10 **Abstract.** Temporal and spatial precipitation information is key to conducting effective hydrological process simulation and forecasting. Herein, we implemented a comprehensive evaluation of three selected precipitation products in the Jialing River Watershed (JRW) located in southwest China. A number of indices were used to statistically analyze the differences between two open-access precipitation products (OPPs), i.e. Climate Hazards Group Infra-Red Precipitation with Station (CHIRPS) and CPC-Global (CPC), and the rain gauge (Gauge). The three products were then categorized into sub-basins to drive SWAT

15 simulations. The results show: (1) the three products are highly consistent in temporal variation on a monthly scale, yet distinct on a daily scale. CHIRPS is characterized by overestimation of light rain, underestimation of heavy rain, and a high probability of false alarm. CPC generally underestimates rainfall of all magnitudes; (2) Both OPPs satisfactorily reproduce the stream discharges at the JRW outlet with slightly worse performance than the Gauge model. Model with CHIRPS as inputs performed slightly better in both model simulation and fairly better in uncertainty analysis than that of CPC. On a temporal scale, the

20 OPPs are inferior with respect to capturing flood peak, yet superior at describing other hydrograph features, e.g. rising and falling processes and baseflow. On a spatial scale, CHIRPS offers the advantage of deriving smooth, distributed precipitation and runoff due to its high resolution; (3) The water balance components derived from SWAT models with equal simulated streamflow discharges are remarkably different between the three precipitation inputs. The precipitation spatial pattern results in an increasing surface flow trend from upstream to downstream. The results of this study demonstrate that with similar

25 performances in simulating watershed runoff, the three precipitation datasets tend to conceal the identified dissimilarities through hydrological model parameter calibration, which leads to different directions of hydrologic processes. As such, multiple-objective calibration is recommended for large and spatial resolved watershed in future work. The main findings of this research suggest that the features of OPPs facilitate the widespread use of CHIRPS in extreme flood events and CPC in extreme drought analyses in future climate.

30 1. Introduction

Precipitation has been established as the most significant meteorological parameter with respect to forcing and calibrating hydrologic models; as its spatial–temporal variability considerably influences hydrological behavior and water resource availability (Galván et al., 2014; Lobligeois et al., 2014; Roth & Lemann, 2016). Previous studies have demonstrated that reducing precipitation data uncertainty has a sizeable impact on stabilizing model parameterization and calibration (Mileham et al., 2008; Cornelissen et al., 2016; Remesan & Holman, 2015). However, accurate portrayal of authentic basin rainfall inputs’ spatial–temporal variability has severe limitations (Bohnenstengel et al., 2011; Liu et al., 2017), and successfully acquiring such data from available resources has typically posed numerous challenges for hydrologic modeling (Long et al., 2016; Zambrano-Bigiarini et al., 2017).

Conventionally, hydrologists have regarded gauge measurements as actual rainfall (Zhu et al., 2015; Musie et al., 2019), and used point rainfall measurements from rain gauges to perform spatial interpolation and illustrate rainfall field in basin/sub-basin regions (Weiberlen & Benitez, 2018; Belete et al., 2019). Ideally, if rain gauges are positioned with reasonable density and uniform distribution, the spatial precipitation variation described by this method is still valid (Duan et al., 2016). However, in remote or developing regions, the meteorological stations are usually scarce and irregularly distributed, resulting in inconsistent and erroneous distributed rainfall field (Hwang et al., 2011; Peleg et al., 2013; Cecinati et al., 2018; Luo et al., 2019). In other cases, when data observation is accidentally missing, the data quality might be unreliable (Alijanian et al., 2017; Sun et al., 2018). These challenges make ground-based precipitation measurements subject to large uncertainties for driving and calculating hydrologic models.

Over the last few decades, open-source precipitation products (OPPs) have provided a promising alternative for detecting temporal and spatial precipitation variability (Qi et al., 2016; Jiang et al., 2018; Jiang et al., 2019). A variety of studies have demonstrated the accuracy differences among the various OPPs, as well as within the same OPP among different regions (Gao et al., 2017; Zambrano-Bigiarini et al., 2017; Lu et al., 2019; Wu Y et al., 2019). Sun et al (2018) evaluated and compared the advantages and disadvantages of 29 OPPs with different spatial and temporal resolutions with respect to their ability to describe

global precipitation. Unlike most OPPs with a spatial resolution of $0.25^{\circ}\sim 0.5^{\circ}$, the Climate Hazards Group Infra-Red Precipitation with Station (CHIRPS), a “satellite-gauge” type precipitation product, provides very fine spatial resolution (Funk et al., 2015), with 0.05° being equivalent to a resolution of one gauge station for every 30.25 km^2 area. This characteristic has facilitated widespread use and consistent admiration of CHIRPS in recent years. Duan Z et al. (2019) evaluated three precipitation products in Ethiopia and found that CHIRPS performed best among them; Lai et al. (2019) used PERSIANN-CDR and CHIRPS driven hydrological simulation in the Beijiang River basin of China, and determined that CHIRPS performed significantly better than the PERSIANN-CDR. The Climate Prediction Center Gauge-Based Analysis of Global Daily Precipitation (CPC-Global) is a unified precipitation analysis product from the National Oceanic and Atmospheric Administration (NOAA) Climate Prediction Center (CPC) (Xie et al., 2007) that contains unified precipitation data collected from $> 30,000$ monitoring stations belonging to the WMO Global Telecommunication System, Cooperative Observer Network, and other national meteorological agencies. The product was created using the optimal interpolation objective analysis technique and the data is considered to be relatively accurate. Tian et al. (2010) used CPC as reference data to evaluate the applicability of GSMaP in the United States; and Beck et al. (2017) used CPC to modify the MSWEP data product they built. Marked differences have been found in the accuracy and spatio-temporal patterns of different precipitation datasets, which highlights the critical importance of dataset selection for both scientific researchers and decision makers.

The hydrological model or rainfall-runoff model is an important tool for understanding hydrological processes and aids water resources operation decision-makers (Yilmaz et al., 2012; Yan et al., 2016; Wu J et al., 2019). Most frequently used hydrologic models have been shown to efficiently incorporate data from rain gauges, while open-access precipitation has also been continuously improved and adopted into different modules that evaluate its performance in simulating watershed runoff (Bhuiyan et al., 2019; Solakian et al., 2019). Among all the various existing hydrologic models, the Soil & Water Assessment Tool (SWAT) is widely employed by the scientific community and others interested in watershed hydrology research and management (Price et al., 2013; Wang et al., 2017; Li et al., 2018; Qiu et al., 2019). ~ 4000 peer-reviewed papers in reputable academic journals worldwide (SWAT literature database, from 1984 to 2020) have used SWAT modeling results to support their scientific endeavors. Moreover, a new version (SWAT+) is currently in development that will provide a more flexible

spatial representation of interactions and processes within a watershed (Volk et al., 2009; Gabriel et al., 2014; Ayana et al., 2015; Jin et al., 2018). As mentioned above, numerous researchers concur that designing accurate watershed models requires realistic depiction of temporal and spatial precipitation variability. Huang et al. (2019) used hourly, sub-daily, and diurnal precipitation data to simulate runoff from Baden-Württemberg state in Germany and found a positive correlation between higher rainfall temporal resolution and model performance. As such, hydrological processes simulated by the SWAT model, that were based on environmental data lacking accurate regional precipitation distribution figures, will unquestionably be faulty and unreliable. For example, Lobligeois et al. (2014) used rain-gauge measurements (2,500 stations within an area of 550,000 km²), and Weather radar network data with a spatial resolution of 1km, to simulate runoff from France. Their results clearly showed that the higher resolution radar data significantly improved the simulation accuracy.

To date, the effect of combined ground-based and satellite-based precipitation estimates on streamflow simulation accuracy is not well understood, particularly when the data covers a variety of temporal and spatial resolutions. Hence, this study aims to elucidate these unknowns. More importantly, hydrologic models are expected to describe internal hydrologic processes and subsequently present a unique interpretation of the water balance components (Pellicer-Martínez et al., 2015; Tanner & Hughes, 2015; Wang et al., 2018); yet very limited studies have been conducted to investigate the effects of temporal and spatial resolution on hydrologic processes or water balance components. Thus, this fundamental issue must be addressed before hydrologic modeling with open-access precipitation datasets can be utilized at maximum capacity; as without a thorough understanding of the water cycle's inner processes, the hydrologic models may be highly misleading and facilitate inappropriate management decisions. Bai & Liu (2018) used a HIMS model to simulate the runoff driven by CHIRPS, CMORPH, PERSIANN-CDR, TMPA 3B42, and MSWEP at the source regions of the Yellow River and Yangtze River basins in the Tibetan Plateau. They reported that parameter calibration significantly counterbalanced the impact of diverse precipitation inputs on runoff modeling, resulting in substantial differences in evaporation and storage estimates. Their research helps enhance our understanding of how water balance components are impacted by precipitation data and hydrologic model parameters. However, evidence for water balance component variations under the influence of different precipitation inputs

100 has not been fully investigated. In this study, we aimed to verify the ability of CPC-global and CHIRPS to accurately simulate watershed runoff, and analyze how different OPP characteristics modify the hydrological processes simulation.

The Yangtze River is the largest river in China. Its upper segment is home to its primary tributary with the largest drainage area—the Jialing River, which exhibits spatial heterogeneity with respect to climate, geomorphologies, and land cover conditions. Over the past six decades, anthropogenic activity in conjunction with climate change have substantially reduced the drainage basin's streamflow (Meng et al., 2019), which significantly impacts the inflow condition of the three Gorge reservoir. Therefore, it is debatably imperative to elucidate how varying rainfall characteristics impact runoff and hydrological processes in the Jialing River Watershed (JRW), especially in spatio-temporal dimensions. Given the above considerations, herein, we attempt to: (1) statistically quantify the differences of ground-based and typical open-source precipitation datasets in the JRW, (2) evaluate the performances of different precipitation datasets in simulating the watershed streamflow using SWAT, and (3) investigate the potential behaviors of different precipitation dataset in describing hydrologic processes. All of the above objectives were analyzed on temporal and spatial scales. The goal of this study was to surpass an accuracy assessment of rainfall estimates, and evaluate the use of diverse precipitation data types as model operation forcing data and in hydrologic process portrayal.

