Abstract

The assessment of future impacts of climate change is associated with a cascade of uncertainty linked to the modelling chain employed in assessing local scale changes. Understanding and quantifying this cascade is essential to developing effective adaptation actions. We evaluate and quantify uncertainties in future flood quantiles associated with climate change for four Irish catchments, incorporating within our modelling chain uncertainties associated with 12 Global Climate Models contained in the Coupled Model Intercomparison Project Phase 6, five different bias correction approaches, hydrological model parameter uncertainty and use of three different extreme value distributions for flood frequency analysis. Results indicate increased flood ~~risk~~hazard in all catchments for different Shared Socioeconomic Pathways (SSPs), with changes in flooding ~~related to~~consistent with changes in annual maximum precipitation. We use ~~a sensitivity test based on the additive chains and~~ analysis of variance (ANOVA) to quantify and decompose uncertainties and their interactions in estimating selected flood quantiles ~~in the 2080s~~ for each catchment. We find that ~~not only do the contributions of different sources of uncertainty vary by catchment, but that~~ the dominant sources of uncertainty ~~vary between catchments, calling into question the ability to generalise about the importance of different components of the cascade~~ can be very different on a catchment by catchment basis. While uncertainties in future projections are widely assumed to be dominated by the ensemble of ~~uncertainty~~climate models used, we find that in future flood risk. ~~For two one~~ of our catchments, uncertainties associated with bias correction methods ~~and~~dominate, while in another uncertainty associated with use of different extreme value distributions outweigh the uncertainty associated with the ensemble of climate models. ~~For all catchments and flood quantiles examined, hydrological model parameter~~These findings highlight the inability to generalise a priori about the importance of different components of the cascade of uncertainty is the least important component of our modelling chain, while the uncertainties derived from future flood hazard at the catchment scale. Moreover, we find that the interaction of components of the modelling chain employed are substantial (>20 percent of overall uncertainty in two catchments). While our sample is small, there is evidence that the dominant components of the cascade of uncertainty may be linked to catchment characteristics and rainfall-runoff processes. Future work that seeks to further explore the ~~dominant components~~characteristics of the uncertainty cascade as

they relate to catchment characteristics may provide insight into a-priori identifying the key components of modelling chains to be ~~included~~targeted in climate change impact assessments.

Keywords: modelling, flood, climate change, uncertainty, impact, bias correction, GLUE, GR4J

35 1 Introduction

Climate change is likely to increasingly affect hydrological regimes and flood hazards over coming decades. ~~Significant~~Considerable changes in atmospheric temperature, precipitation, humidity, and circulation are expected, which may result in increasing extreme events, including floods (IPCC, 2013). ~~According to Rojas et al. (2013), flood frequency in Europe will increase due to climate change, with significant socio-economic implications for the region. Blöschl et al., (2017) and Blöschl et al., (2019) conclude that the timing and magnitude of European floods are shifting due to climate change and its consequences are not uniform across the region, with north-western Europe experiencing earlier and higher flood peaks. Modelling and understanding of catchment scale flood risk. According to Rojas et al. (2013), flood frequency in Europe will increase due to climate change, with significant socio-economic implications for the region. Blöschl et al. (2017) and Blöschl et al. (2019) conclude that the timing and magnitude of European floods have shifted due to climate change and its~~
40 ~~consequences are not uniform across the region, with north-western Europe experiencing earlier and higher flood peaks. Modelling and understanding of catchment scale flood hazard~~ projections is therefore an important endeavour for informing adaptation strategies.
45 ~~consequences are not uniform across the region, with north-western Europe experiencing earlier and higher flood peaks. Modelling and understanding of catchment scale flood hazard~~

