Abstract. Plant – soil water isotopic dynamics in northern forests have been understudied relative to other forest types; nevertheless, such information can provide insight into how such forests may respond to hydroclimatic change. This study examines the co-evolution of xylem water and soil water stable isotopic compositions in a northern mixed forest in Ontario, Canada. Gross precipitation, bulk soil water and xylem water were sampled from pre-leaf out to post-senescence in 2016 for eastern white cedar, eastern hemlock, red oak and eastern white pine. Near-bole soil water contents and mobile soil water isotopic compositions were measured for the last three species. Mobile soil water did not deviate significantly from the local meteoric water line (LMWL). In contrast, near-surface bulk soil water showed significant evaporative enrichment relative to the LMWL from pre-leaf out to peak leaf out under all tree canopies, while xylem water was significantly depleted in ¹⁸O and particularly ²H relative to bulk soil water throughout the growing season. Inter-species differences in deviation of xylem water from the LMWL and their temporal changes emerged during the growing season, with coniferous species xylem water becoming isotopically enriched while that of red oak became more depleted in ²H and ¹⁸O. These divergences occurred despite thin soil cover (generally < 0.5 m depth to bedrock) which would constrain inter-species differences in tree rooting depths in this landscape. Isotopic fractionation at the tree root and fractionation of xylem water via evaporation through the tree bark are among the most plausible potential explanations for deviations between xylem and soil water isotopic compositions. Differences in the timing and intensity of water use between deciduous and coniferous trees may account for inter-specific variations in xylem water isotopic composition and its temporal evolution during the growing season in this northern forest landscape.

1 Introduction

Northern forest landscapes are highly sensitive to climate change (Laudon et al. 2017, Sprenger et al. 2018a) and may experience marked hydrological shifts in the future, such as changes in the amount, form and timing of precipitation (Carey et al. 2010, Hartmann et al. 2013) as well as increases in drought frequency and intensity (Brinkmann et al. 2019). Alterations in snow accumulation and ablation have important implications for soil water availability to plants at the start of the growing season (Smith et al. 2011, Carey et al. 2013), and vegetation in northern landscapes can

34 exhibit rapid responses to such changes (e.g. Myers-Smith et al. 2019). Understanding how northern forests may
35 respond to these anticipated hydrological changes would benefit from greater knowledge of the sources of water taken
36 up by major tree species in these landscapes (Guswa et al. 2020). Environmental isotopes have often been used to
37 study water use by vegetation (e.g. Evaristo et al. 2015), and efforts to account for the isotopic composition of plant
38 water in relation to that of major water pools in forest landscapes has led to the ecohydrological separation or “two
39 water worlds” hypothesis (Brooks et al. 2010, McDonnell 2014). This hypothesis proposes that a highly mobile pool
40 of soil water similar in isotopic composition to precipitation contributes to groundwater and streamflow while a less
41 mobile pool of evaporatively-enriched soil water supplies plant transpiration (Goldsmith et al. 2012, Knighton et al.
42 2019, Sprenger and Allen 2020).

43 McCutcheon et al.’s (2017) review of the ecohydrological separation hypothesis presented three assumptions that
44 must be met for the hypothesis to be supported:

- 45 1. There is a distinct difference between the isotopic composition of water taken up by plant roots and the water
46 that drains through the soil profile.
- 47 2. This difference can be linked to isotopically distinct soil water sources.
- 48 3. These isotopically distinct soil water sources arise from differences in soil water mobility.

49 Studies have called one or more of these assumptions into question, such as the assumption that mobile and tightly
50 retained subsurface waters are independent water pools (Sprenger et al. 2018b), and there is mounting evidence that
51 the two water worlds hypothesis is overly simplistic (Penna et al. 2018). For example, Bowling et al. (2017) noted
52 that the assumption that plants extract more strongly held soil water in the presence of less strongly retained soil water
53 near the plant roots violates currently physiological understanding of how plants take up water, which is primarily
54 driven by a potential gradient between the soil and the plant leaf or needle.

55 Nevertheless, the interface between soils and plants represents the potential source of novel advances in process
56 understanding in ecohydrology, and systematic assessments of plant – soil water isotopic dynamics need to be
57 examined across distinct soil types and vegetation structures (Dubbert and Werner 2019). There is a particular need
58 to examine relationships between the isotopic composition of xylem water in relation to that of potential source waters
59 in northern forests (Tetzlaff et al. 2015, Penna et al. 2018), since much previous research into water use by vegetation
60 using environmental isotopes has focused on tropical, seasonally dry or arid regions (Evaristo et al. 2015, Gaines et
61 al. 2016). Most ecohydrological separation studies have also been restricted to the growing season (Liu et al. 2020),
62 and greater consideration should be paid to the full seasonal variability of soil and plant water isotopic composition
63 (McCutcheon et al. 2017, Sprenger et al. 2018a, Tetzlaff et al. 2021). This variability in northern landscapes is driven
64 in part by a pronounced annual cycle that ranges from isotopically-depleted snowfall to isotopically-enriched summer
65 rainfall (Birks and Gibson 2009), with important implications for the isotopic composition of source water available
66 for plant uptake at the start of the growing season (McCutcheon et al. 2017, Allen et al. 2019). Plant – soil water
67 isotopic dynamics may also differ between tree species in northern landscapes. Trees cannot be treated as “simple
68 transport vessels, or straws” (Evaristo et al. 2019, p 18), and inter-specific differences in the interplay between rooting
69 depth and architecture and water flowpaths and storage in the soil profile may manifest themselves in the resulting
70 isotopic composition of plant water uptake (Geris et al. 2015, Allen et al. 2019).

71 The purpose of this study is to examine the co-evolution of the isotopic composition of xylem water and soil water
72 from pre-leaf out to post-senescence for some common tree species in Canada's northern forest landscapes. We
73 address the following questions:

- 74 1. What are the temporal changes in the isotopic composition of soil water and xylem water throughout the complete
75 growing season in a northern forest landscape, and do the trajectories of such changes differ between tree species?
- 76 2. What are the potential drivers of any inter-specific differences in the deviation of the isotopic composition of
77 xylem water from that of soil water?

78 Answering these questions may improve our understanding of relationships between soil water and water taken up for
79 transpiration by different tree species in northern forests and provide insight into how these species may respond to
80 hydroclimatic change in northern landscapes.