2. Materials and methods

115 2.1. Study area

The Jialing River is the primary tributary of the Yangtze River, with the largest drainage area of 159,812 km² and a total length of ~1345 kilometers. The JRW is situated between 29°17'30" N and 34°28'11" N and 102°35'36" E and 109°01'08" E and geographically extends over the northern part of the transition zone under the eastern Tibet Plateau. The JRW's elevation difference is ~5000 m and the average gradient is ~ 2.05 %. Due to the sharply changing topographic gradients, the area features northwest highlands, northern mid-low mountains, middle-eastern hills, and southern plains (Fig. 1). The hydrometeorological conditions follow a similar spatial distribution pattern, i.e., relatively colder and drier in the north and

warmer and wetter in the south (Meng et al., 2019). The long-term annual precipitation, based on records from 1956–2018, ranges from ~ 900 to 1200 mm, a product of southwest China’s warm, low latitude air. The rainfall is mainly concentrated from May to September, which accounts for about 60% of the annual precipitation. The annual average temperature ranges from 4.3 to 27.4°C, and the annual average actual evapotranspiration (ET) ranges from 800 to 1000 mm. The daylight duration is ~1890 h/year, with an annual wind speed of 0.7 ~ 1.8 m/s. Annual relative humidity ranges from 57 to 79 % (Herath et al., 2017). The controlled hydrologic Beibei station is gauged at the JRW outlet, and the long-term mean annual runoff is ~ 6.55 × 10⁸ m³ year⁻¹, according to the Changjiang Sediment Bulletin. The Digital Elevation Model (DEM), river network, and meteorological stations are shown in Fig.1.

2.2. Data sources

The data required for SWAT modeling and validation consisted of geographic information, meteorological, and hydrological datasets.

2.2.1 Geographic information dataset

The Geographic dataset included the DEM, land use and land cover data (LULC), and soil properties. SRTM 90 m resolution data was the DEM used in this study and was provided by the Geospatial Data Cloud (<http://www.gscloud.cn/>). LULC data was obtained by manual visual interpretation based on 2010 Landsat TM/ETM remote sensing images, which were preprocessed by Beijing Digital View Technology Co., Ltd, with a spatial resolution of 30 m. The data included six primary classifications—cultivated land, woodland, grassland, water area, construction land, and unused land, as well as 25 secondary classifications. After checking the quality of data products by combining field survey and random sampling dynamic map spots for repeated interpretation analysis, it is proved that the cultivated land’s classification accuracy was 85 %, and other data classification accuracies reached 75 %. The soil data included a soil type distribution map and soil attribute database. The soil type distribution map is a product of the second national land survey provided by the Nanjing Institute of Soil Research, Chinese Academy of Sciences. It depicted a spatial resolution of 1 km and used the FAO-90 soil classification system.

Harmonized World Soil Database v1.2, which was provided by the Food and Agriculture Organization (FAO), was the soil attribute database used in this study and can be downloaded from <http://www.fao.org/land-water/databases-and-software/hwsd/zh/>. Most soil attribute data can be obtained directly from HWSD v1.2, such as soil organic carbon content, soil profile maximum root depth, and soil concrete gradation, etc. Parameters that cannot be directly obtained from the HWSD, e.g., texture class, matrix bulk density, field capacity-wilting point, and saturation hydraulic coefficient, can be calculated from the acquired data using the Soil-Air-Water Field & Pond Hydrology model developed by Washington State University. All the above geographic information data were processed by ArcMap 10.2 to obtain 250 m spatial resolution data of the JRW, using the Beijing_1954_GK_Zone_18N Projection coordinate system and GCS_Beijiing_1954 Geographic coordinate system.

2.2.2 Meteorological and hydrological dataset

Daily observed discharges are documented from 1997–2018 at Beibei hydrological station. The daily meteorological records—including precipitation, temperature, relative humidity, sunshine hours, and wind velocity, were measured by 20 meteorological stations in and around the JRW, which were provided by the China meteorological data network (<http://data.cma.cn/>). The solar radiation data required for establishing the meteorological database was calculated using the sunshine hours (n), and the calculation method consisted of employing the solar radiation (R_s) index in the FAO-56 Penman-Monteith method.

The first gridded format CHIRPS product was released in February 2015, which has first recorded in 1981 and continues to be updated. The dataset provides daily precipitation data with a spatial resolution of 0.05° in a pseudo-global coverage of 50° N - 50° S. The data is available for download at <http://chg.geog.ucsb.edu/data/chirps/>. The CHIRPS product is composed of various types of precipitation products, including ground measurement, remote sensing, and reanalysis data—e.g. The Climate Hazards Group Precipitation Climatology (CHPclim) is built from monthly precipitation data supplied by the United Nations FAO, Global Historical Climate Network (CHCN), Cold Cloud Duration from NOAA, and TRMM 3B42 Version 7 from NASA, etc. Essentially, the above-mentioned data were synthesized into 5-day rainfall records, and then the rain gauge

observations from multiple data sources were used to correct the deviation, which was further interpolated to daily scaled CHIRPS product. More detailed information about CHIRPS products is available in Funk et al. (2015).

CPC-Global, in gridded format, is the first generation product of NOAA's ongoing CPC unified precipitation project. This product offers daily precipitation estimates from 1998 to the present, at a spatial resolution of 0.5° over land. Daily precipitation data for CPC-Global can be downloaded from: http://ftp.cpc.ncep.noaa.gov/precip/CPC_UNI_PRCP/GAUGE_GLB/V1.0/. This dataset integrates all existing CPC information sources and employs the optimum-interpolation objective analysis technique to form a set of cohesive precipitation products with consistent quantity and enhanced quality. The data was collected from > 30,000 monitoring stations belonging to the WMO Global Telecommunication System, Cooperative Observer Network, and other national meteorological agencies (Xie et al., 2007). For the sake of brevity, the CPC-Global data is referred to as CPC in this article, and the corresponding SWAT model is denoted as the CPC model.

In the SWAT model, all meteorological data were categorized into sub-basins according to the "nearest distance" principle. As such, for the point-formatted gauge observations, a SWAT sub-basin will read the precipitation records from the weather station that is closest to its centroid. Similarly, for the grid-formatted estimates, i.e. CHIRPS and CPC, a SWAT sub-basin will read the precipitation observations from the grid that is closest to its centroid. Using this method, the grid records of high-resolution CHIRPS products within the same sub-basin will be uniformly assigned the grid value closest to the centroid, which will offset the high resolution advantage of CHIRPS products. In order to incorporate the advantages of CHIRPS' spatial resolution and the SWAT model's effectiveness when using the other two products, we selected 400 sub-basins, so that the number of effective CHIRPS is ~ 20 times greater than that of the Gauge and CPC. Note that all of the precipitation statistics in this study are based on the sub-basin scale, which ensures that the precipitation data was correctly categorized in the SWAT model.

2.3. Statistical analysis method

The following indices were selected to statistically compare the three precipitation products:

(1) *CC* value. The correlation coefficient (*CC*) is a numerical measure (ranging from -1 to 1) of the linear statistical

190 relationship between two variables, e.g., simulations and observations, with respect to strength and direction. The closer the absolute value of *CC* to 1, the higher the correlation between simulation and observation. *CC* is mathematically expressed as follows:

$$CC = \frac{\sum_{i=1}^n (Q_i - \bar{Q})(S_i - \bar{S})}{\sqrt{\sum_{i=1}^n (Q_i - \bar{Q})^2} \sqrt{\sum_{i=1}^n (S_i - \bar{S})^2}}, \quad (1)$$

Where *n* is the number of the time series; Q_i and S_i are measured values and estimated values, respectively; and \bar{Q} and \bar{S}

195 are the mean values of the measured and estimated values, respectively. The value may refer to either precipitation (mm) or streamflow discharge (m^3/s).

(2) *STD* value: Standard deviation (*STD*) represents the discretization degree of the datasets (mm). The *STD* of Gauge

observations is used to normalize the OPPs' *STD*, and denoted as STD_n to compare the dispersion of OPPs relative to Gauge.

The STD_n values range from 0 to ∞ , and the optimal value is 1. The STD_n value is mathematically expressed as follows:

$$STD = \sqrt{\frac{1}{n} \sum_{i=1}^n (S_i - \bar{S})^2}, \quad (2)$$

$$STD_n = STD_{OPP} / STD_{Gauge}, \quad (3)$$

Where STD_{OPP} and STD_{Gauge} are the *STDs* of OPPs and Gauge, respectively.

200 (3) *RSR* value: observations standard deviation ratio (*RSR*) is an error index statistic between the OPPs and Gauge datasets.

Root mean square error (*RMSE*) divided by *STD* values would derive the *RSR* value. *RSR* has a range from 0 to ∞ with 0 as the optimal value. The calculation equation is expressed as follows:

$$RSR = \frac{RMSE}{STD} = \frac{\sqrt{\sum_{i=1}^n (S_i - Q_i)^2}}{\sqrt{\sum_{i=1}^n (S_i - \bar{S})^2}}, \quad (4)$$

(4) *POD* value: Probability of detection (*POD*) is a ratio that reflects the number of times OPPs correctly detected the

frequency of rainfall relative to the total number of rainfall events. *POD* has a range from 0 to 1, and an optimal value of 1. It

205 is mathematically expressed as follows:

$$POD = \frac{t_H}{t_H + t_M}, \quad (5)$$

Where t is the number of qualified data pairs; H denotes when the Gauge and OPPs both detect a rainfall event; and M represents when Gauge detects a rainfall event, but the OPPs do not.

(5) *FAR* value: False-alarm rate (*FAR*) represents the frequency that precipitation is detected using OPPs, but not detected using Gauge. *FAR* has a range from 0 to 1, and an optimal value of 0. The *FAR* value is mathematically expressed as

210 follows:

$$FAR = \frac{t_F}{t_H + t_F}, \quad (6)$$

Where F denotes that the OPPs detected a rainfall event, while the Gauge does not.

2.4. Hydrological model

2.4.1 SWAT description

The process-based SWAT model is an all-inclusive, temporally uninterrupted, and semi-distributed simulation that was developed by the Agricultural Research Service of the United States Department of Agriculture (Arnold et al., 1998; Arnold & Fohrer, 2005). The model's smallest simulation unit is the Hydrological Response Unit (HRU). Fields with a specific LULC and soil, which may be scattered throughout a sub-basin, are lumped together in one HRU. The model assumes that there is no interaction between HRUs in any one sub-basin. According to the water balance cycle, the HRU hydrologic process is first calculated and then summed to obtain the total hydrologic process of the sub-basin (Arnold et al., 1998; Arnold et al., 2012).