~~However, this task~~Climate change impact assessment is subject to considerable uncertainties (Wilby and Dessai, 2010; Smith et al., 2018); ~~Blöschl et al. (2019) recently highlighted uncertainty in hydrology as one of the 25 challenges in hydrological science.~~ Traditional or top-down climate change impact assessments typically follow a modelling chain where output from Global Climate Models (GCMs), forced with estimates of future greenhouse gas concentrations, are extracted, and scaled to represent a study catchment. Hydrological models, calibrated for current conditions, are then forced with these GCM outputs to create discharge series spanning multiple decades into the future. When assessing flood ~~risk~~hazard, extreme value
50 distributions are typically fitted to samples of extreme events (e.g. annual maximum flood series) representing current and future climates to evaluate changes in the characteristics of flooding. This modelling chain is replete with uncertainties that propagate and interact, resulting in potential large ranges ~~of~~in projected change at the catchment scale (e.g. Meresa, 2019) that can impede decision making (Smith et al., 2018). ~~Over recent decades many~~

60 Numerous studies have attempted to quantify the uncertainties in future climate change impacts due to the use of different climate models (e.g. ~~Knutti & Sedláček, 2013~~Knutti & Sedláček, 2013), natural variability (e.g. ~~Hughes et al., 2011~~Giuntoli et al., 2018; Hughes et al., 2011), bias correction techniques (e.g. ~~Kay et al., 2009; Saini et al., 2015; Soriano et al., 2019~~Kay

Formatted: Font: 12 pt

et al., 2009; Saini et al., 2015; Soriano et al., 2019), downscaling approaches (e.g. Fowler et al., 2007; Fowler et al., 2007; Gutmann et al., 2014; Gutmann et al., 2014), hydrological modelling uncertainties (e.g. Wilby & Harris, 2006; (e.g. Wilby & Harris, 2006; Bastola et al., 2011; Meresa & Romanowicz, 2017; Broderick et al., 2019) Addor et al., 2014; Meresa & Romanowicz, 2017; Broderick et al., 2019) and the application of different extreme value distributions for flood risk hazard estimation (e.g. Meresa & Romanowicz, 2017; Lawrence, 2020). Findings from such studies confirm that the dominant source of uncertainty varies across studies. For example, Jobst et al. (2018) concluded that the GCM structure is the dominant contributor followed by emission scenario, bias correction, and hydrological model structure in New Zealand catchments. Peleg et al. (2015) found that the hydrological regimes are highly sensitive to changes in convective precipitation in eastern Mediterranean catchments. Gosling et al. (2011) evaluated seasonal flow changes in UK catchments and found greater uncertainty in future estimates due to climate models than hydrological models. In Norwegian catchments Lawrence (2020) highlighted that climate models and frequency models are dominant sources of uncertainty in future flood projections. Therefore, the key components of the uncertainty cascade and their contributions tend to vary depend on the region, precipitation type, and catchment.

Recognition of the uncertainties inherent in future climate risk have change impacts has also given rise to novel approaches to decision-making that embrace uncertainties (e.g. Wilby & Murphy, 2019; Clark et al., 2016). Rather than aiming to derive precise assessments of future risk, such approaches aim to stress test and evaluate adaptation options, in static or dynamic ways (Mazzorana et al., 2012), to identify actions that are functional across a range of plausible future conditions, rather than optimised to a certain outcome (e.g. structured decision making (SDM), robust decision making, decision scaling, adaptation pathways). Each of these approaches require the cascade of uncertainty to be evaluated or navigated in ways that can better inform adaptation. For example, in Ireland Shepherd et al., (2018) recommend a storyline approach for navigating uncertainty, whereby examination of recent, notable extremes and the development of plausible narratives of change in their drivers enable novel assessment of future changes, placing emphasis on physical processes. Each of these approaches require the cascade of uncertainty to be evaluated or navigated in ways that can better inform adaptation. For example, Broderick et al. (2019) employ a scenario neutral framework (Prudhomme et al., 2011) to evaluate design allowances for flood defences taking into account uncertainties derived from a large climate model ensemble, natural variability and hydrological models.