81 **2 Study Area and Methods**

82 **2.1 Study Area**

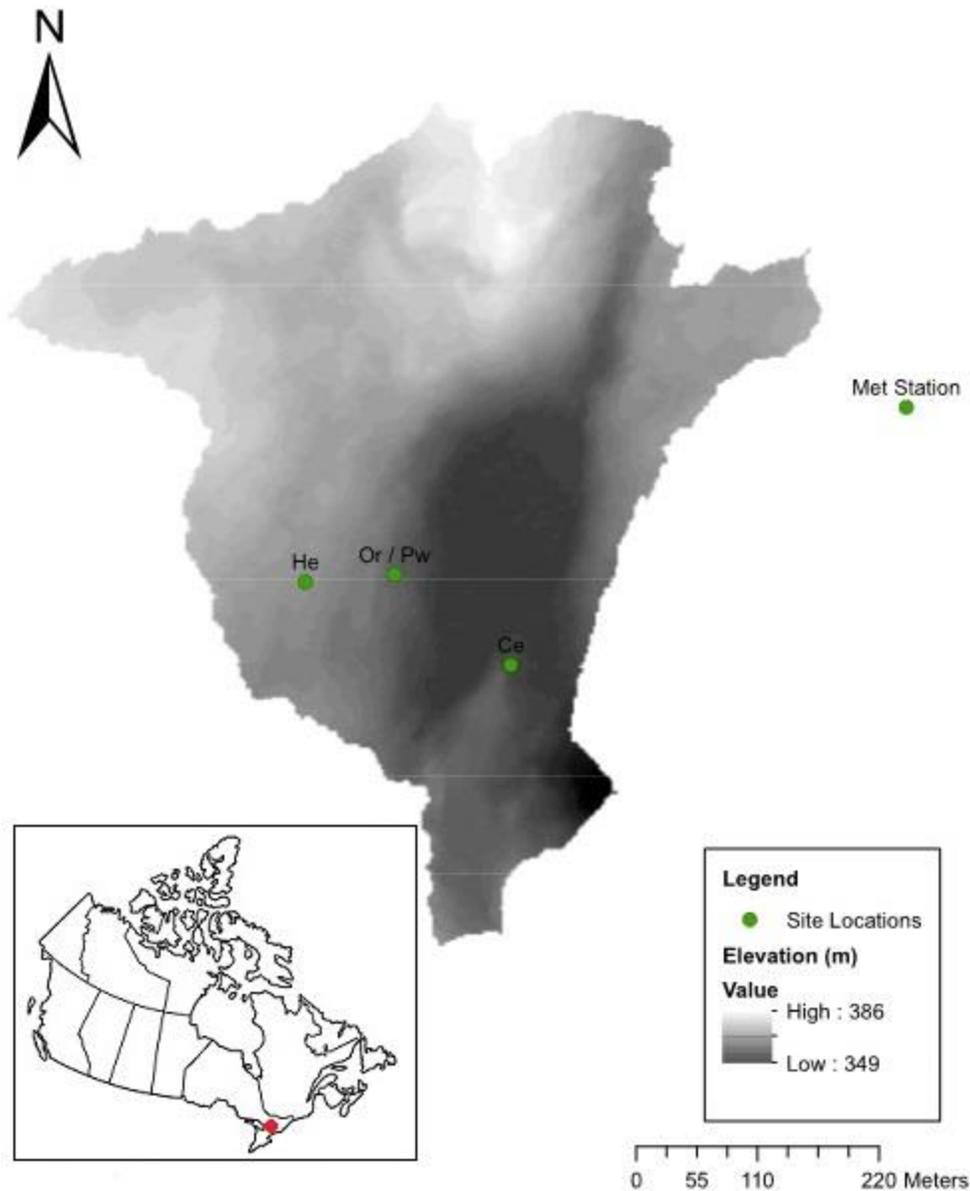

83 The study was conducted in the Plastic-1 (PC-1, 23.3 ha) sub-catchment of Plastic Lake (Fig. 1) on the southern edge
84 of the Canadian Shield near Dorset, Ontario, Canada (45°11' N, 78°50' W). Pleistocene glacial till overlies
85 Precambrian metamorphic silicate bedrock (Wels et al. 1990), and thin soil cover is formed from sandy basal tills with
86 an average depth of ~0.4 m to bedrock (Neary et al. 1987, Watmough et al. 2007). Visual observations of outcrops in
87 PC-1 suggest the bedrock is relatively unfractured. Soils are overlain with a ~5 cm thick LFH layer (Neary et al. 1987)
88 and are sandy with minor clay and low organic matter contents showing little decline with depth (Buttle and House
89 1997). Forest cover is largely coniferous and dominated by red oak (*Quercus rubra*, Or), eastern white pine (*Pinus*
90 *strobus*, Pw), eastern hemlock (*Tsuga canadensis*, He), white cedar (*Thuja occidentalis*, Ce), and black spruce (*Picea*
91 *mariana*). The latter is confined to a wetland occupying the central portion of PC-1. Leaf-out of Or is in mid-May
92 while senescence occurs by early October. A meteorological station ~500 m from the study site (Fig. 1) operated by
93 the Dorset Environmental Science Centre (DESC) provides temperature and precipitation data. Daily average
94 temperatures range between -10° C and 18° C throughout the year, based on meteorological station data between 1981
95 and 2010. Mean annual precipitation is ~799 mm y⁻¹ of rain and ~260 mm y⁻¹ of snow water equivalent.

96 **2.2 Gross rainfall sampling and potential evapotranspiration estimation**

97 Gross precipitation (P_g) was measured weekly for amount and isotopic composition from May 27 to October 21, 2016
98 using a bulk collector at the meteorological station which minimized isotopic fractionation via air exchange with the
99 external environment by reducing the water surface exposed to the atmosphere (Gröning et al. 2012). Snowmelt
100 samples were obtained from a snowmelt runoff plot at Paint Lake, ~12 km northwest of PC-1 (Lane et al. 2020). Daily
101 potential evapotranspiration (PET) values were taken from Sprenger et al. (2018a), based on meteorological station
102 data and the Penman-Monteith equation (Allen et al. 1998).

103 **2.3 Xylem water sampling**

104 Four tree species in PC1 were selected to conduct xylem water sampling: Ce, He, Or and Pw. Five mature trees with
105 similar diameter at breast heights (DBH) were chosen for each species (Table 1). Sampled Or and Pw trees were

107

108 **Figure 1: Digital elevation model of the PC-1 catchment, showing the location of trees sampled for xylem water and bulk**

 110 **station.**

111 intermixed, while He trees were ~100 m away from the Or/Pw stand and Ce trees were ~200 m from the He trees and
 112 ~130 m from the Or/Pw stand (Fig. 1). Xylem water was sampled six times between October 2015 to November 2016,
 113 including post-senescence 2015 (October 26 to November 3, 2015), pre-leaf-out 2016 (April 26 to April 29, 2016),
 114 post-leaf-out 2016 (June 20 to June 22, 2016), peak-leaf-out 2016 (August 8 to August 10, 2016), pre-senescence 2016
 115 (September 23 to September 24, 2016), and post-senescence 2016 (November 2 to November 4, 2016). Xylem cores
 116 were extracted from each tree at breast height using an increment borer (3-thread, 5.15 mm core). Cores were extracted

123
 124 a few cm above or below the preceding core. Bark was removed from retrieved cores which were immediately stored
 125 in 200 mL glass scintillation vials with zero headspace. These were taped, sealed with Parafilm, and stored in a freezer
 126 to prevent exchange with the atmosphere. Elapsed time between core extraction and storage in the sealed vials was on
 127 the order of 1 minute.

128 **2.4 Soil water isotopic sampling and soil water content**

129 Bulk soil samples were obtained concurrent with xylem water sampling in a randomized direction 1 m from the bole
 130 of each tree sampled for xylem water. Following litter layer removal, a minimum of 40 g of soil was collected using
 131 an auger at 5 cm depth increments until bedrock was reached. An average of six samples was obtained at a given tree,
 132 ranging from one to 16 samples. Samples were double bagged in Ziploc bags while minimizing any stored air and
 133 stored at 4°C prior to analysis. Samples were stored for no more than 2 weeks prior to analysis, and Hendry et al.
 134 (2015) indicated that any water losses and resulting changes in soil water isotopic content for these short storage

135 periods would be negligible. This bulk soil water was assumed to represent all water stored within the soil, including
136 both mobile and more tightly held soil water.

137 Mobile soil water was sampled from tension lysimeters installed at 0.1 and 0.4 m depths at 0.1 and 1 m from the
138 tree bole in a randomized direction for three He, three Or and three Pw trees sampled for xylem water (Snelgrove et
139 al. 2019). Tension lysimeters were manufactured using Soil Test™ 2 bar ceramic cups and PVC tubing. Tension
140 lysimeters were sampled weekly between June 2 and October 21, 2016 and re-set to a minimum negative air pressure
141 of 60 kPa using a hand pump. Samples were stored in sealed glass vials with zero headspace at 4°C prior to isotopic
142 analysis.

143 Soil water content (SWC) was measured at two ATL-1 access tubes (<http://www.delta-t.co.uk>, last accessed May
144 30, 2019) installed 0.1 and 1 m from the bole of each of the three trees of a given species sampled for mobile soil
145 water. Tubes were installed in a randomized direction from the bole. Measurements were concurrent with tension
146 lysimeter sampling. A Delta T PR2/6 Soil Moisture Profile Probe™ measured SWC at each access tubes at 0.1-, 0.2-,
147 0.3-, and 0.4-m depths. Measurements at each depth were made three times per access tube and averaged to obtain
148 mean SWC at each depth. These values were used to estimate the total depth of water held in the upper 0.5 m of soil
149 as described in Snelgrove et al. (2019).

150 **2.5 Isotopic analyses**

151 All isotope ratios are expressed relative to Vienna Standard Mean Ocean Water- Standard Light Antarctic Precipitation
152 (VSMOW-SLAP, Coplen et al. 2002) using standard ‰ notation. Tree core samples were analyzed at the Boise State
153 University Stable Isotope Laboratory. Xylem water was obtained from the cores by cryogenic extraction, followed by
154 mass spectrometry using a Thermo Delta V Isotope Ratio Mass Spectrometer (IRMS) coupled with Thermo TC/EA
155 configured for water injection analyses (Koeniger et al. 2011), with a precision of ± 1.0 ‰ for $\delta^2\text{H}$ and ± 0.1 ‰ for
156 $\delta^{18}\text{O}$. An extreme maximum limit on external reproducibility can be estimated from the compositional consistency
157 among analyses of the same species on a single sampling date (e.g., all Or data on 4/26/16, etc.). This limit is a
158 maximum because different trees are expected to have different compositions. The mean and median reproducibilities
159 for these data are ~ 10 ‰ in $\delta^2\text{H}$ and ~ 1 ‰ in $\delta^{18}\text{O}$. Bulk soil water, tension lysimeter and P_g samples were analyzed at
160 the University of Saskatchewan using Los Gatos Research Liquid Water Off-Axis Integrated-Cavity Output
161 Spectroscopy (Off-Axis ICOS) with a precision of $\leq \pm 1.0$ ‰ for $\delta^2\text{H}$ and ± 0.2 ‰ for $\delta^{18}\text{O}$. The ICOS instrument at
162 the University of Saskatchewan was cross-correlated with the IRMS at Boise State University. Bulk soil samples were
163 analyzed using vapour extraction of water in an equilibrium state from the sealed Ziploc bags. We are aware that
164 different methods of soil water extraction have been a major focus of research in the past few years, with no definitive
165 agreement on a standard method (e.g. Araguas-Araguas et al. 1995, Orlowski et al. 2016, 2018). Previous work has
166 shown the direct equilibrium method to give similar results to those from cryogenic extraction for sandy soils with
167 low organic matter contents such as those at PC-1 (Sprenger et al. 2018a, b). The accuracy of the direct water-vapour
168 equilibration method was ± 0.3 ‰ for $\delta^{18}\text{O}$ and ± 1.1 ‰ for $\delta^2\text{H}$. For a detailed description of the procedure, we refer
169 to Sprenger et al. (2018a). Snowmelt samples were analyzed at the University of Toronto using a Los Gatos Research
170 DLT-100 liquid water isotope analyser with a precision of $\leq \pm 1.0$ ‰ for $\delta^2\text{H}$ and ± 0.12 ‰ for $\delta^{18}\text{O}$.