220 Water balance, including precipitation, surface runoff, actual evapotranspiration, infiltration, lateral and baseflow, and percolation to shallow and deep aquifers, is mathematically expressed as follows:

$$SW_t = SW_0 + \sum_{i=1}^t (P - Q_{surf} - ET - W_{seep} - Q_{lat} - Q_{gw}), \quad (7)$$

Where, SW_t is the soil's water content at the end of period t (mm); SW_0 is the soil water content at the beginning of period t (mm); and t is the calculation period length. P = precipitation; Q_{surf} = surface runoff; ET = actual evapotranspiration; W_{seep} =

the amount of percolation and bypass flow exiting the soil profile bottom; Q_{lat} = lateral flow, and Q_{gw} = baseflow, including
225 return flow from the shallow aquifer (GW_Q) and flow out from the deep aquifer (GW_Q_D)—all on day i in (mm).

Surface runoff, lateral flow, and baseflow add up to Water Yield (WYLD). SWAT uses the Soil Conservation Services-
Curve Number method (SCS-CN) to simulate surface runoff. Surface runoff is mathematically expressed as follows:

$$\frac{F}{S} = \frac{Q_{surf}}{P - I_a}, \quad (8)$$

Where I_a is the initial loss (mm)—i.e., precipitation loss before surface runoff; F is the final loss— i.e., precipitation loss
after surface runoff is generated; S is the maximum possible retention in the basin at that time (mm), and is the upper limit of
230 F .

The WYLD from the sub-basin forms in the connected channel network, then, through routing water processes, enters
the downstream reach segment and repeats the water balance process, eventually converging at the drainage outlet. This is the
watershed hydrological process simulated in SWAT that is shown in Fig. 2.

2.4.2 SWAT calibration and validation

235 In this study, the period of calibration and validation are set for 1999-2008 and 2009-2018, respectively. The two years
before both the calibration and validation periods are delineated as the warmup phase for the purpose of initializing model
state variables, e.g., soil moisture and groundwater concentration. The model is automatically calibrated using the Sequential
Uncertainty Fitting algorithm version 2 (SUFI-2) in the SWAT- Calibration and Uncertainty Program (SWAT-CUP). This
algorithm has been successfully applied in many related studies (Abbaspour et al., 2017; Shivhare et al., 2018; Tuo et al., 2018).
240 The model parameters and the initial calibration range are shown in Table 1. The parameters were selected based on literature
published by Arnold et al. (2012) and Tuo et al. (2016) and the official manual. In order to consider the impact of elevation on
precipitation and the fact that precipitation in the OPPs is horizontal, we introduced the Precipitation Lapse Rate (PLAPS)
parameter and divided each sub-basin into 10 Elevation Bands. Tuo et al (2016) demonstrated that this method is able to correct
the rainfall error caused by ignoring elevation and effectively improve the model's simulation performance. Furthermore, the
245 models were calibrated following three iterations of 1000 times each. Following each iteration, the SWAT-CUP generated a

fresh set of parameter ranges. This new set was used for the next iteration after considering the upper and lower bounds of the physical meaning. The above method was repeated for the three different precipitation data sets. The Nash efficiency coefficient (*NSE*) was used as the objective function to optimize the model calibration, and is mathematically expressed as follows:

$$NSE = \frac{\sum_{i=1}^n (S_i - Q_i)^2}{\sum_{i=1}^n (Q_i - \bar{Q})^2}, \quad (9)$$

250 The model performance was classified using *RSR*, *NSE*, and percentage bias (*PBIAS*) values defined by Moriasi et al. (2007), which is shown in Table 2. Parameter ranges of the three models after 3000 iterations are shown in Table 3. *CC*, *NSE*, *PBIAS* and *RSR* were used to evaluate the model simulation results.

PBIAS describes the OPPs' systematic bias (%). *PBIAS* ranges from 0 to $+\infty$ %, and the optimal value is 0 %. The calculation equation is expressed as follows:

$$PBIAS = \frac{\sum_{i=1}^n (S_i - Q_i)}{\sum_{i=1}^n Q_i} \times 100\%, \quad (10)$$

255 The quality of model input data and the parameterization process increase the uncertainty risk associated with the model results, which has been identified in the application of SWAT (Thavhana et al., 2018; Tuo et al., 2018; Zhang et al., 2020). There are two factors, *p-factor* and *r-factor*, which are used for uncertainty analysis in SUFI-2 algorithm of SWAT CUP. *p-factor* refers to the percentage of the measured data distributed within the 95% prediction uncertainty (95PPU) band of the model results (%), and the *r-factor* graphically means the average thickness of the 95PPU band divided by *STD* of the measured records (Abbaspour, 2017). Theoretically, *p-factor* ranges from 0 to 100% and takes 100% as the optimal value, and *r-factor* ranges from 0 to ∞ and takes 0 as the optimal value. It should be noted that the increase in the *p-factor* comes at the expense of the increase in the *r-factor*. It was stated in the study of Roth & Lemann (2016) that combined values of *p-factor* > 70% and *r-factor* < 1.5 are preferably uncertainty range, which is also referred to in this paper.

260

3. Results

3.1. Evaluation of the OPPs on a temporal scale

3.1.1. Monthly scale

A comparison of the monthly precipitation time series (Gauge, CHIRPS, and CPC) across the watershed is shown in Fig. 3. Note that the time series in Fig. 3 represents the average value of the whole watershed and was calculated as follows: the original point or grid formatted rainfall records were first categorized into every SWAT model sub-basin, according to the nearest distance principle, and then spatially synthesized into one time series by sub-basin area using the weighted average method. Fig. 3 shows that the rainfall values in the rainy season (especially in July) captured by Gauge are higher than those of CHIRPS and CPC. Moreover, the CC values between CHIRPS and Gauge records, as well as CPC and Gauge records, are 0.97 and 0.98 ($P < 0.01$, i.e., extremely significant positive correlation), respectively. The high CC values demonstrate the highly correlated linear relationship between the two OPPs and Gauge records on a monthly scale, indicating that both CHIRPS and CPC products are equally as effective at describing the monthly precipitation variation within the JRW as the Gauge records.

The box diagrams of the three precipitation records are shown in Fig. 4. Note that July is the largest contributor to the yearly precipitation, as well as the annual flood peak calculation. According to the July results, when compared with Gauge records, the CHIRPS product has a large median, small maximum, and large minimum, while the three CPC values are all smaller than the Gauge values. These characteristics will potentially lead to different hydrological modeling in flood peak simulation. The STD_n values for Gauge-CHIRPS and Gauge-CPC are 1.06 and 0.94, respectively. The RSR values for Gauge-CHIRPS and Gauge-CPC are 0.27 and 0.22, respectively. These statistics indicate that both CHIRPS and CPC estimates are able to provide equally effective precipitation values compared with that of the Gauge records. Nevertheless, $PBIAS$ values of Gauge-CHIRPS and Gauge-CPC were 9.58 % and -6.70 %, respectively, indicating the overestimation of CHIRPS products and underestimation of CPC products compared with that of the Gauge records. Specifically, overestimation of the CHIRPS products mainly occurs between April and September, which is the JRW rainy season; while during the dry season, i.e., October

- March, the CHIRPS estimates are closely consistent with the Gauge records. In contrast, the CPC estimates parallel the Gauge records for the rainy season, yet rainfall is underestimated during dry season.

3.1.2. Daily scale

Intensity and frequency are the most critical parameters for characterizing rainfall features on a daily scale (Azarnivand et al., 2019; Wen et al., 2019). The scatter plots in Fig. 5 depict a precipitation intensity comparison between the OPPs and Gauge records, at a daily scale, at Beibei hydrological station (NO.411). Based on Fig. 5, the angle between the CHIRPS' 95 % line estimates and the horizontal axis is > 45 degrees (the 1:1 line), indicating that CHIRPS overestimates precipitation relative to the Gauge records. CPC estimates demonstrate the exact opposite. More specifically, the scatter distribution indicates that compared to the Gauge records, the CHIRPS' estimates tend to overestimate precipitation for light rains, and underestimate it for heavy rains. Meanwhile, the CPC products underestimate both light and heavy rains. Statistically, the CC , STD_n , and RSR values between CHIRPS and the Gauge records are 0.53, 1.14, and 1.04, respectively, and 0.64, 0.87, and 0.80, respectively, between the CPC and Gauge products. At the daily scale, the OPPs and Gauge products showed an evident decrease in consistency when compared with the monthly scale. The above indicators demonstrate the decreased consistency of the OPPs' estimates and Gauge observations; while the CPC shows superior performance relative to the CHIRPS.

The three precipitation products' cumulative daily precipitation intensity frequencies are shown in Fig. 6. Note that on the right side of the figure, the 50 mm/day demarcation divides the horizontal axis into two sections of rainfall intensity, in order to depict the three products' frequency trends more clearly. Overall, the three products display a high probability of occurrence for precipitation intensity of 0.1~25 mm/day—87 %, 94 %, and 98 % for CHIRPS, Gauge, and CPC, respectively. However, the probability for precipitation intensity > 100 mm/day is 99.70 %, 99.73 % and 99.99 %, respectively, indicating the potential upper limit extreme rainfall event value within this area. The CPC product fails to detect extreme rainstorm events.

Table 4 is the recognition capability evaluation of the two OPPs for rainfall intensity between 0.1 and 50 mm and > 50 mm events. The CPC and CHIRPS POD values for rainfall intensity between 0.1 and 50 mm are 83.53 % and 27.29 %, respectively, demonstrating that the CPC product has a strong ability to capture the onset of rainfall. Nevertheless, the CPC

310 *POD* value for rainfall intensities ≥ 50 mm decreases to 9.42 %, indicating its poor ability to capture rainstorms, while that of the CHIRPS product is relatively higher, with a *POD* value of 18.12 %. Moreover, the *FAR* fractions for both OPPs are between 44 % and 66 %, demonstrating its lower ability to detect rainstorm values.