Whether employing traditional impact led or novel decision centric approaches, it is critical that key components of the cascade of uncertainty are adequately included. Research over the past two decades clearly shows that methodological choices made in assessing future climate change fundamentally impact on the portrayal of climate risk (Clark et al., 2016; Melsen et al., 2019). Top-down approaches must a-priori decide on the components of the modelling chain to include. Including all relevant components is typically a very resource expensive task (Smith et al., 2018) and it may not be apparent at the outset which components of the modelling chain to include for specific catchments. For bottom up approaches, such as the scenario neutral method (Broderick et al., 2019), the modeller is forced to choose which aspects of uncertainty to prioritise in assessing

sensitivity to future changes. Again, this may not be apparent from the outset. It is widely acknowledged that climate models exhibit biases in their outputs (Krinner & Flanner, 2018; Giorgi & Gao, 2018), with numerous studies highlighting the need to post-process climate model output before use in simulating hydrological response (Ehret et al., 2012; Teng et al., 2012; Osuch et al., 2017; Meresa & Romanowicz, 2017). Dobler et al. (2012) suggest that the dominant components of the modelling chain may further vary depending on which part of the flow regime (low, mean, high flows) is of interest. They highlight, for example, that the importance of bias correction approaches to the overall uncertainty in hydrological response increases for high flows. Moreover, deep uncertainty can arise by virtue of the ad-hoc ways in which components of possible modelling chains are assembled and characterised within the overall modelling framework adopted (Wilby and Murphy 2019). Yet there are no established ways of sampling from the hierarchy of models used to evaluate impacts of climate change (Clark et al., 2016). Therefore, an important step in better integrating future climate risk into decision-making is the development of techniques that allow the contribution of different components of uncertainty and their interactions to be quantified and partitioned to help scientists and decision makers better navigate the cascade of uncertainty. In this regard ANOVA (ANalysis Of Variance) based techniques, which can be used to decompose sources of uncertainty and their interaction, offer significant utility (e.g. Kay et al., 2009; Vetter et al., 2016; Hattermann et al., 2018; Meresa, 2020).

In this study, we explore uncertainties in future flood risk for four Irish catchments and employ variance decomposition to quantify the contribution of various sources of uncertainty, together with their interaction, to the overall uncertainty in flood risk. In doing so we place emphasis on evaluating the uncertainties derived from: i) climate models in the newly available Coupled Model Inter-comparison Project Phase 6 (CMIP6) ensemble (Wyser et al., 2019); ii) widely used bias correction techniques; iii) hydrological model parameter uncertainty, and iv) the use of different extreme value distributions. The remainder of the paper is organised as follows: Section 2 outlines the study design and data/methods employed. Section 3 presents key results, exploring uncertainties for key steps in the modelling chain examined, together with their contributions and interactions to the full range of project change in flood risk. Section 4 provides a discussion of key insights, limitations and future directions before drawing main conclusions in Section 5.

2 Modelling and numerical experiments

Our study design is illustrated in Figure 1. We quantify uncertainties and their interaction in projected flood hazards using 12 Global Climate Models (GCMs) contained in the Coupled Model Inter-comparison Project Phase 6 (CMIP6) ensemble (<https://esgf-node.llnl.gov/search/cmip6/>), forced using three Shared Socioeconomic Pathways (SSP) scenarios. We use five bias correction techniques (Change factor (CF), Double Gamma Distribution Quantile (DGQM), Birnbaum distribution Quantile-mapping (BQM), Single Gamma Distribution Quantile (SGQM), and Empirical Quantile (EQM)) to post-process climate model outputs (daily precipitation and air temperature time series). The daily bias corrected precipitation and temperature data are used as input to the Génie Rural à 4 paramètres Journalier (GR4J) hydrological model (Perrin et al., 2003).

GR4J has been previously applied to simulate high flows in Ireland, showing good performance in capturing a range of hydrological signatures across diverse catchments (Broderick et al., 2019). The Generalized Likelihood Uncertainty Estimation (GLUE) technique is used to quantify GR4J parameter uncertainty. In assessing future flood hazard the sensitivity of results to different extreme value distributions is examined. In addition to evaluating each source of uncertainty independently, we use variance decomposition to quantify the contribution of each methodological choice and their interactions to the overall uncertainty in assessing flood risk. The climate change impact is evaluated based on relative future changes in the magnitude of floods for the 2020s (2010-2039), 2050s (2040-2069) and 2080s (2070-2099) with respect to the reference period (1976-2005). The following sections provide further details on the study catchments and each stage of the modelling chain employed.