171 The local meteoric water line (LMWL) was determined by regressing $\delta^2\text{H}$ on $\delta^{18}\text{O}$ for all snowmelt and P_g samples
172 (Klaus et al. 2015). Isotopic compositions of soil water and xylem water samples were compared with the LMWL
173 using the line-conditioned excess (lc-excess), which defines the degree of deviation from the LMWL using:

$$174 \quad lc - excess = \delta^2H - a \times \delta^{18}O - b \quad (1)$$

175 where a and b are the LMWL's slope and intercept, respectively (Landwehr and Coplen 2006). Negative lc-excess
176 indicates evaporative enrichment relative to the LMWL (Landwehr and Coplen 2006). McCutcheon et al. (2017) noted
177 the benefit of lc-excess values in showing "isotopic distinction" between two water samples. These may differ
178 markedly in their δD and $\delta^{18}\text{O}$ values but can be considered genetically similar if they both plot on the LMWL.

179 **2.6 Statistics**

180 All statistical analyses were performed using the *stats* package in R Statistical Software (R Core Team 2019). Shapiro-
181 Wilks tests were used to assess normality of xylem water lc-excess values for each sampling period and species. One-
182 way ANOVAs were used to compare differences in xylem water lc-excess between sampling periods for each tree
183 species. Levene's test confirmed homogeneity of variances. Tukey HSD tests identified significant differences in the
184 data for each tree species. Inter-specific differences in xylem water lc-excess for a given sampling period were
185 assessed using t-tests (unequal variances, Bonferroni-corrected). Successive sampling of the same trees meant that the
186 isotopic composition of xylem water on a given sampling date was partly dependent on that from the previous
187 sampling. Nevertheless, our approach allowed us to examine the temporal trajectory of xylem water for each of the
188 sampled trees. We feel this is preferable to deriving this trajectory by sampling different trees at different times, which
189 could be influenced by inter-tree differences in xylem water isotopic composition on a given sampling date.

190 **3 Results**

191 **3.1 Hydrometeorological conditions during the sampling period**

192 Precipitation data for the PC-1 meteorological station were not available for the Fall 2015 period. Total precipitation
193 at the station for January 1 to October 31, 2016 (957 mm) exceeded the 30-year normal precipitation for January to
194 October (854 mm) at the nearby Dorset MOE climate station (station i.d. 6112072). This was the result of above-
195 average precipitation (largely as snow) in February and March, and a wetter-than-normal August (173 mm/mo vs. 76
196 mm/mo). Conversely, September 2016 was much drier than normal (47 mm/mo vs. 114 mm/mo). Daily PET ranged
197 from 1 to 6.8 mm/day, peaking in mid-June and declining to late October. Total PET from May 27 to October 21,
198 2016 was 597 mm, while total P_g for the same period was 440 mm. The Canadian Drought Monitor
199 (www.agr.gc.ca/atlas/maps_cartes/canadianDroughtMonitor/ accessed June 18, 2020) indicated that the April –
200 October 2016 growing season was relatively dry, with conditions ranging from abnormally dry (April) through to
201 moderate (July to October) and severe drought (June).

202 **3.2 Soil water contents**

203 Total water depth in the upper 0.5 m of soil at 0.1 and 1 m from He, Or and Pw tree boles showed similar trends from
204 early June 2016 to late October 2016 (Fig. A1): gradual draining through June into early August, a marked increase
205 following 123 mm of rain between August 9 and August 17, and relatively high $SWCs$ until the end of monitoring (see

206 Snelgrove et al. 2019 for greater detail). *SWCs* were similar at 0.1 m and 1 m from the boles of trees of a given species.
207 Greatest variability in *SWC* was seen around Or trees, while the least was around He trees.

208 **3.3 Isotope results**

209 **3.3.1 Precipitation**

210 Figure 2a shows dual isotope plots of snowmelt and rainfall separated into periods prior to bulk soil water and xylem
211 water sampling. Snowmelt samples represented pre-leaf out values, which were depleted in ^2H and ^{18}O relative to
212 rainfall for the other periods; however, there was considerable overlap in rainfall isotopic composition with no clear
213 demarcation between sampling periods. The local meteoric water line (LMWL) using all samples was:

$$214 \delta ^2H = 7.0395 * \delta^{18}O + 4.6032; R^2 = 0.97 \quad (2)$$

215 Most throughfall and stemflow samples for He, Or and Pw trees fell on the LMWL, indicating limited isotopic
216 enrichment of P_g as it passed through the forest canopy (Snelgrove et al. 2019).

217 **3.3.2 Mobile and bulk soil water**

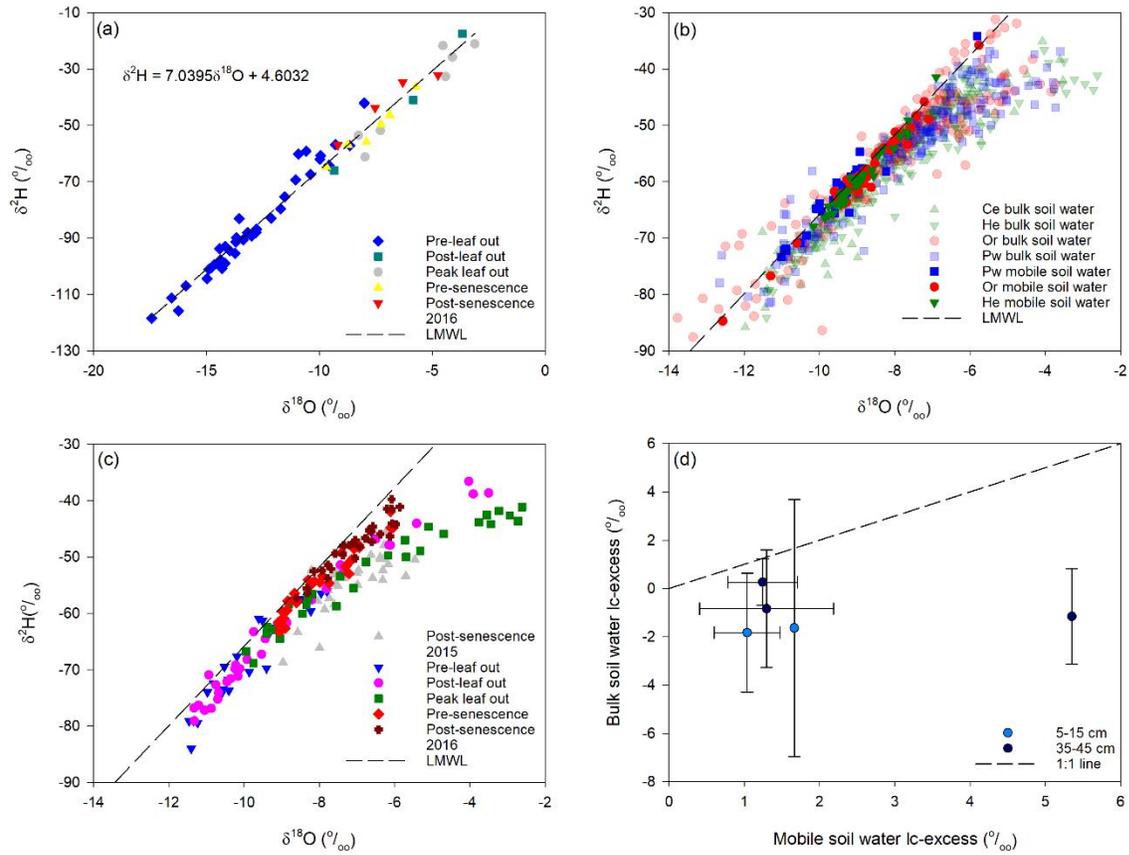

218 Mobile soil water fell on the LMWL (Fig. 2b), particularly deeper samples and those taken post-senescence in 2015
219 and 2016. Snelgrove et al. (2019) also found limited evaporative enrichment of mobile soil water and weak
220 correspondence between isotopic composition of mobile soil water and that of P_g , throughfall or stemflow inputs to
221 the soil.