3.2. Evaluation of OPPs on a spatial scale

315 Spatial variations of the three products' long-term mean annual precipitation, for all of the partitioned sub-basins, are shown in Fig. 7. The three products' precipitation values exhibit an obvious upward trend from the JWR's upstream to downstream region. The precipitation's shifting pattern in space highly correlates with the topography variation (shown in Fig. 1), indicating that meteorological and hydrologic variables throughout the region are potentially influenced by and respond to catchment landscape modification. It should be noted that in Fig. 7(a), all the sub-basins are divided into several regions, each of which has the same rainfall value, while abrupt rainfall value changes occurred between adjacent regions. In Fig. 7(c), the transition between adjacent sub-basins is smoother than that observed with Gauge. In Fig. 7(b), the CHIRPS product shows 320 the smoothest precipitation transition between the adjacent sub-basins, illustrating the advantages of the high resolution CHIRPS product. In this study, precipitation records from 20 rain gauge stations, 411 CHIRPS grids, and 76 CPC grids were categorized into the SWAT sub-basins (as mentioned in section 2.3), leading to differences in the continuity or smoothness of rainfall spatial distribution among the three products. Compared with the Gauge observations, the overall precipitation values estimated by the CHIRPS are relatively higher, while that of the CPC is relatively lower.

325 The *CC*, *STD_n*, and *RSR* values of precipitation spatial distribution between CHIRPS and Gauge are 0.89, 0.96, and 0.55, respectively, and 0.82, 0.87, 0.62 between CPC and Gauge, respectively. These statistics indicate that both CHIRPS and CPC estimates can describe the spatial distribution of precipitation in JRW, among which CHIRPS depicts better performance. The correlation coefficients between the Gauge and OPPs at monthly or daily scales for every sub-basin are illustrated in Fig. 8. Overall, the monthly scale *CC* values (with a rang of 0.7~1) are comparably larger than that of the daily scale values (with a 330 rang of 0.5~0.7). Spatially, the higher *CC* values between the Gauge and CPC at the monthly scale are mainly distributed in areas with comparably low or high rainfall amounts, such as Wudu and Wangyuan. Yet, the *CC* value was less relevant in areas

with moderate rainfall (e.g., Suining) relative to that of the Gauge and CHIRPS. However, at the daily scale, the correlation of Gauge and CPC is higher than that of Gauge and CHIRPS, except for a few individual sub-basins located in the east-south area.

335 3.3. Hydrological performance of different precipitation products in the SWAT model

3.3.1 Spatio-temporal performance at a monthly scale

OPPs ignores terrain differences when forcing the model, which may increase potentially systematic errors in hydrologic modeling (Tuo et al., 2016). Thus, in this work, elevation bands (see Sect. 2.4.1) were used to normalize precipitation at different elevations. The monthly observed runoff and simulated runoff subjected to this procedure, and used for the SWAT
340 model during the calibration and validation periods, are presented in Fig. 9. The results show that the three precipitation inputs successfully stimulated the model to reproduce the discharge records at the Beibei station; the rising and falling simulated flood event processes are in good agreement with that of the observed ones. Based on the model performance classification scheme designed by Moriasi et al. (2007), Gauge and CHIRPS achieved “very good” performance for both the calibration and validation periods, although the Gauge model attained the highest *NSE* (0.92 for calibration and 0.87 for validation) values
345 and lowest *RSR* (0.28 and 0.36) values, while CPC only reached the level of "Good" due to higher *PBIAS* (10.8 %) (Fig. 9). Further, among all the three models, the model with Gauge inputs performed best in uncertainty analyses (*p-factor* = 98%, *r-factor* = 0.86 for calibration and *p-factor* = 92%, *r-factor* = 0.78 for validation), which is followed by the model using CHIRPS as input (*p-factor* = 84%, *r-factor* = 0.88 and *p-factor* = 83%, *r-factor* = 0.80). Using CPC datasets as precipitation inputs
350 resulted in the highest degree of uncertainty level (*p-factor* = 57%, *r-factor* = 0.57 and *p-factor* = 57%, *r-factor* = 0.53), which fails to reach a preferable level. The underestimation of the peak flows during flood seasons (June to August), would be the main reason of the slightly worse performance of the two OPPs inputs. The Gauge model demonstrates the best performance, which may reflect its strong ability to ascertain the peak rainfall during the flood seasons (Fig. 4). Note that in Fig. 4, the CHIRPS medians are larger than that of the Gauge, while the maxima are smaller, and the minima are larger during the flood seasons. These features facilitated the best performance for describing the baseflow and medium floods, like those in years

355 2003 and 2014. As a result, the CHIRPS model achieved the best simulation baseflow; although it overestimated the precipitation with light rain intensity, and obviously overestimated the streamflow with discharge < 6000m³/s, which also led to its final performance deviation. CPC showed significant overestimation in 2017 and 2018 during the validation period. Although it approximated CHIRPS' estimated results, it clearly deviated from its previous tendency to underestimate precipitation during these two years.

360 In terms of simulated WYLD spatial variation at the sub-basin scale (as shown in Fig. 10), the consistency of the Gauge and CHIRPS models is slightly better than that of the CPC model, potentially demonstrating the advantage of the CHIRPS' high resolution in simulating precipitation. Furthermore, the WYLD distribution pattern is highly consistent with the corresponding precipitation distribution (Fig. 7). The spatial correlation between WYLD and precipitation for rainfall for the Gauge, CHIRPS, and CPC products reached 0.85, 0.84, and 0.91, respectively. Compared to the Gauge simulation, the
365 CHIRPS overestimated and the CPC underestimated the WYLD. The *PBIAS* values for Gauge-CHIRPS and Gauge-CPC are 5.85 % and -5.38 %, respectively.

3.3.2. Spatial-temporal performance at a daily scale

As shown in Fig. 11, the three precipitation inputs also successfully forced the model to replicate the discharge records at the Beibei station at a daily scale, with performance evaluations of “good,” “satisfactory,” and “satisfactory” for Gauge,
370 CHIRPS, and CPC models, respectively. Different from the monthly scale, the CHIRPS-driven daily scale model showed lowest uncertainty level among the three precipitation datasets. The *p-factor* of Gauge, CHIRPS and CPC were 93%, 95%, and 77% for calibration and 84%, 91%, and 73% for validation, respectively, and *r-factor* were 1.16, 1.25, and 0.98 for calibration and 1.08, 1.27, and 0.93 for validation, respectively. Overall, the uncertainties of daily scale models with all three precipitation datasets as inputs were significantly lower than those of monthly scale, and the CPC-driven monthly model
375 success to reach a preferable level. The performances in describing the peak flows were not good for all three products, among which, the Gauge model performs best. The peak flows are usually caused by extreme precipitation events, like rainfall events with an intensity > 80 mm/day. As shown in Fig. 5 and Fig. 6, both the CHIRPS and CPC underestimate heavy rainfall

intensities compared with the Gauge observations. Conversely, the CHIRPS model performs best in simulating the baseflow, since CHIRPS tend to capture higher values of light rainfalls than that of the Gauge and CPC.

380 The WYLD spatial variation for all sub-basins at the daily scale are shown in Fig. 12. The spatial variation of daily and monthly scale of the three precipitation datasets is basically the same. The *CC* values between the daily and monthly WYLD spatial variation for Gauge, CHIRPS, and CPC at the daily scale are 0.98, 0.99 and 0.97, respectively. Similar to the results from the monthly scale, the WYLD spatial pattern is highly correlated with that of precipitation. The *CC* values between the WYLD and precipitation for Gauge, CHIRPS, and CPC at the daily scale are 0.83, 0.84 and 0.92, respectively, which are even
385 higher than those of the monthly scale. The *CC*, *STD_n*, and *RSR* values between CHIRPS and Gauge are 0.92, 1.06, and 0.46, respectively, and 0.81, 0.94, 0.66 between CPC and Gauge, respectively.

4. Discussion

4.1. Comparison of precipitation products in terms of rainfall events with different magnitudes

In the aforementioned results, compared to Gauge product, the CHIRPS tends to overestimate the intensity and frequency
390 of light rain, but underestimate heavy rain, which is consistent with the results reported by Gao et al. (2018). However, CPC tends to underestimate the intensity and overestimate the frequency of rainfall for light and heavy rain, although light rain is more underestimated. These results are consistent with those reported by Ajaaj et al. (2019). The differences in the capture of different magnitude rainfall intensities may potentially influence hydrologic process and forecasting. From Eq. (8), the basin's WYLD is directly proportional to the amount of precipitation. In other words, heavy rainfall tends to produce large amounts
395 of streamflow. Duan J et al. (2019) conducted a slope experiment and found that there was a significant difference in the runoff coefficients between extreme rainfall events and normal rainfall events; the former produced much more runoff and sediment than the latter. Solano-Rivera et al. (2019) experimented in the San Lorencito headwater catchment and found that the rainfall-runoff dynamics before extreme events were mainly related to antecedent conditions. After extreme flood events, antecedent conditions had no effect on rainfall-runoff processes, and rainfall significantly affected the streamflow discharge. Moreover,

400 the evaluation index *NSE* performance is mainly determined by the peak streamflow. Thus, it is critical to identify the magnitudes of different rainfall events at both a temporal and spatial scale. As a consequence, we derived the temporal and spatial distributions of the rainfall events with different magnitudes. The spatial scale dimension was implemented by identifying the serial numbers of all sub-basins (Fig. 13); and the temporal dimension was fulfilled by detecting rainfall events of different magnitudes throughout the study period (Fig. 14).

405 Overall, Fig.14 shows that the CPC tends to capture more light rainfall events with precipitation intensities between 0.1 and 50 mm/day (LR events), the CHIRPS identified more medium rainfall events with precipitation intensities between 50 and 100 mm/day (MR events), and both the Gauge and CHIRPS detected more heavy rainfall events with precipitation intensities larger than 100 mm/day (HR events). Accordingly, the total annual precipitation amounts of the three products are ranked as CHIRPS (956.4 mm) > Gauge (872.8 mm) > CPC (814.3 mm). Even with the advantage of detecting MR and HR events, the
410 CHIRPS' ability to simulate flood events is inferior to that of the Gauge. Potential reasons may consist of: 1) the HR events detected by CHIRPS are more scattered at a temporal scale, which disperses the flood peak value; and 2) the high frequency of the MR detected by CHIRPS resulted in parameter sets in the SWAT model that tended to derive a lower runoff coefficient, in order to avoid a large systematic bias in terms of *PBIAS*.

The CPC estimates, 60% of which are detected as LR, tend to be incapable of driving the SWAT model to capture small
415 streamflow discharge, especially the ones equivalent to baseflow. Consequently, the CPC model *CC* values are relatively low. A potential reason for this phenomenon may be that the rainfall during LR events tends to be easily lost in the initial- and post-loss processes, resulting in very limited or even no WYLD. Furthermore, the CHIRPS has a high probability of MR event false-alarm, which is consistent with the results reported by Zambrano-Bigiarini et al. (2017). Thus, a significant number of erroneous peaks exist in the CHIRPS, just like the temporal variation at a daily scale, which has a very low correlation with
420 the Gauge. Erroneous precipitation peaks tend to produce erroneous streamflow peaks. Although SWAT can repair the peak position deviation to some extent, the *CC* is inevitably reduced.