2.1 Study catchments and hydro-climate datasets

Simulations are undertaken for four catchments (Boyne, Blackwater, Newport and Slaney), each representing different flood response types across the Ireland as evaluated by Broderick et al. (2019). Their location, together with a summary of hydro-climatic conditions for each catchment is summarized in Table 1 and Figure 2. Catchment area ranges from 146 km² (Newport) to 2447 km² (Boyne), while elevation ranges from 56 m (Newport) to 112 m (Blackwater). For each catchment we use gridded (1 × 1 km) daily precipitation and temperature data (Walsh, 2012) area averaged for the period 1976-2005 to provide a single representative baseline series for each catchment. Daily potential evapotranspiration is derived using air temperature and elevation following the method of Hamon (1964). This approach is favored over less parsimonious but more physically based methods (e.g. Penman-Monteith), which have greater data input requirements (e.g. wind speed, humidity) not available for all study catchments. Daily discharge data for each catchment was obtained from the Office of Public Works (OPW) (<http://www.epa.ie/hydronet/>).

2.2 Climate Projections and Bias Correction

Daily precipitation (pr) and air temperature (tas) time series for the period 1971-2100 were extracted for 12 members of the CMIP6 ensemble (<https://esgf-node.llnl.gov/search/cmip6/>) forced by each of three Shared Socioeconomic Pathway (SSP) (SSP1, SSP3 and SSP5) scenarios (see Table 2 for details). For each catchment daily precipitation and air temperature were extracted from the closest land based GCM grid overlying the catchment centroid. It is widely acknowledged that climate models exhibit biases in their outputs (Krinner & Flanner, 2018; Giorgi & Gao, 2018), with numerous studies highlighting the need to post-process climate model output before use in simulating hydrological response (Ehret et al., 2012; Teng et al., 2012; Osuch et al., 2015; Meresa & Romanowicz, 2017). However, there is still no consensus on which bias correction techniques are most effective, nor in how bias correction techniques can modify future climate change signals. For instance, Teutschbein & Seibert (2013) and Yang et al. (2010) showed distribution mapping based on theoretical distributions outperforms other bias correction methods. Similarly, Berg et al. (2012) and Chen et al. (2013) and Berg et al. (2012) Chen et al. (2013) show that theoretical distribution mapping performs similar to, or marginally better than, empirical quantile mapping. On the contrary,

160 Gudmundsson et al. (2012), Gutjahr & Heinemann, (2013) and Lafon et al. (2013), show that empirical quantile mapping demonstrates higher skill than theoretical distribution mapping in systematically correcting precipitation.

165 Moreover, deep uncertainty can arise by virtue of the ad-hoc ways in which components of possible modelling chains are assembled and characterised within the overall modelling framework adopted (Wilby and Murphy 2019). Yet there are currently no established ways of sampling from the hierarchy of models used to evaluate impacts of climate change (Clark et al., 2016). Therefore, an important step in better integrating future climate risk into decision-making is quantifying and partitioning the contribution of different components of uncertainty and their interactions to help scientists and decision makers better navigate the cascade of uncertainty by identifying contributing sources that should be more fully explored (Smith et al., 2018). In this regard ANOVA (ANalysis Of Variance) based techniques, which can be used to decompose sources of uncertainty and their interaction, offer considerable utility (e.g. Kay et al., 2009; Vetter et al., 2016; Hattermann et al., 2018; Meresa, 2020). In this study, we explore uncertainties in future flood hazard for four catchments, representative of different flood response types, in Ireland and employ additive chains and variance decomposition to quantify and examine the contribution of various sources of uncertainty, together with their interaction, to the overall uncertainty in flood hazard projections. In doing so we place emphasis on evaluating the uncertainties derived from: i) climate models in the newly available Coupled Model Inter-comparison Project Phase 6 (CMIP6) ensemble (Wyser et al., 2019); ii) widely used bias correction techniques; iii) hydrological model parameter uncertainty, and iv) the use of different extreme value distributions. The remainder of the paper is organised as follows; Section 2 outlines the study design and data/methods employed, Section 3 presents key results, exploring uncertainties for key steps in the modelling chain examined, together with their contributions and interactions to the full range of projected change in flood risk. Section 4 provides a discussion of key insights, limitations and future directions before drawing main conclusions in Section 5.