222 Most bulk soil water samples also plotted along the LMWL. However, the best-fit line of $\delta^2\text{H}$ vs. $\delta^{18}\text{O}$ for bulk
223 soil water had a slope of 5.3, shallower than for meteoric water (7.0, Eq. 2), indicating evaporative enrichment of
224 some samples. Enrichment was most pronounced at peak leaf out (Fig. 2c). It is important to note the poor agreement
225 between bulk soil water and mobile soil water *lc-excess* sampled within two days or less of one another for a given
226 tree species (Fig. 2d). Bulk soil water tended to be evaporatively enriched (more negative *lc-excess*) relative to mobile
227 soil water sampled on or close to the same day.

228 Bulk soil water *lc-excess* values showed broadly similar distributions with depth beneath all tree species (Fig. 3).
229 Post-senescence 2015 samples showed considerable variability at a given depth and no obvious trends with depth,
230 with a tendency for negative *lc-excess* values for all tree species. *Lc-excess* at all depths became more positive at pre-
231 leaf out in late April, which may reflect large preceding inputs of snowmelt water which flushed the soil profile. *Lc-*
232 *excess* was more negative at post-leaf out in late June, indicating evaporative enrichment. This was least pronounced
233 for Pw relative to the other species. All species showed negative *lc-excess* for near-surface bulk soil water and
234 increasing values with depth at peak leaf out in early August. *Lc-excess* approached or equalled 0 at pre-senescence
235 sampling in late September, consistent with decreased evaporation (Snelgrove et al. 2019). *Lc-excess* values at post-
236 senescence 2016 were similar to those at post-senescence 2015 for Ce; however, 2016 values were generally more
237 positive than 2015 values for He, Or and Pw.

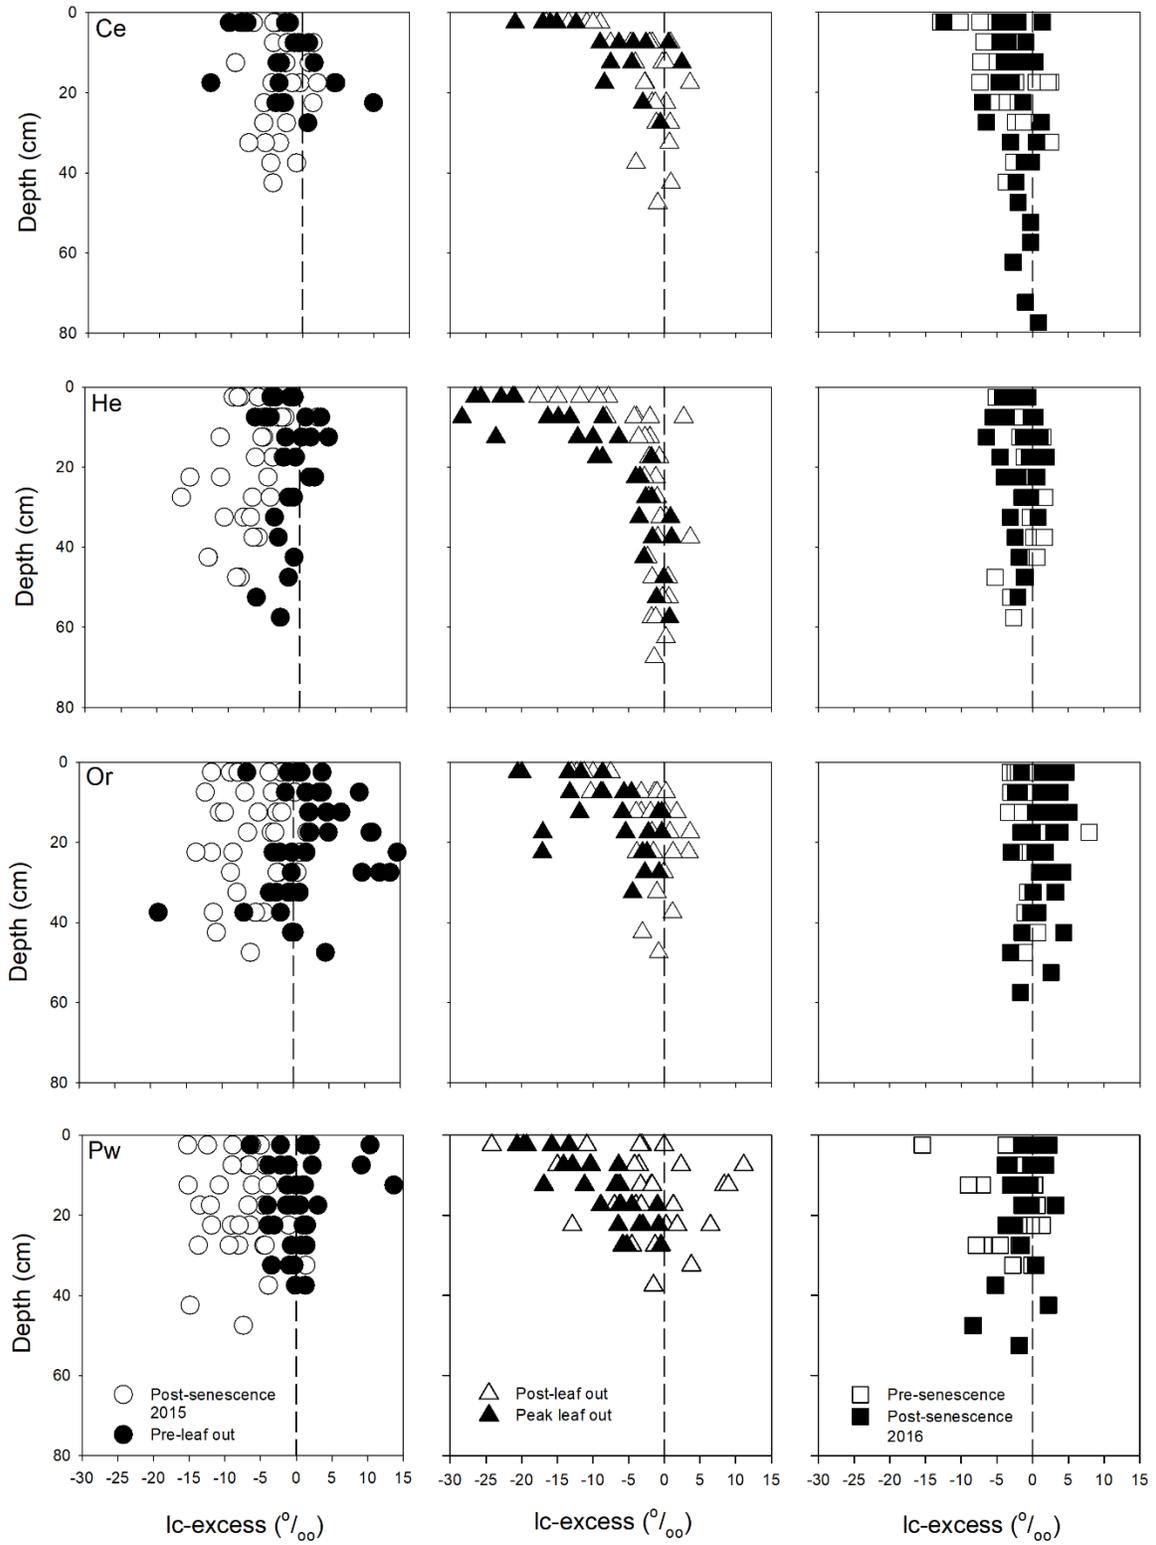

238 **3.3.3 Xylem water**

239 Xylem water isotopic composition changed during the growing season, with the trajectory of this change differing
240 between species (Fig. 4). Coniferous species saw gradual enrichment of ^2H and ^{18}O from pre-leaf out to post-
241 senescence in 2016. This transition was most pronounced for Ce and Pw, while He saw greater overlap in isotopic
242 compositions of post-leaf out, peak leaf and pre-senescence samples. Xylem water for Or had a different temporal