4.2. Effect of OPPs difference on hydrological process simulation

In general, simulated and observed streamflow hydrographs, using OPPs and Gauge inputs, can successfully match at both monthly and daily scales. However, consistency between simulated and observed streamflow does not guarantee identical hydrologic processes. For example, the SWAT model calibrated parameters are not the same for all precipitation inputs, meaning that the hydrologic mechanics during SWAT modeling are also different. As such, it is critical that researchers and decision makers adequately understand the benefits and limitations of different precipitation products in modeling the hydrologic processes.

According to the SWAT model's water balance equation (Eq. 7), WYLD equals the sum of Q_{surf} , Q_{lat} and Q_g , where Q_{gw} can be divided into flow out from a shallow aquifer (GW_Q) and flow out from a deep aquifer (GW_Q_D). If the soil water content W and percolation/bypass flow into the deep aquifer w_{seep} remains unchanged over a long time period, then the equation is modified to $P = Q_{surf} + ET + Q_{lat} + Q_{gw}$. Thus, we calculated the water balance component portions, Q_{surf} , Q_{lat} , Q_{gw} , and ET , for all the JRW sub-basins. With differing parameterizations, different precipitation inputs tend to derive completely different hydrological component amounts at different time scales (Fig. 15 & Table 5). At monthly scale, all three models, with Gauge, CHIRPS and CPC as inputs, have similar ET portions, which account for above 54%. The major components of Gauge model are SURQ and LATQ, accounting for 25.92 % and 16.72 %, respectively, the major component of CHIRPS model is SURQ, which accounts for 34.80 %, and the primary component of CPC model is LATQ, which accounts for 33.62 %. However, at daily scale, SURQ of Gauge model increased largely, reaching a proportion 32.61%, while LATQ decreased to 10.92%; LATQ of CPC model decreased and SURQ and ET increased, accounting for 14.41%, 15.60% and 58.73%, respectively; water balance components proportions of CHIRPS model slightly changed.

The above water balance component regularities are primarily the result of two causes. First, the differences in the above hydrological component proportions are highly possibly related in parameter adjustment. As shown in Table 3, the SURQ of Gauge and CPC models were significantly increased due to the decrease of the parameter SOL_K, which stands for saturated hydraulic conductivity. The decrease of the parameter ESCO in CPC model led to the increase of ET ratio, which influenced

445 soil evaporation compensation. The variation of parameter ALPHA_BF, which is baseflow recession constant, caused the GW_Q components of the three models to vary in the same direction. This result is consistent with that reported by Bai & Liu (2018), who conducted a study at the source regions of the Yellow River and Yangtze River basins in the Tibetan Plateau. They further concluded that the impact of different precipitation inputs on runoff simulation is largely offset by parameter calibration, resulting in significant differences in evaporation and storage estimates.

450 Second, rainfall characteristics also have a significant impact on hydrological processes in the watershed. A large number of studies show that rainfall intensity is a key player in the watershed's hydrological process (Zhou et al., 2017; Du et al., 2019; Zhang et al., 2019). Studies conducted by Redding & Devito (2010) showed that the occurrence of lateral flow is mainly determined by rainfall intensity. When the rainfall intensity is greater than the surface soil hydraulic conductivity, the rainfall mainly forms surface runoff. When rainfall intensity is between the soil surface and bedrock hydraulic conductivity, the rainfall
455 mainly forms lateral flow. When rainfall intensity is less than the bedrock's hydraulic conductivity, the rainfall will infiltrate into the groundwater. In this study, the precipitation recorded by CHIRPS was mainly distributed between 25 and 100 mm/day, while that of CPC was mainly distributed between 0.1 and 25 mm/day. This may be the reason why CHIRPS overestimated the proportion of surface runoff and CPC overestimated the proportion of lateral flow, compared with that of the Gauge model. Moreover, precipitation in the watershed's upstream area tended to infiltrate into the land surface due to the lower precipitation
460 detection (see Fig. 7); yet when the river flow converged in the watershed's downstream area, the surface flow increased due to the larger detected precipitation values. The results of these findings demonstrated that although the river runoff simulated by the three models are basically consistent, hydrologic components exhibited distinct behaviors due to the different features in precipitation detection. CHIRPS has a stronger ability to recognize heavy rain and tends to produce more surface runoff, while CPC's strong ability to identify light rain produces more lateral flow. As such, multi-objective calibration approach
465 would be recommended for flood prediction in future climate. Tuo et al. (2018) use water yield (WYLD), snow water equivalent (SWE), combining WYLD and SWE as objectives to for parameter calibration and optimization in the SWAT model, and verified the effectiveness of the multi-object procedure.

5. Conclusions

The sparsity and unevenness of ground-based precipitation observations pose great challenges to the establishment of hydrological models. In this study, the Gauge, CHIRPS, and CPC were evaluated by statistically comparing the different precipitation products as well as their performance at driving the hydrological model. Specifically, the potential behaviors of different precipitation datasets in describing precipitation magnitudes and hydrologic processes in terms of water balance components are further discussed. The main conclusions are summarized as follows:

1. The three precipitation datasets exhibited similar temporal records at a monthly scale, and the Gauge measures were more capable of capturing maxima than those of the OPPs. During rainy seasons, the CHIRPS median, maxima, and minima were larger, smaller, and larger, respectively, than that of the Gauge records, while all three CPC statistical values were smaller than that of the Gauge. At a daily scale, the CHIRPS tends to overestimate light rains and underestimate heavy rains, while all the CPC rainfall intensities were underestimated. Spatially, precipitation in all sub-basins increases from the upstream to the downstream region, and the CHIRPS derives the most smoothly distributed precipitation pattern.

2. All three precipitation inputs successfully forced the model to replicate the discharge records at the Beibei station at monthly and daily scale, and results at monthly scale presented slightly better performance than that of daily scale. However, the differences of precipitation inputs in the statistics at monthly and daily scales correspondingly affected the streamflow hydrograph, e.g. flood peak, base flow, and the rising and falling processes. Overall, the CHIRPS dataset performs better in hydrological evaluation because of its lower uncertainty level and higher spatial accuracy than that of CPC, thus it can be a fairly good option for researchers who are interested in this study area. The three models' spatial WYLD distributions are highly correlated to that of the precipitation records. While there were equivalent performances in simulating streamflow hydrographs, it should be noted that the calibrated parameters in all three models (Gauge, CHIRPS, and CPC models at monthly and daily scales, see Table 3) were quite different. In other words, evaluating only the streamflow simulation accuracy of the precipitation products will conceal the differences between these precipitation products, which is primarily because that

490 hydrological models are able to offset the influences of precipitation inputs on streamflow simulations using parameter calibration and validation.

3. The calibrated parameters are adjusted to alter the hydrologic mechanics in terms of water balance components. Thus, they effectively fill the potential gaps in the WYLD that may be introduced by the varying precipitation amounts and intensities detected by different precipitation products. In particular, according to parameter adjustment, the three products' precipitation
495 detection features resulted in significantly different water balance component portions, i.e., the overestimation of MR by CHIRPS resulted in a larger portion of surface flow, while the underestimation of all rainfall by CPC reduced a larger portion of lateral flow. Multi-objective calibration would be recommended for hydrological modelers in parameter calibration and optimization, especially for large and spatial resolved watersheds. Lastly, the spatial precipitation pattern also significant impacted the spatial distribution of the water balance components from upstream to downstream.

500 Although the OPPs have advantages and limitations with respect to the accuracy of precipitation estimates at different spatial and temporal scales, as well as in hydrological modeling and describing hydrologic mechanics, they demonstrate good potential in our case study within the JRW. As such, the OPPs should merge the advantages of satellite, ground observations, as well as the reanalyzed data. Fully consideration on performing the hydrological evaluation from both spatial and temporal scales is also key for the future development of OPPs. Furthermore, CHIRPS is advantaged in extreme rainfall detection and
505 thus good as flood prediction, while CPC would be more potentially used in extreme drought analysis in future climate analyses and hydrologic modelling.

Data availability

Sources of the geospatial and climate forcing data used to configure the SWAT model have been described in the “2.2. Data sources”. The simulations of streamflow data are shown in the figures of the paper and are available through contacting
510 the authors.

Author contributions

HZ conceptualized the work. HZ and JP designed the core structure and collected the data required. JP conducted the data analyses and model simulation and drafted the manuscript. HZ revised the manuscript. QX collected data and contributed to key analyses and discussions. YJW, YQW and OZ contributed to the discussion of the results, and JH assisted carrying out model configuration and data analyses.

Competing interests

The authors declare that they have no conflict of interest.

Table 1: Hydrological parameters considered for sensitivity analysis (“a_”, “v_” and r_” means an absolute increase, a replacement, and a relative change to the initial parameter values, respectively).

Parameters	Description	Range	Default
v__PLAPS.sub	Precipitation lapse rate[mm]	-1000/1000	0
a__SOL_K().sol	Saturated hydraulic conductivity [mm/h]	-10/10	Soil layer specific
r__SOL_BD().sol	Moist bulk density [g/cm ³]	-0.5/0.5	Soil layer specific
a__CN2.mgt	SCS streamflow curve number	-20/20	HRU specific
v__ESCO.hru	Soil evaporation compensation factor	0/1	0.95
a__HRU_SLP.hru	Average slope steepness [m/m]	-0.2/0.4	HRU specific
a__SLSUBBSN.hru	Average slope length [m]	-9/130	HRU specific
v__CH_K2.rte	Effective hydraulic conductivity [mm/h]	0/400	0
v__CH_N2.rte	Mannings n value for main channel	0/0.3	0.014
a__GWQMN.gw	Threshold depth of water in the shallow aquifer required for return flow to occur [mm]	-500/500	1000
a__REVAPMN.gw	Threshold depth of water in the shallow aquifer for “revap” to occur [mm]	-500/500	750
v__ALPHA_BF.gw	Baseflow alpha factor [days ⁻¹]	0/1	0.048
v__GW_REVAP.gw	Groundwater “revap” coefficient	0.02/0.2	0.02
v__GW_DELAY.gw	Groundwater delay [days]	0/300	31
v__ALPHA_BNK.rte	Baseflow alpha factor for bank storage	0/1	0

Table 2. General performance ratings statistics recommended by Moriasi et al. (2007).

