{silicate\ cations} = \frac{\tau + \gamma_{rock}}{(1 - \gamma_{rock})}, \quad (S10)$$

Now we substitute eq. S10 in eq. S8 and simplify to the final equation 2 from the main text:

$$\kappa_{rock} = \frac{1}{2}(\tau + \gamma_{rock} + \zeta_{rock}), \quad (2)$$

135 When $\kappa_{rock} < 0$, the rock has sequestered CO₂ over the weathering duration and when $\kappa_{rock} > 0$ the rock on net released CO₂.

Mathematically, this equation is only valid as long as $\tau < -\gamma_{rock}$. The minimum value of κ_{rock} is -0.5, which is a pure silicate rock dissolved only by CO₂. The maximum value of κ_{rock} is 0.25, which is a pure carbonate rock weathered only by sulfuric acid. It is mathematically impossible for $\kappa_{rock} < -0.5$; however, it is mathematically

possible to have $\kappa_{\text{rock}} > 0.25$. In these situations, there is more sulfuric acid in the system than can be buffered by both carbonate and silicate weathering.

2.4 Lag-time Calculation

Using rain chemistry data from the National Atmospheric Deposition Program (NADP; <http://nadp.slh.wisc.edu/>) site PA42, we calculated the annual flux of sulfate into Shale Hills from wet deposition. We used the flux data to calculate a trend in wet deposition over time and then used the regression to calculate when $39.5 \text{ mmol m}^{-2} \text{ yr}^{-1}$ was deposited (i.e., 31 years prior to today). Next we added dry deposition as an input (estimated as 30% wet deposition; Lynch and Corbett; 1989), fit a new regression to wet+dry deposition over time, and recalculated the lag time (i.e., 19 years; Fig. 3C). Although not explicitly calculated here, Hubbard Brook also shows a lag in deposition to export on similar timescales, which is consistent with the excess sulfate export observed in other studies (Likens et al., 2002).

2.5 Mineral-derived Solute Concentrations

The contributions of ankerite and calcite to the Ca^{2+} budget were calculated using the composition of the appropriate endmember (deep flowpath for SH and ER). Based on the stoichiometry of ankerite at Shale Hills and assuming all Mg^{2+} in this endmember derives from ankerite, the concentration of Ca^{2+} from ankerite in any given sample,

$[\text{Ca}^{2+}]_{\text{ankerite}}$, is calculated using the following equation.

$$[\text{Ca}^{2+}]_{\text{ankerite}} = 1.6 \left(\frac{\text{Mg}^{2+}}{\text{SO}_4^{2-}} \right)_{\text{deep}} \alpha_{\text{deep}} [\text{SO}_4^{2-}]_{\text{Total}},$$

(S11)

Here, $\text{Mg}^{2+}/\text{SO}_4^{2-}$ is the model-derived ratio of Mg to SO_4^{2-} from the deep weathering endmember for that sample (subscript deep), α_{deep} is the sulfate mixing proportion for the deep weathering endmember for that sample, $[\text{SO}_4^{2-}]_{\text{Total}}$ is the total concentration of sulfate in that sample, and 1.6 is the stoichiometric number relating Mg^{2+} to Ca^{2+} in Ankerite (see Table S2). The concentration of calcite-derived Ca^{2+} is calculated as the difference between the total Ca^{2+} and the ankerite-derived Ca^{2+} .

Similarly, the contributions of chlorite and illite to the Mg^{2+} budget were calculated using the composition of the appropriate endmember (shallow flowpath for SH). Based on the stoichiometry of illite at Shale Hills and

assuming all K^+ in this endmember derives from illite, the concentration of Mg^{2+} from illite in any given sample, $[\text{Mg}^{2+}]_{\text{illite}}$, is calculated using the following equation.

$$[\text{Mg}^{2+}]_{\text{illite}} = 0.28 \left(\frac{\text{K}^+}{\text{SO}_4^{2-}} \right)_{\text{shallow}} \alpha_{\text{shallow}} [\text{SO}_4^{2-}]_{\text{Total}},$$

(S12)

Here, $\text{K}^+/\text{SO}_4^{2-}$ is the model-derived ratio of K to SO_4^{2-} from the shallow weathering endmember for that sample (subscript shallow), α_{shallow} is the sulfate mixing proportion for the shallow weathering endmember for that sample, $[\text{SO}_4^{2-}]_{\text{Total}}$ is the total concentration of sulfate in that sample, and 0.28 is the stoichiometric number relating K^+ to Mg^{2+} in illite (see Table S2). The concentration of chlorite-derived Mg^{2+} is calculated as the difference between the

total Mg^{2+} , the ankerite-derived Mg^{2+} and the illite-derived Mg^{2+} . Fluxes of solutes derived from each mineral are summarized in Table S5.

175

Section 3 Seasonality of Pyrite-sulfate Fluxes:

At Shale Hills, the proportion of pyrite-derived sulfate leaving the catchment accounts for 23% of the annual sulfate flux (Table 1) but ranges up to 99% of total sulfate in the dry season (summer, fall) and to as low as 3% in the wet season (winter, spring, Fig. 3A). This is easily explained because the stream is sustained by deep groundwater that flows up into the stream from the deep pyrite reaction front during the dry summer and fall but not in the winter and less acid rain enters the catchment in the dry season (Li et al., 2017).