 256 **isotopically-depleted snowmelt sample measured in 2016.**

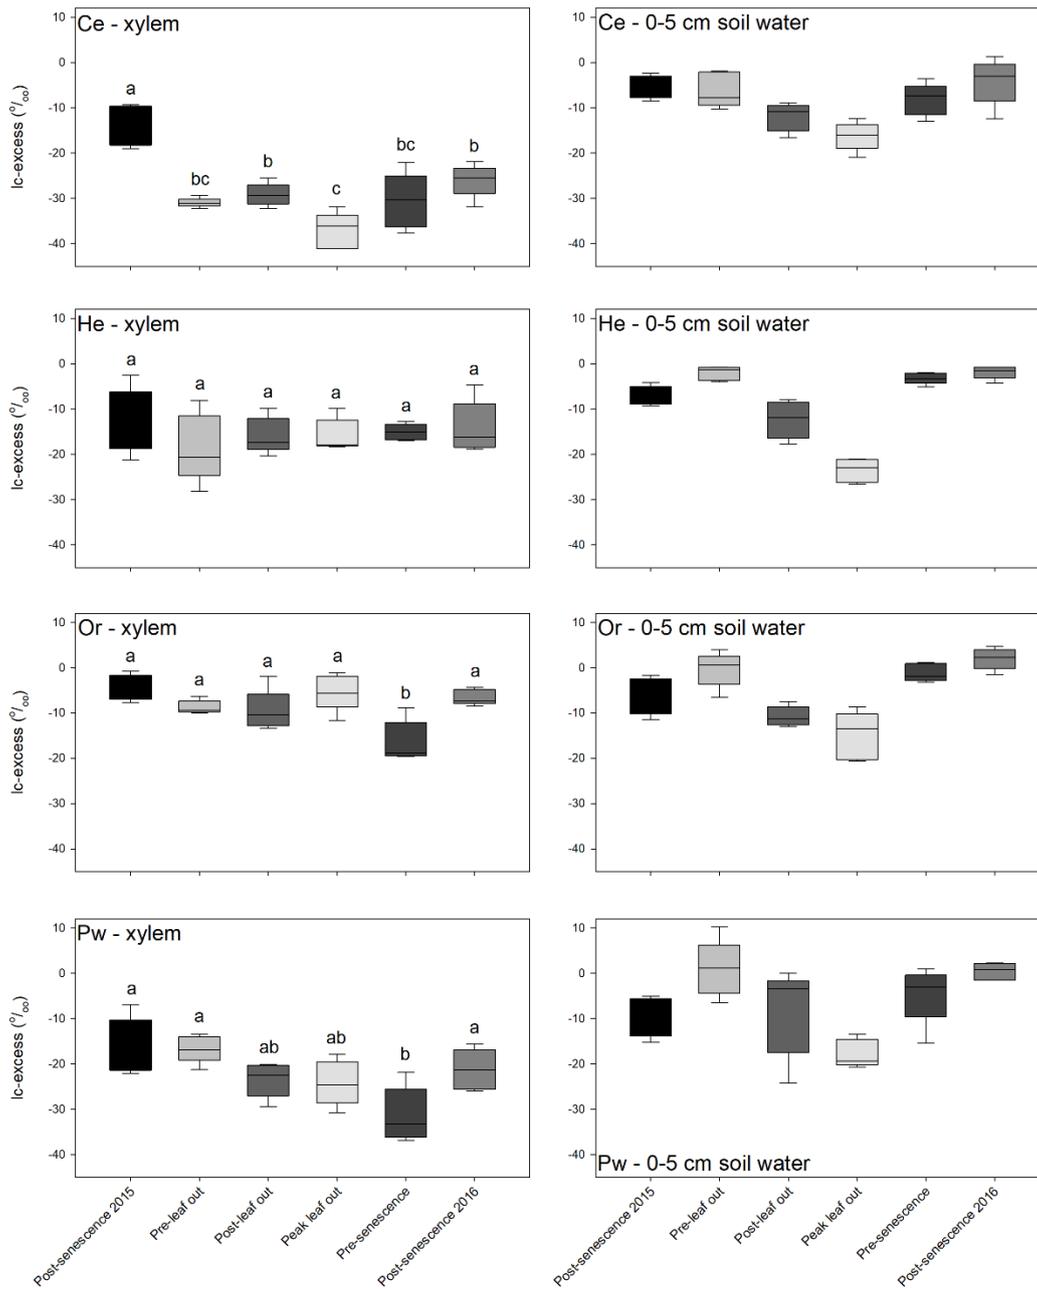

257 trajectory: both ^2H and ^{18}O became depleted from pre-leaf out to peak leaf out, followed by slight depletion of ^2H from peak
258 leaf out to pre-senescence, and slight depletion of ^{18}O from pre-senescence to post-senescence 2016.

259 Inter-specific differences and temporal changes in xylem water isotopic composition at PC-1 exceeded inter-tree
260 differences for a given species. Standard errors for xylem water for a given species and sampling date ranged from 0.39 to
261 5.13 ‰ for $\delta^2\text{H}$ and 0.06 to 0.79 ‰ for $\delta^{18}\text{O}$ and were similar to previously reported results. Retzlaff et al. (2001) found
262 insignificant differences in xylem water $\delta^2\text{H}$ between trees of a given species on a given measurement date, with standard
263 errors of 5 ‰ or less, while White and Smith (2015) found maximum standard errors for xylem water $\delta^2\text{H}$ and $\delta^{18}\text{O}$ of 5.49 ‰
264 and 0.84 ‰ for *Acer negundo* L. and 3.83 ‰ and 0.65 ‰ for *Betula nigra* L.

265 Shaded areas in Fig. 4 represent the typical range in evaporation line slopes (2.5 – 5, Benettin et al. 2018) originating from
266 the most depleted snowmelt sample ($\delta^{18}\text{O} = -9.48\text{‰}$, $\delta^2\text{H} = -118.10\text{‰}$) measured in spring 2016. These areas overlap most
267 xylem water samples for Ce and Pw, and many He and Or samples. Overlap with samples plotting above the steepest
268 evaporation line slope is obtained by shifting the origin of the evaporation lines along the LMWL to less-depleted snowmelt
269 samples.

270 There was little overlap of xylem water and bulk soil water in dual isotope space (Fig. A2), with the former having much
271 more negative $\delta^2\text{H}$ and to a lesser extent $\delta^{18}\text{O}$ relative to bulk soil water. There were pronounced inter-species differences in
272 xylem-water lc-excess values and their relationship with near-surface soil water (Fig. 5). Bulk soil water lc-excess at 0-5 cm
273 depth is shown, since near-surface soil experienced the greatest evaporative enrichment and thus the most negative lc-excess.
274 Xylem water lc-excess values for a given sampling period and tree species were normally distributed. One-way ANOVA
275 indicated no significant difference in xylem water lc-excess between sampling periods for He; conversely, other species
276 showed significant differences between some sampling periods. There were no significant inter-species differences in xylem
277 water lc-excess post-senescence 2015; however, distinctions emerged during subsequent sampling periods (Fig. 5, Table 2).
278 Lc-excess for Or xylem water was less negative compared to other species and showed considerable overlap between sampling
279 periods, with the most negative values at pre-senescence. They also often overlapped near-surface soil water lc-excess. Lc-
280 excess for He was similar for all sampling periods, although inter-tree variability declined progressively from pre-leaf out to
281 pre-senescence. There was occasional overlap of xylem water and near-surface bulk soil water lc-excess values. A different
282 relationship occurred for Ce and to a lesser extent Pw. Xylem water lc-excess for the former became more negative from post-
283 senescence 2015 to peak leaf out and then became more positive. Lc-excess for Ce was generally more negative than for other
284 species and was often more negative than the most evaporatively-enriched bulk soil water. Lc-excess for Pw also declined
285 from post-senescence 2015, becoming most negative at pre-senescence. Pw lc-excess also tended to fall outside the near-
286 surface bulk soil water range, although there was more overlap than for Ce xylem water.

287 Figure 6 presents soil water – xylem water offsets for $\delta^2\text{H}$ throughout the study period, defined as the difference between
288 the mean isotopic composition of soil water surrounding a sampled tree and xylem water for that tree. Offsets for $\delta^{18}\text{O}$ showed
289 similar patterns to those for $\delta^2\text{H}$ and are not shown. Intra-species differences in $\delta^2\text{H}$ offsets on a given sampling date could be