Performance Rating	<i>RSR</i>	<i>NSE</i>	<i>PBIAS</i> (%)
Very good	$0.00 < RSR \leq 0.50$	$0.75 < NSE \leq 1.00$	$PBIAS \leq \pm 10$
Good	$0.50 < RSR \leq 0.60$	$0.65 < NSE \leq 0.75$	$\pm 10 < PBIAS \leq \pm 15$
Satisfactory	$0.60 < RSR \leq 0.70$	$0.50 < NSE \leq 0.65$	$\pm 15 < PBIAS \leq \pm 25$
Unsatisfactory	$RSR > 0.70$	$NSE < 0.50$	$PBIAS > \pm 25$

Table 3: Optimal parameters calibrated for all three models.

	> 0.1mm		≥ 50mm	
	<i>POD</i>	<i>FAR</i>	<i>POD</i>	<i>FAR</i>
CHIRPS	27.29%	54.12%	18.12%	65.56%
CPC	83.53%	46.76%	9.42%	44.71%

Table 5: Summarization of water balance components of the three models for the whole JRW.

Time scale	Datasets	Statistics	SURQ	LATQ	GW Q	GW Q D	ET	Summation
Monthly	Gauge	Average amount/mm	4500.00	2977.22	299.07	60.61	9076.60	16913.50
		Percentage/%	26.61%	17.60%	1.77%	0.36%	53.66%	
	CHIRPS	Average amount/mm	6068.35	773.24	949.56	140.79	9046.83	16978.78
		Percentage/%	35.74%	4.55%	5.59%	0.83%	53.28%	
	CPC	Average amount/mm	1087.19	5577.20	583.45	30.15	8694.40	15972.40
		Percentage/%	6.81%	34.92%	3.65%	0.19%	54.43%	
Daily	Gauge	Average amount/mm	5544.88	1856.00	244.94	48.29	9309.37	17003.48
		Percentage/%	32.61%	10.92%	1.44%	0.28%	54.75%	
	CHIRPS	Average amount/mm	6202.63	834.78	1167.37	59.75	10434.58	18699.11
		Percentage/%	33.17%	4.46%	6.24%	0.32%	55.80%	
	CPC	Average amount/mm	2493.11	2302.28	1709.95	88.66	9384.90	15978.90
		Percentage/%	15.60%	14.41%	10.70%	0.55%	58.73%	

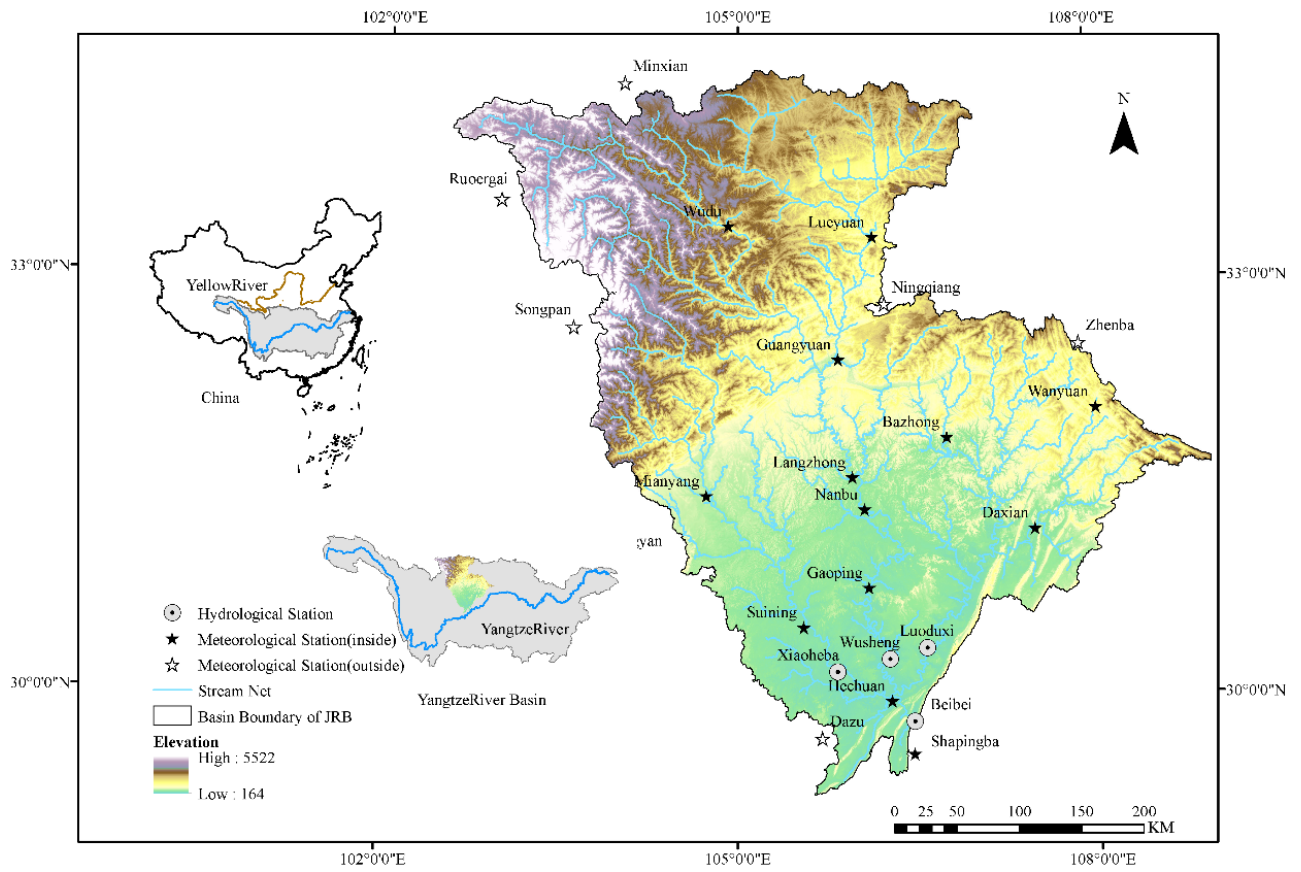

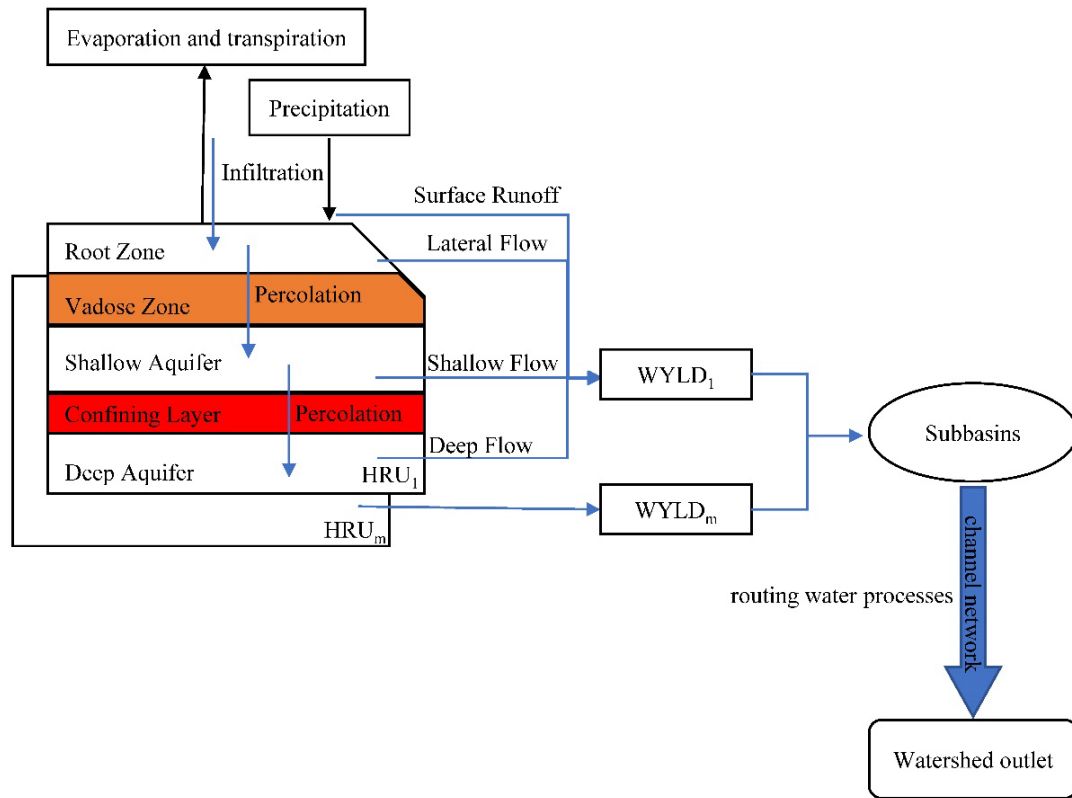

Figure 1. Sketch map of the Jialing River Basin with meteorological stations.

740 **Figure 2.** Schematic representation of the modified SWAT model structure.

Figure 3. Time series of three different precipitation records at monthly scale in JRW (the CC values of 0.97 and 0.98 indicating extremely significant positive correlation ($P < 0.01$, where P stands for the probability of being rejected when there was a significant difference)).

745

750

Figure 4. Box Diagrams of three different precipitation records at monthly scale in JRW.

755 **Figure 5.** Scatter plot of the OPPs records comparing with Gauge records at daily scale: (a) comparison of CHIRPS and Gauge; (b) comparisons of CPC and Gauge.

760

Figure 6. Cumulative Frequencies of daily precipitation intensity for the three precipitation products (Gauge, CHIRPS, CPC) in JRW: (a) distribution of all precipitation values; (b) distribution of precipitation values that are <100 mm; (c) distribution of precipitation values that are ≥ 100 mm.

765

770 **Figure 7.** Spatial variation of annual precipitation at sub-basin scale for (a) Gauge (b) CHIRPS and (c) CPC.