2 Models and Study Design

Our study design is illustrated in Figure 1. We quantify uncertainties and their interaction in projected flood hazards using 12 Global Climate Models (GCMs) contained in the Coupled Model Inter-comparison Project Phase 6 (CMIP6) ensemble (<https://esgf-node.llnl.gov/search/cmip6/>), forced using three Shared Socioeconomic Pathways (SSP) scenarios. We use five bias correction techniques (Change factor (CF), Double Gamma Distribution Quantile (DGQM), Birnbaum distribution Quantile mapping (BQM), Single Gamma Distribution Quantile (SGQM), and Empirical Quantile (EQM)) to post-process climate model outputs (daily precipitation and air temperature time series). The daily bias corrected precipitation and temperature data are used as input to the Génie Rural à 4 paramètres Journalier (GR4J) hydrological model (Perrin et al., 2003). The Generalized Likelihood Uncertainty Estimation (GLUE) technique is used to quantify GR4J parameter uncertainty. In assessing future flood hazard the sensitivity of results to different extreme value distributions is examined. In addition to evaluating each source of uncertainty independently, we use variance decomposition to quantify the contribution of each

185
190

methodological choice and their interactions to the overall uncertainty in assessing flood risk. The climate change impact is evaluated based on relative future changes in the magnitude of floods for the 2020s (2010-2039), 2050s (2040-2069) and 2080s (2070-2099) with respect to the reference period (1976-2005). The following sections provide further details on the study catchments and each stage of the modelling chain employed.

2.1 Study catchments and hydro-climate datasets

Simulations are undertaken for four catchments (Boyne, Blackwater, Newport and Slaney), representing different flood response types across the Ireland (Broderick et al., 2019). Their location, together with a summary of hydro-climatic conditions for each catchment is summarized in Table 1 and Figure 2. Catchment area ranges from 146 km² (Newport) to 2447 km² (Boyne), while mean elevation ranges from 56 m (Newport) to 112 m (Blackwater). For each catchment we use gridded (1 × 1 km) daily precipitation and temperature data (Walsh, 2012) area averaged for the period 1976-2005 to provide a single representative baseline series for each catchment. Daily potential evapotranspiration is derived using air temperature and elevation following the method of Hamon (1964). This approach is favored over less parsimonious but more physically based methods (e.g. Penman-Monteith), which have greater data input requirements (e.g. wind speed, humidity) not available for all study catchments. Daily discharge data for each catchment was obtained from the Office of Public Works (OPW) (<http://www.epa.ie/hydronet/>).

2.2 Climate Projections and Bias Correction

Daily precipitation (pr) and air temperature (tas) time series for the period 1971-2100 were extracted for 12 members of the CMIP6 ensemble (<https://esgf-node.llnl.gov/search/cmip6/>) forced by each of three Shared Socioeconomic Pathway (SSP) (Given these varied results, we SSP126, SSP370 and SSP585) scenarios (see Table 2 for details). For each catchment daily precipitation and air temperature were extracted from the closest land based GCM grid overlying the catchment centroid. We employ five commonly used techniques to bias correct raw climate model output and to examine the contribution of the selected bias correction methods to the total uncertainty in future flood hazard.

2.2.1 Change factor /delta change (CF)

The change factor technique applies multiplicative (for precipitation) and/or additive (for temperature) procedures for correcting raw model output. This involves correcting simulated daily precipitation ($P_{fut,corr}$) by multiplying the ratio of observed precipitation (P_{obs}) and reference precipitation simulation ($P_{ref,raw}$) to future simulations of raw climate model precipitation ($P_{fur,raw}$). For correcting future air temperature ($T_{fut,corr}$), the difference in observed air temperature (T_{obs}) and simulated temperature in the reference period ($T_{ref,raw}$) is added to raw climate output ($T_{fur,raw}$).

$$P_{fut,corr} = P_{fur,raw} * \frac{P_{obs}}{P_{ref,raw}} \quad (1)$$

$$T_{fut,corr} = T_{fur,raw} + (T_{obs} - T_{ref,raw}) \quad (2)$$

2.2.2 Empirical quantile mapping (EQM)

225 Empirical quantile mapping is based on pair-wise comparison between the empirical cumulative density functions (ecdf) of observed and simulated daily precipitation time series during the reference period (1976-2005). This is a purely empirical approach with direct matching of the histogram of the observed precipitation to the future period. Future precipitation and temperature are corrected using the inverse of the ecdf ($ecdf^{-1}$) and fitted ecdf $ecdf_{hst,m}$.