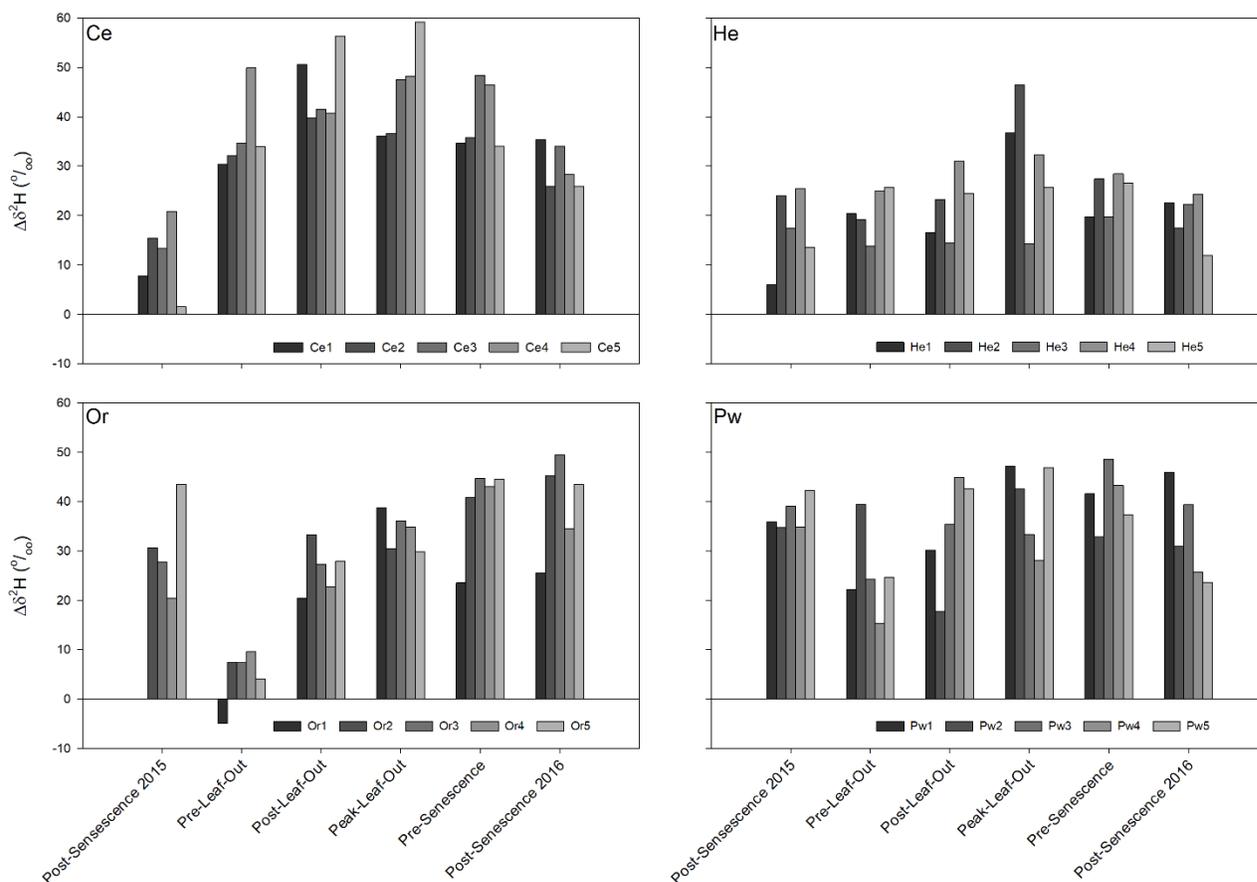

290

300 **Figure 6: Bulk soil water – xylem water $\delta^2\text{H}$ offsets ($\Delta\delta^2\text{H}$) for the sampled trees for each sampling period. See text for**
 301 **details on derivation of offsets. Positive values of $\Delta\delta^2\text{H}$ indicate that xylem water $\delta^2\text{H}$ is more negative than the**
 302 **corresponding mean bulk soil water $\delta^2\text{H}$.**

303 appreciable; however, inter-tree differences for a given species between sampling times did not appear to be
304 consistent. Temporal trajectories of these offsets showed inter-specific differences. Minimum offset values for Ce
305 occurred at post-senescence in 2015. Values rose to maxima either at post-leaf out or peak leaf out before declining
306 to post-senescence 2016. Offsets were more temporally-constant for He with maxima at peak leaf out. There was a
307 marked decline in the Or $\delta^2\text{H}$ offsets from 2015 post-senescence to pre-leaf out, followed by a gradual increase to
308 maxima at either pre-senescence or 2016 post-senescence. Pw had more temporally constant $\delta^2\text{H}$ offsets with
309 minima at either pre-leaf out or post-leaf out.

310 **4 Discussion**

311 **4.1 Temporal changes in the isotopic composition of soil water and xylem water in northern forests**

312 Bulk soil water isotopic composition exhibited similar trends between the different tree species' canopies. Near-
313 surface bulk soil water showed evaporative enrichment at peak leaf out, when SWCs reached a minimum (Fig. 4, Fig.
314 A1). Increased enrichment of bulk soil water relative to both the LMWL and corresponding mobile water with
315 declining SWCs was also observed by Zhao et al. (2013) in a loamy soil and by Sprenger et al. (2018b) at PC-1. The
316 bulk soil water slope in dual isotope space at PC-1 (5.3) agreed with values of 5.3 to 5.8 reported by Bowling et al.
317 (2017) for riparian soils in eastern Utah, while lc-excess values for near-surface soils were within the range given in
318 McCutcheon et al. (2017) for a semi-arid landscape in southwest Idaho. Bulk soil water isotopic composition following
319 senescence did not return to that of the previous year for all tree species (Fig. 4). Brooks et al. (2010) also noted an
320 inter-annual difference in soil water isotopic composition at the same location and depth for the same time of the year.

321 In contrast to similar trends in bulk soil water isotopic composition, xylem water showed intra- and inter-specific
322 differences in its displacement from both bulk soil water and the LMWL, and the temporal trajectory of that
323 composition throughout the growing season. Distinctions between xylem water and bulk soil water isotopic
324 compositions have been noted elsewhere. Brooks et al. (2010) found some plant water plotting beyond (and generally
325 below) the range of soil water $\delta^2\text{H}$ and $\delta^{18}\text{O}$ in dual isotope space but did not address it, with Goldsmith et al. (2012)
326 later suggesting this xylem water may have undergone further evaporation. Of the 17 isotope-based studies of plant
327 water use in temperate forests (similar to the PC-1 forest landscape) cited by Evaristo et al. (2015), 13 reported both
328 soil water and xylem water offsets (analogous to lc-excess used here) and four indicated xylem water offsets falling
329 below the range (i.e. were more negative) of the corresponding soil water offsets. More recent work (e.g. Geris et al.
330 2015, White and Smith 2015, Bowling et al. 2017, Hervé-Fernández et al. 2016, McCutcheon et al. 2017, Brinkmann
331 et al. 2019) also saw a distinction between the isotopic composition of xylem water and possible water sources that
332 might support transpiration. Pronounced soil water – plant water $\delta^2\text{H}$ offsets observed for all species at PC-1 (Fig. 6)
333 may be a general occurrence in temperate forests (Barbeta et al. 2020). However, these values exceeded the mean $\delta^2\text{H}$
334 offset of 10.6 ± 3.05 ‰ reported by Barbeta et al. (2020) for potted saplings of European beech (*Fagus sylvatica* L.).

335 Inter-specific differences in the degree to which the isotopic composition of xylem water deviates from soil water
336 have been observed in previous work. Gaines et al. (2016) found xylem water from oak (*Quercus*) and hickory (*Carya*)
337 trees tended to be more depleted in heavy isotopes than that of *Acer*. Xylem water ^2H for deciduous (beech and oak)

338 species in Switzerland was more depleted compared to spruce (Allen et al. 2019). Our results contrast with those of
339 White and Smith (2015), who saw limited inter-specific differences in the isotopic composition of plant water for box
340 elder (*Acer negundo* L.) or river birch (*Betula nigra* L.) at a given phenological stage in the foothills of the southern
341 Appalachian Mountains. Inter-specific variations in xylem water isotopic composition and its temporal changes at PC-
342 1 are likely not due to distinct environmental conditions for the different tree species, given the close proximity of the
343 sampled trees and similar soil conditions under the tree canopies.

344 **4.2 Potential drivers of plant – soil water isotopic differences**

345 Several factors have been suggested which might account for the observed differences between the isotopic
346 compositions of xylem water and bulk soil water in PC-1. Some of these may be common to all studied tree species,
347 while others cannot account for interspecific differences in the temporal trajectory of xylem water isotopic
348 composition during the study period.

349 **Errors in measuring xylem water composition.** We do not fully know what kind of vegetation water is mobilized
350 by cryogenic extraction (the approach used here to obtain xylem water samples), although it is usually assumed to
351 characterise xylem water (Tetzlaff et al. 2021). Millar et al. (2018) noted that cryogenic extraction resulted in more
352 depleted xylem water ^2H in spring wheat compared to other extraction methods. However, such an experimental issue
353 might be expected to influence measured xylem water isotopic compositions relatively consistently across species and
354 seasons and does not readily account for the inter-specific differences in xylem water $\delta^2\text{H}$ at PC-1. We have noted our
355 previous work that found no significant difference between the isotopic composition of soil water determined by
356 cryogenic extraction and the direct equilibration method (Tetzlaff et al. 2021), and others have found no consistent
357 evidence that cryogenic extraction alters xylem water's isotopic values (Barbeta et al. 2015, Grossiord et al. 2017).
358 Berry et al. (2017) suggested cavitation (air entry) during extraction of stem cores from trees and increasing time lags
359 between extraction and sealing the sample allows evaporation that fractionates the remaining sample water. Given the
360 rapid processing of xylem water samples at PC-1, the interspecific and temporal variation in xylem water isotopic
361 composition and its pronounced divergence from that of all other potential water sources, the displacement of xylem
362 water from bulk soil water is likely not attributable to a methodological issue.