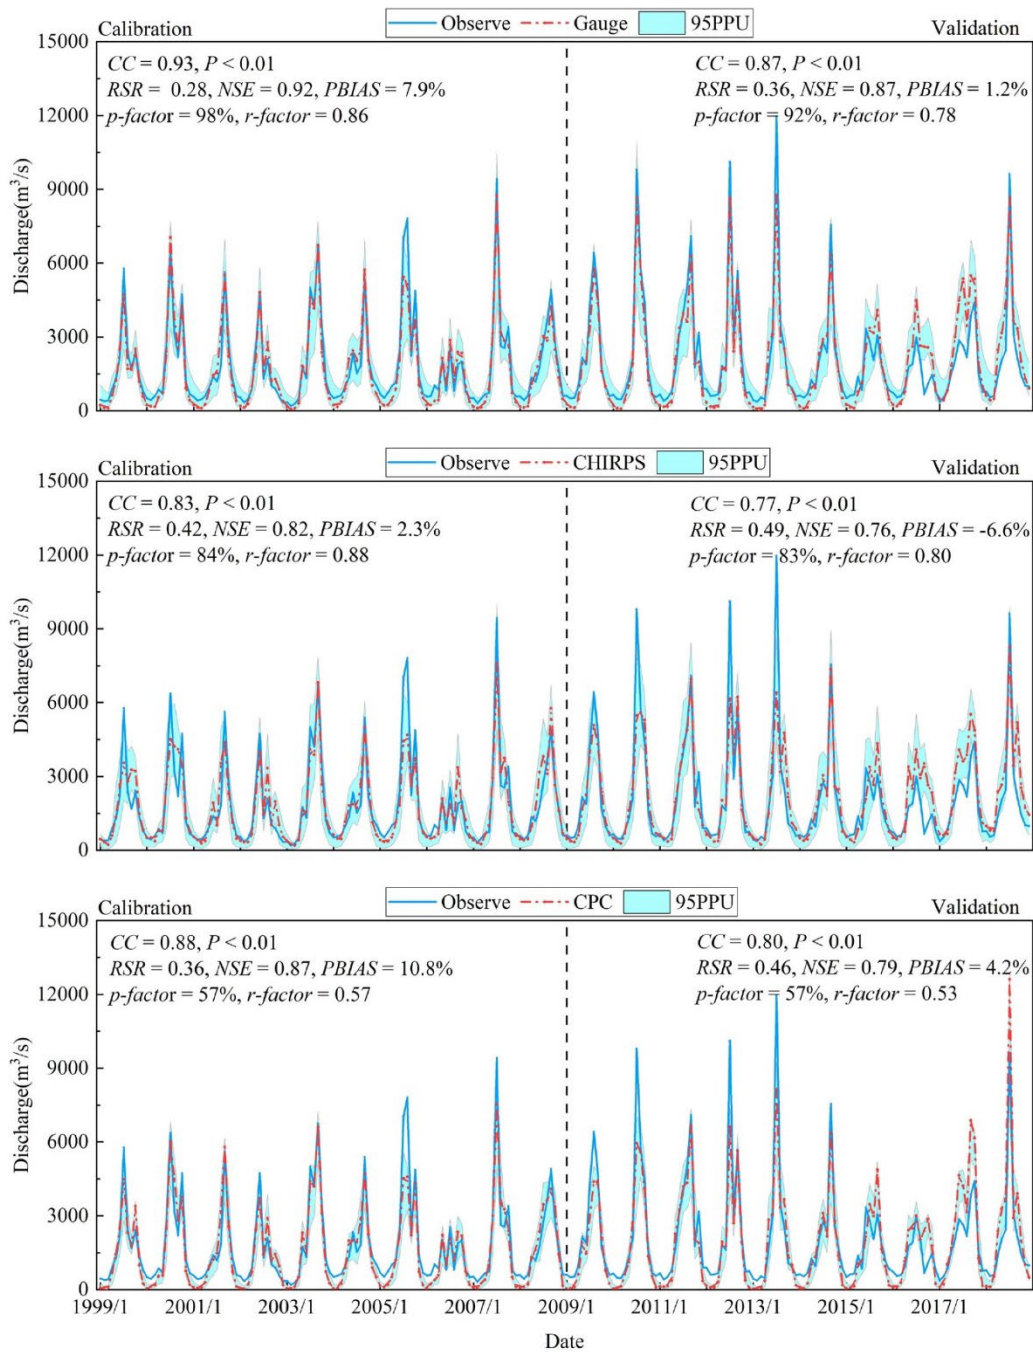

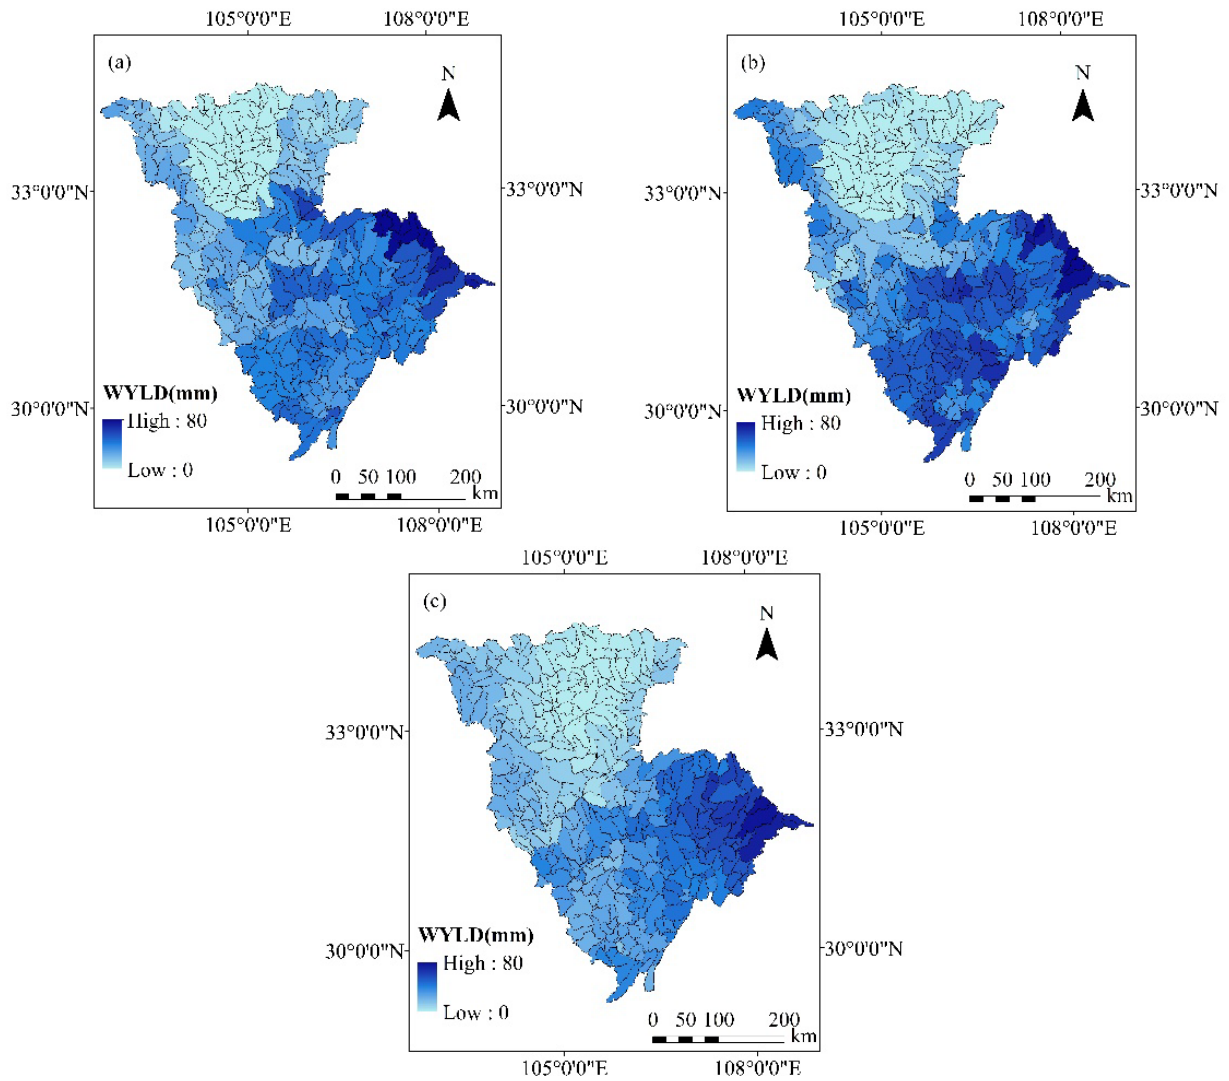

Figure 8. Spatial variation of CC values of the precipitation between (a) Gauge and CHIRPS, (b) Gauge and CPC at monthly scale and (c) Gauge and CHIRPS, (d) Gauge and CPC at daily scale.