$$230 P_{hst,m}^{cor} = (ecdf_{obs,m}^{-1}(ecdf_{hst,m}(P_{hst,m}))) \quad (3)$$

$$T_{hst,m}^{cor} = (ecdf_{obs,m}^{-1}(ecdf_{hst,m}(T_{hst,m}))) \quad (4)$$

The non-parametric quantile matching was performed first in the reference period (m, modeling period) using an exponential transfer function assumption. Then the calibrated coefficients were used to correct the future daily precipitation and air temperature.

2.2.3 Distribution Quantile Mapping (DQM)

Distribution quantile mapping is a distribution parameter dependant bias correction technique. The parameters are extracted by fitting Gamma distribution to observed and simulated time series data, and matching its corresponding quantiles from the observed and raw climate model output in the reference period (1976-2005) (Piani et al., 2010). We applied two types of DQM to correct climate biases: Single Gamma Distribution Quantile Mapping (SGDQM) and Double Gamma Distribution Quantile Mapping (DGDQM), together with the Birnbaum-Sanders distribution method (BSM) (Marzena Osuch et al., 2016). These methods also allow for the any excess in the number of dry, drizzle and wet days to be considered and corrected. In the case of SGQM, the first step is fitting a Gamma distribution to the upper 75 % of daily observed and raw climate output precipitation distribution. Whereas in the DGDQM, the Gamma distribution is fitted to both the upper ≥ 75 % and to the lower < 75 % of the daily observed and raw climate output precipitation in the reference period (1976-2005). In both cases, non-rain days were removed and only wet days were considered. Similarly, BSM used the Birnbaum-Sanders distribution to transfer the precipitation quantile from the observed time series to raw output of the GCMs in the reference period.

$$250 P_{corr} = F_{dg}^{-1}(F_{dg}(P_{raw}(t), \alpha_{raw}, \beta_{raw}), \alpha_{obs}, \beta_{obs}) \quad (5)$$

$$P_{corr} = F_{db}^{-1}(F_{db}(P_{raw}(t), \alpha_{raw}, \beta_{raw}), \alpha_{obs}, \beta_{obs}) \quad (6)$$

$$T_{corr} = F_{db}^{-1}(F_{db}(T_{raw}(t), \alpha_{raw}, \beta_{raw}), \alpha_{obs}, \beta_{obs}) \quad (7)$$

$$T_{corr} = F_{dn}^{-1}(F_{dn}(T_{raw}(t), \alpha_{raw}, \beta_{raw}), \alpha_{obs}, \beta_{obs}) \quad (8)$$

Where P_{corr} and T_{corr} are the bias corrected daily precipitation and temperature, respectively. Likewise, $P_{raw}(t)$ and $T_{raw}(t)$ represent for raw climate model output for precipitation and temperature. The raw climate output inverse cumulative density (CDF) is symbolized by F_{dg}^{-1} , F_{db}^{-1} , and F_{dn}^{-1} for precipitation and temperature, respectively. The dn, db and dg subscripts represent the normal (for temperature), Birnbaum-Sanders (for both precipitation and temperature) and Gamma (for precipitation) distributions, respectively. The Gamma (for precipitation) and Birnbaum-Sanders distributions have two parameters – the shape and scale parameters which are symbolised by α and β , and the normal (for temperature) distribution, with mean and standard deviation represented by μ and σ , respectively.