363 **Unsampled water sources.** The possibility that bulk soil water does not represent root-absorbed water implies plants
364 selectively access an isotopically-fractionated portion of soil water (McCutcheon et al. 2017). However, soils in PC-
365 1 at peak leaf out were very dry while Ce xylem water lc-excess was much more negative than corresponding bulk
366 soil water (Fig. 7). Presence of sufficient soil water with very negative lc-excess values that could both match the
367 xylem water lc-excess and supply the tree's transpiration demand is unlikely under these circumstances. Trees may
368 have accessed water held in bedrock fractures that may be isotopically distinct from mobile soil water (Oshun et al.
369 2016). However, bedrock in PC-1 appears to be relatively unfractured, making it difficult to envisage sufficient water
370 held in fractures that could supply transpiration to a significant extent. This echoes Gaines et al. (2016), who saw little
371 evidence that roots within or below fractured bedrock in central Pennsylvania were consistent major contributors to
372 transpiration.

373 **Soil water content.** Evaristo et al. (2019) found differences between the isotopic compositions of plant water and low
374 mobility soil matrix water to be greatest under drought conditions and least at the transition from drought to rewetting.

375 The greatest differences between xylem water and bulk soil water isotopic compositions at PC-1 for Ce and He were
376 generally at peak leaf-out (Fig. 8) following a protracted decline in *SWCs* (Fig. 2); however, these differences persisted
377 following soil rewetting. Barbeta et al. (2020) found soil water – plant water $\delta^2\text{H}$ offsets increased with soil water
378 content, whereas the smallest offsets at PC-1 were either at post-senescence 2015 (Ce) or pre-leaf out (He, Or, Pw)
379 when *SWCs* would be relatively large as shown by previous work in PC-1 (e.g. Devito and Dillon 1993). Thus, the
380 influence of soil water content on differences in xylem water – soil water isotopic composition is unclear and deserves
381 further study.

382 **Storage effect.** Xylem water at a given time may be influenced by the isotopic composition of water taken up days or
383 months beforehand (McCutcheon et al. 2017, Penna et al. 2018, Evaristo et al. 2019). Sprenger et al. (2018c) estimated
384 median ages of total soil water storage in PC-1 ranging from 31 (25th percentile) to 74 days (75th percentile). This
385 storage effect may assist in explaining the frequent distinction between xylem water and bulk soil water *lc*-excess for
386 a given sampling period, and is supported by partial (He, Pw) or complete (Or) overlap of the *lc*-excess of post-
387 senescence 2015 soil water and pre-leaf out xylem water in 2016 (Fig. 7). However, Ce xylem water *lc*-excess was
388 much more negative than post-senescence 2015 bulk soil water, suggesting this mechanism may differ in importance
389 between tree species. Such a mechanism also fails to account for Ce and to some extent Pw *lc*-excess values that were
390 much more negative than any bulk soil water (Figs. 3 and 5).

391 **Interactions with carbonates or other geochemical and organic constituents.** These include isotopic effects
392 between soil water and cations/clay minerals (Oerter et al. 2014), organic matter (Orlowski et al. 2016), and rock-
393 water interactions (Lin and Horita 2016, Oshun et al. 2016) that differ for H and O. The potential for any or all of
394 these processes to induce differences in xylem water isotopic composition relative to soil water at PC-1 is not known,
395 although the low clay contents of PC-1 soils make significant isotopic effects with clay minerals unlikely (Sprenger
396 et al. 2018b). Regardless, it would be reasonable to expect that such processes would be similar in the soil water
397 surrounding the different tree species. Thus, they do not easily explain interspecific differences in the degree of
398 isotopic displacement of xylem water from the LMWL and bulk soil water.

399 **Fractionation during water uptake.** There is increasing recognition that differences between xylem water and soil
400 water isotopic compositions may result from isotopic fractionation induced by internal plant processes during water
401 uptake (Berry et al. 2017). Ellsworth and Williams (2007) showed that 12 of 16 species of woody plants demonstrated
402 H isotope fractionation at the soil-root interface, while Vargas et al. (2017) found plants discriminated against ^{18}O and
403 ^2H during water uptake with differences between $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in soil water relative to plant water increasing with
404 transpiration water loss. This would lead to more negative $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in plant water relative to soil water, as seen
405 at PC-1. It also suggests the greatest differences between xylem water and soil water *lc*-excess would be at peak leaf
406 out when PC-1 soils were at their driest (Fig. A1). This was the case for Ce which showed clear separation between
407 soil and xylem water *lc*-excess at peak leaf out (Fig. 5). This also occurred at pre-senescence for Pw; however, there
408 was overlap between soil water and xylem water *lc*-excess for Or and He. Thus, the potential for fractionation during
409 water uptake may be a major cause of deviations between soil water and xylem water isotopic compositions and may
410 differ between tree species in northern mixed forests.

411 **Fractionation following uptake.** Changes in the isotopic composition of xylem water relative to that of soil water
412 have been attributed to such processes as xylem-phloem exchange during water stress (Cernusak et al. 2005, Bertrand
413 et al. 2014), isotopic depletion of storage water in xylem tissue compared to water moving via conductive tissues
414 (Barbeta et al. 2020), H fractionation when water movement in the tree occurs predominantly via symplastic rather
415 than via apoplastic pathways (Lin and Sternberg 1993, Ellsworth and Williams 2007), and fractionation within the
416 tree's leaves which then impacts the isotopic composition of phloem sap (Farquhar et al. 2007). We are not able to
417 assess influence of any of these processes on xylem water composition at PC-1. There is also the potential for
418 evaporation through the tree's bark (Dawson and Ehleringer 1991, Smith et al. 1997). Bowling et al. (2017) thought
419 this could not explain evaporative enrichment of xylem water in their study given the large stems sampled and removal
420 of bark from all stem samples, as was the case at PC-1. Nevertheless, the overlap between many xylem water samples
421 and the range in evaporation lines originating from the most isotopically-depleted snowmelt sample (Fig. 4) suggests
422 that uptake of snowmelt water at the start of the growing season and subsequent evaporative enrichment of xylem
423 water post-uptake cannot be ruled out.

424 **Plant physiology, rooting behaviour and water use strategies.** White and Smith (2015) noted a divergence in xylem
425 water $\delta^2\text{H}$ between species from the beginning of the dormant period. This was similar to PC-1, where Or xylem water
426 generally became more depleted moving from pre-leaf out to post-senescence 2016 while the reverse trend occurred
427 for Ce, Pw and to a lesser extent He (Fig. 5). White and Smith (2015) suggested such divergence may be due to
428 differing periods of inactivity for the two species they studied. This may be relevant to deciduous species such as Or
429 that experiences leaf-out and senescence and whose timing and intensity of water use may differ from that of
430 coniferous species. Philips and Ehleringer (1995) found evaporatively enriched stem water in big-toothed maple (*Acer*
431 *grandidentatum* Nutt.) and Gambel's oak (*Quercus gambelii*) before leaf flush and saw stem water move closer to the
432 LMWL at full leaf out. We found similar results for Or where lc-excess became less negative at peak leaf out relative
433 to pre-leaf out, although the difference was not statistically significant (Fig. 5). Gaines et al. (2016) noted xylem water
434 tended to be more depleted in heavy isotopes from larger trees compared to smaller ones. The reverse was the case at
435 PC-1, where the smallest trees (Ce, Table 1) showed the most depleted xylem water ^2H . Shallow soils overlying
436 bedrock at PC-1 would likely constrain the ability of different tree species to develop marked contrasts in rooting
437 architectures (e.g. deep tap roots for some species vs. shallow root networks for others). However, interspecific
438 differences in the rooting behaviour and water use strategies of trees studied at PC-1 is unknown. The issue of root
439 activity is one of the most difficult dilemmas facing plant ecology and ecohydrology (Beyer et al. 2016). Inter-specific
440 differences in plant water lc-excess may reflect variations in rooting characteristics and shifts in the depth of water
441 uptake in response to changes in water availability (McCutcheon et al. 2017, Dubbert and Werner 2019). This topic
442 should be a focus of further work in northern forest landscapes.

443 Despite considering these manifold possible processes, the cause of isotopic distinction between xylem water and
444 potential water sources remains unclear. Nevertheless, some mechanisms noted above (e.g. fractionation at the plant
445 root, evaporation through the bark) are more plausible under conditions at PC-1 than others (e.g. xylem water
446 accessing an unsampled source of water not reflected in bulk soil water isotope values, errors in determination of
447 xylem water isotopic composition).