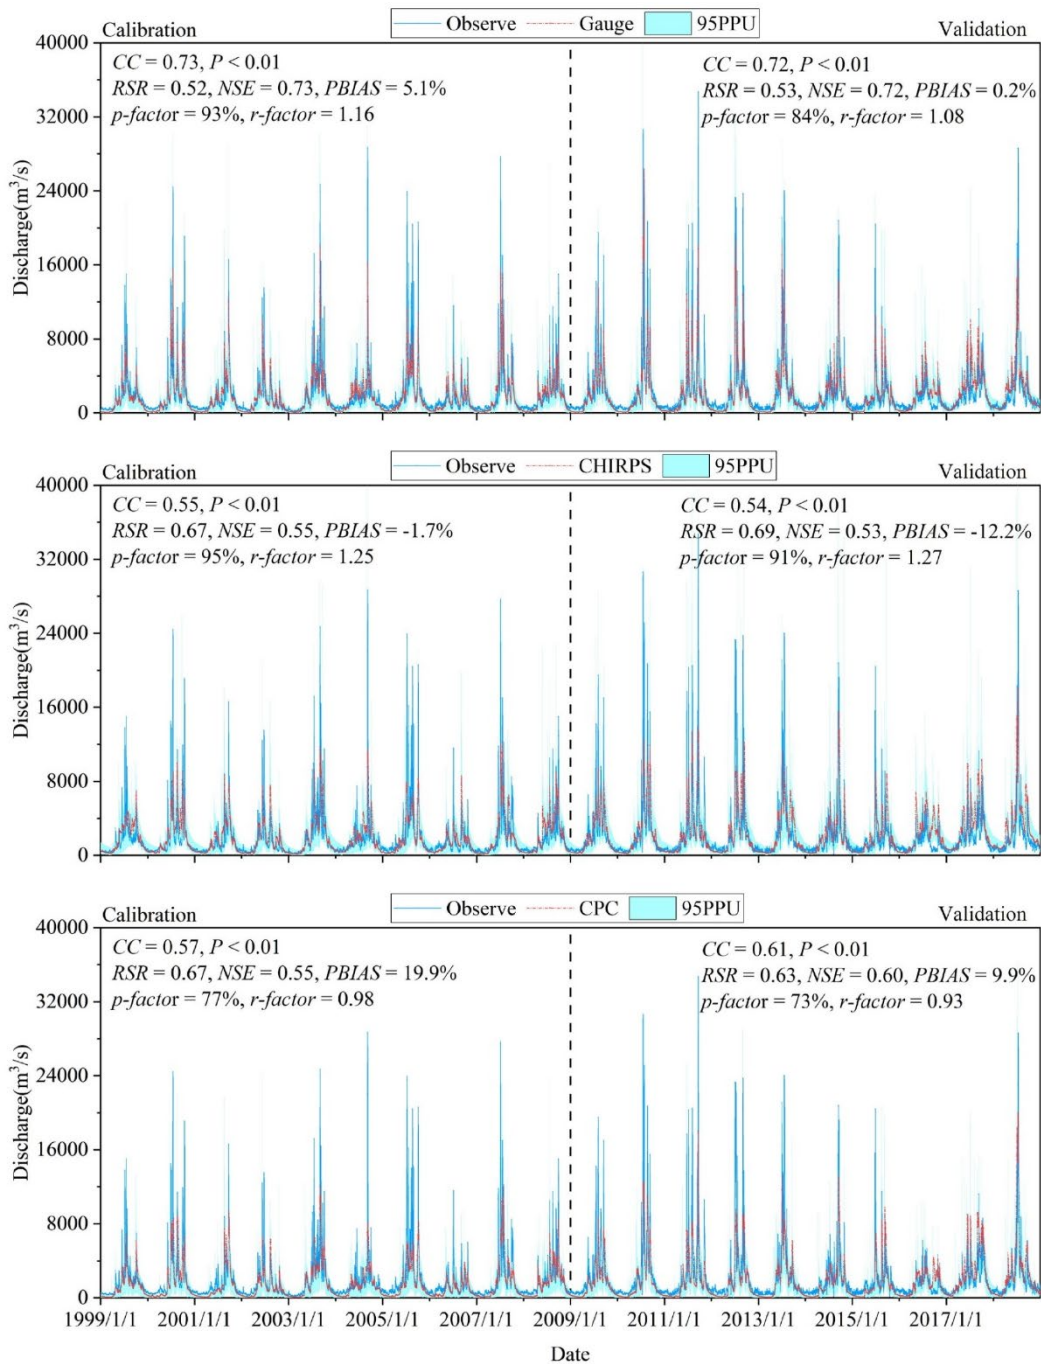

780 **Figure 9.** Observed and simulated discharges at the outlet of JRW at monthly scale using precipitation inputs of Gauge, CHIRPS and CPC, respectively.

785

Figure 10. Spatial variation of water yield at monthly scale for all sub-basins calculated with precipitation inputs of (a) Gauge (b) CHIRPS and (c)CPC.

790 **Figure 11.** Observed and simulated discharges at the outlet of JRW at daily scale using precipitation inputs of Gauge, CHIRPS and CPC, respectively.

Figure 12. Spatial variation of water yield at daily scale for all sub-basins calculated with precipitation inputs of (a) Gauge (b) CHIRPS and (c) CPC.

795

Figure 13. Spatial distribution of sub-basins in SWAT, named by Numbers.

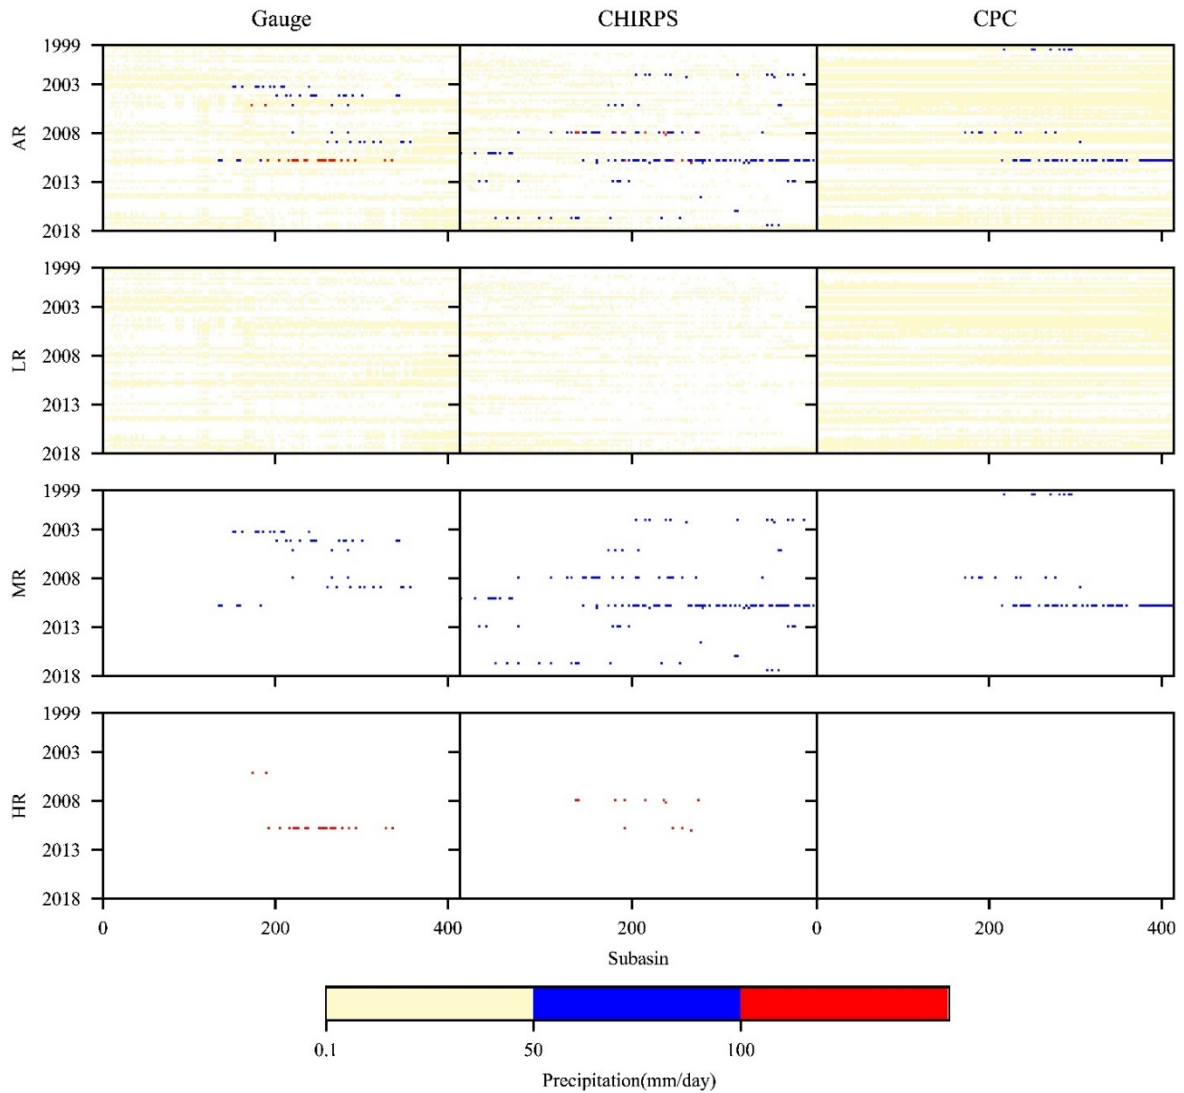

Figure 14. Full records of flood events occurred throughout the study period and all sub-basins detected by three precipitation products, where the AR, LR, MR, HR stand for precipitation of all rainfall intensities, intensity between 0.1 and 50 mm/day, intensity between 50 and 100 mm/day, intensity more than 100 mm/day, respectively.

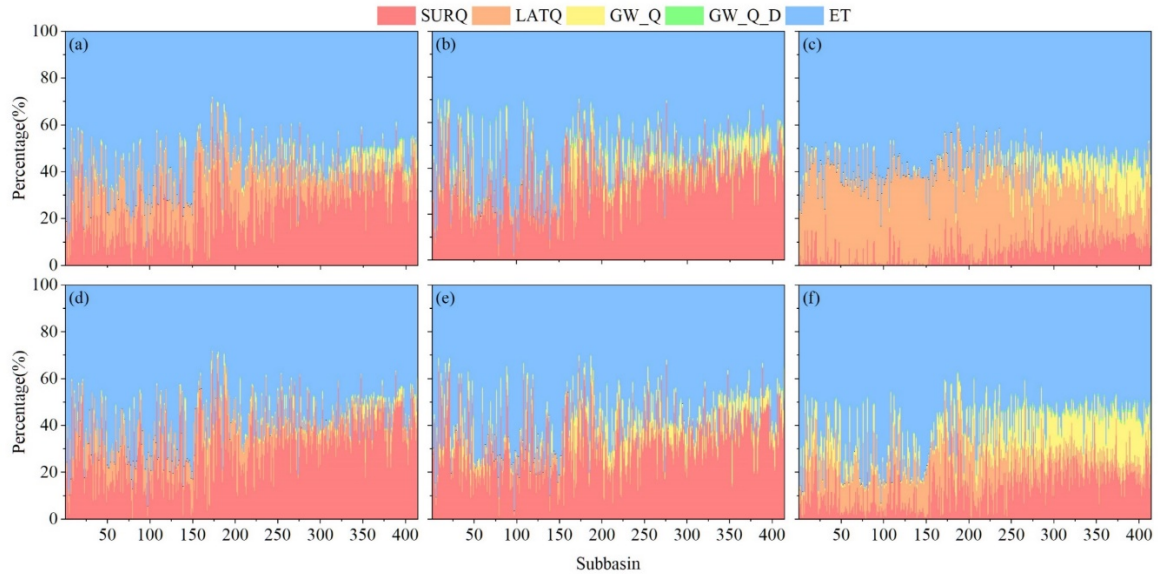

Figure 15. Water balance components for all sub-basins derived from SWAT models using precipitation inputs of (a) Gauge (b) CHIRPS and (c) CPC at monthly scale and (d) Gauge (e) CHIRPS and (f) CPC at daily scale (where SURQ represents surface runoff Q_{surf} ; LATQ represents lateral flow Q_{lat} ; GW_Q is the baseflow from the shallow aquifer; GW_Q_D is the baseflow from the deep aquifer, and the sum of GW_Q and GW_Q_D equals to Q_{gw} ; ET represents actual evapotranspiration ET).