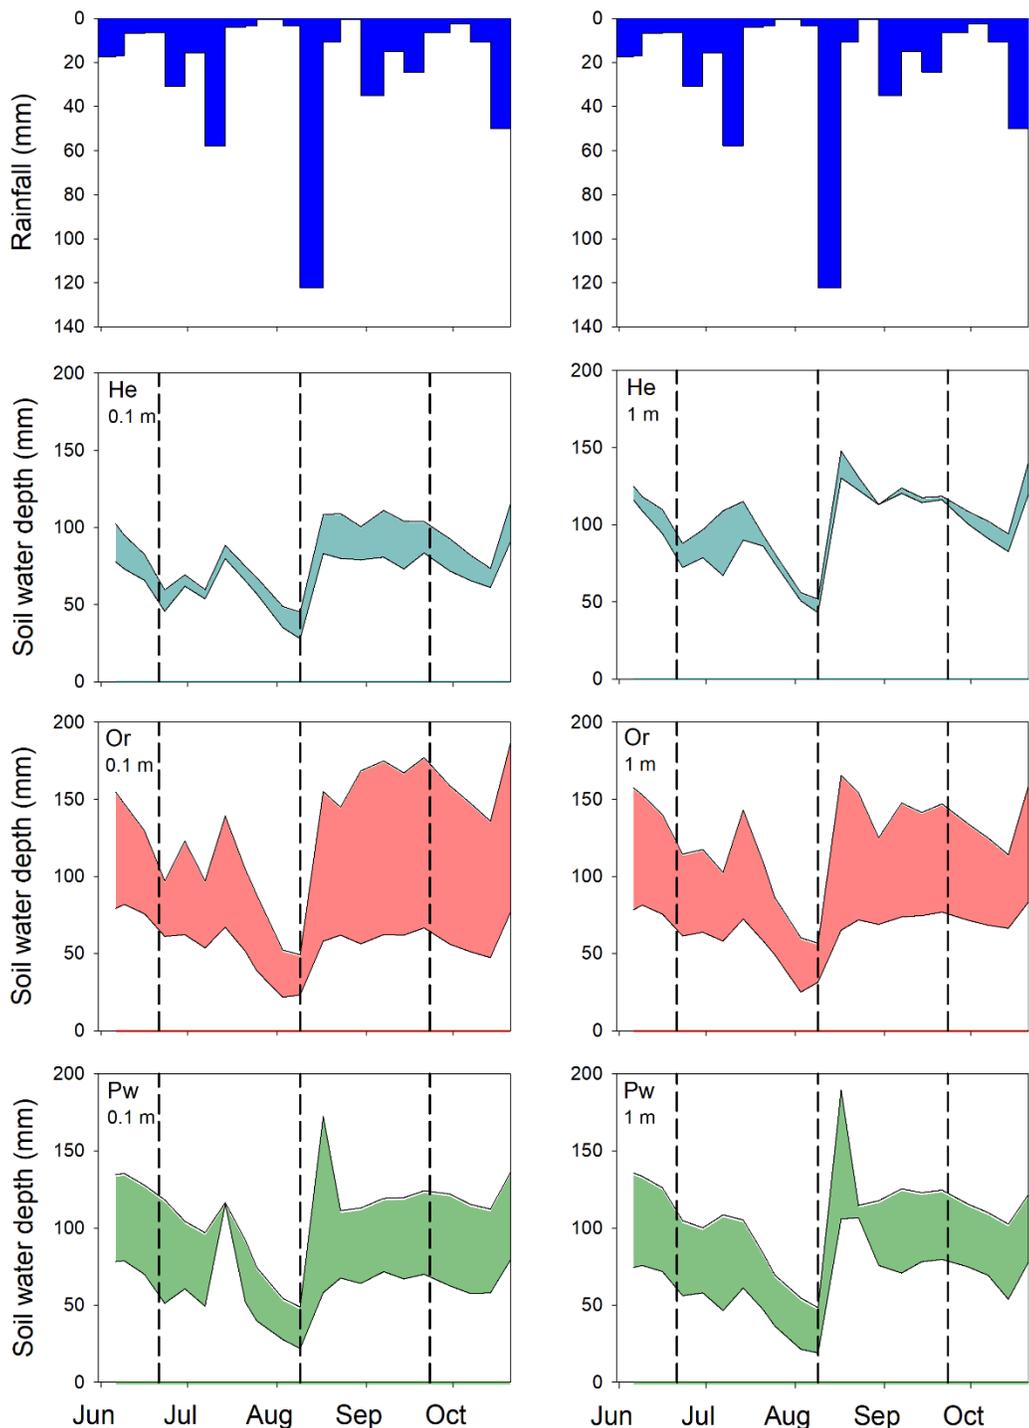

448 Regardless, our results provide novel insight into potential changes in hydroecological fluxes in northern mixed
449 forests in response to hydroclimatic change. The landscape surrounding PC-1 in Ontario is projected to experience
450 increases in summer temperatures above the 1971-2000 baseline of between 2 and 8°C (and presumably
451 accompanying increases in evaporation) and decreases in summer rainfall of up to 25 mm for the 2071-2100 period
452 (McDermid et al. 2015). The 2016 growing season was a particularly dry one; thus, the small *SWCs* and associated
453 inter-specific differences in xylem water – bulk soil water isotopic relationships presented here may become typical
454 of future conditions in this and similar northern forest landscapes across the northern hemisphere.

455 **5 Conclusion**

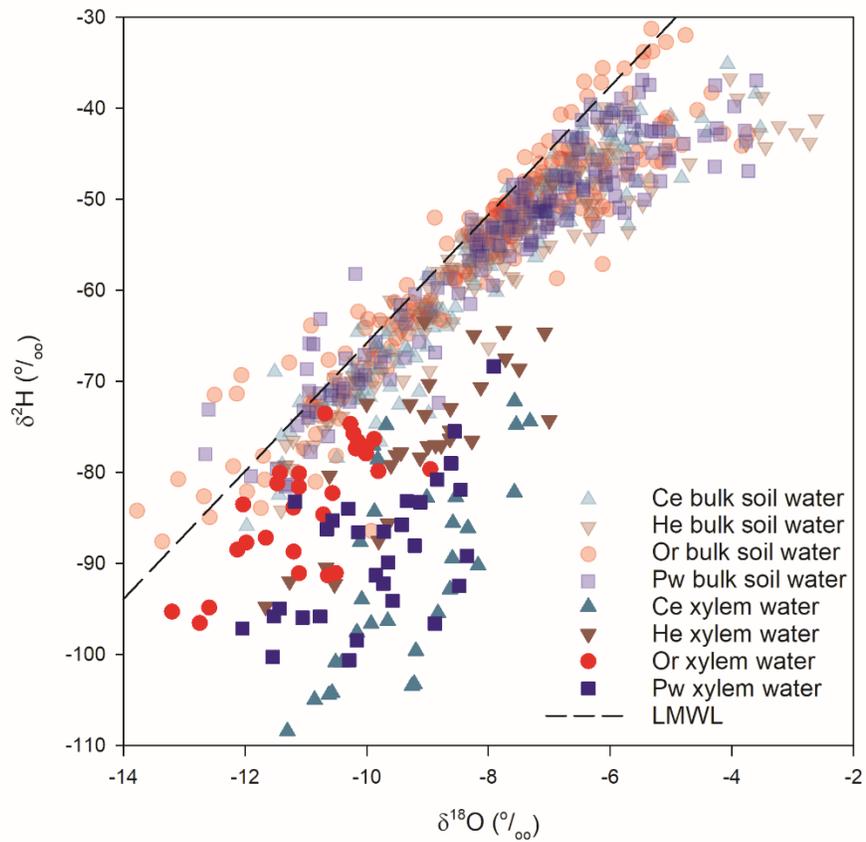

456 We examined the co-evolution of xylem water and bulk soil water isotopic compositions during the growing season
457 for four tree species in a northern mixed forest. The major findings are as follows:

- 458 1 Bulk soil water isotopic composition showed similar temporal changes below the canopies of all tree species, with
459 evaporative enrichment of near-surface soil water from pre-leaf out to peak leaf out followed by a return to values
460 along the LMWL at post-senescence.
- 461 2 In contrast, xylem water isotopic composition showed inter-specific differences in both the degree of its
462 displacement from the LMWL and bulk soil water, and the temporal trajectory of its changes from pre-leaf out to
463 post-senescence.
- 464 3 This trajectory differed between deciduous and coniferous species. Red oak xylem water experienced depletion in
465 both ²H and ¹⁸O during the growing season, while conifer xylem water showed isotopic enrichment. This may be
466 related to inter-specific variations in the timing and intensity of growing season water use in northern mixed forests
467 and requires further study.
- 468 4 A review of possible reasons for distinctions between xylem water and soil water isotopic compositions for these
469 tree species suggested that some mechanisms (e.g. fractionation at the tree root, evaporation through the bark)
470 were more plausible than others (e.g. an unsampled source of water taken up during transpiration) when considered
471 in the context of the study site's characteristics. Nevertheless, inter-specific differences in the degree to which
472 these mechanisms may account for the varying relationships between xylem water and soil water may be related
473 to the physiology, rooting behaviour and water use strategies of deciduous and coniferous trees. These should be
474 explored in further research as we attempt to understand more fully how trees take up water during transpiration
475 in order to predict their response to anticipated hydroclimatic changes in northern forest landscapes.