2.3 Bias correction performance evaluation

The performance of the selected bias correction techniques was evaluated using four statistical measures: Pearson Correlation (RR), Mean Absolute Error (MAE), Root Mean Square Error (RMSE) and Percent Bias (PBIAS). Evaluation was performed by comparing the ability of each approach to capture observed precipitation and temperature.

$$RR = \frac{\sum(P_S - \bar{P}_S)(P_C - \bar{P}_C)}{\sqrt{\sum(P_S - \bar{P}_S)^2 + \sum(P_C - \bar{P}_C)^2}} \quad (9)$$

$$MAE = \frac{\sum_{i=1}^n |P_S - P_C| + 2 \sum_{i=1}^n |P_S - P_C|}{N} \quad (10)$$

$$PBIAS = \frac{\sum_{i=1}^n |P_S - P_C|}{\sum_{i=1}^n P_S} \quad (11)$$

$$RMSE = \left[\frac{\sum_{i=1}^n |P_S - P_C|^2}{N} \right]^{0.5} \quad (12)$$

Where P_S and P_C are observed and corrected precipitation, respectively, \bar{P}_C is the mean of corrected precipitation, \bar{P}_S the mean of observed precipitation and N is the number of observations.

280 2.4 Hydrological modelling

The GR4J model (Perrin et al., 2003) is a parsimonious four parameter, lumped conceptual rainfall-runoff model that has been widely applied in different hydro-climate conditions (Meresa & Gatachew, 2019; Meresa et al., 2017; He et al., 2018). The model is particularly suited to climate change impact studies given its parsimonious structure. GR4J simulates streamflow using precipitation, temperature and potential evapotranspiration (Perrin et al., 2003) and has previously been successfully
 285 used in Ireland to assess climate change impacts (Broderick et al. 2016; Broderick et al., 2019), river flow reconstructions (O'Connor et al., 2020) and seasonal hydrological forecasting (Donegan et al., 2020). Broderick et al. (2019) highlight the good performance of GR4J in capturing a range of hydrological signatures across diverse Irish catchments (Broderick et al., 2019). The model has two consecutive stores: one related to runoff production and the other to runoff routing. Detailed information about the model structure is given in Perrin et al. (2003) Perrin et al. (2003). The upper and lower limits of the four
 290 model parameters are listed in Supplementary Table S1. The model was calibrated and validated using observations over the period 1976-2005. The first four years were used as a model warmup to stabilise the initial states of the hydrological parameters. Calibration was undertaken from 1981-1999 and validation from 2000-2005. The Nash Sutcliffe Efficiency (NSE) objective function was used to evaluate the model performance and to identify behavioural parameter sets (Nash and Sutcliffe, 1970). NSE is defined as:

$$295 \quad NSE = 1 - \frac{\sum_{t=1}^j (Q_{o,t} - Q_{m,t})^2}{\sum_{t=1}^j (Q_{o,t} - \bar{Q}_o)^2} \frac{\sum_{t=1}^j (Q_{o,t} - \bar{Q}_o)^2}{\sum_{t=1}^j (Q_{o,t} - Q_{m,t})^2} \quad (13)$$

where $Q_{o,t}$ and $Q_{m,t}$ are observed and simulated flow at time t , \bar{Q}_o is the mean observed flow and j is the length of the j^{th} time series. The ability of hydrological model simulations to replicate the observations was further evaluated by deriving the proportion of extreme high flows inside the 95% confidence intervals (PCI). This is helpful for identifying a fixed NSE threshold for differentiating between behavioural and non-behavioural simulations (Li et al., 2011; Xu, 2014).

300 The Generalized Likelihood Uncertainty Estimation (GLUE) approach is widely applied to quantify hydrological model parameter uncertainty (Beven & Binley, 1992). GLUE is an informal statistical approach that uses Monte Carlo (MC) simulation to generate many possible hydrological parameter sets from specific ranges. The choice of the number of samples is somewhat subjective with studies typically employing a few thousand to tens of thousands of hydrological model parameter set samples to simulate river flow (Zheng and Bennett, 2002). In applying GLUE, we randomly generated ~~30,000~~ a large
 305 number of parameter sets (30,000) using a uniform distribution) ~~from constrained by~~ the acceptable ranges of each GR4J parameter. Behavioural parameter sets were identified based on ~~the~~ NSE (Equation 13) weighting efficiency function and PCI (Equation (14), with a resultant fixed threshold of NSE \geq scores >0.5 employed.50.

$$PCI = \left[1 - \left| \left(\frac{N_{Q_{ext}}}{x} - 0.95 \right) \right| \right] * \frac{1}{x} * \left(\sum \frac{I_{ext} - I_{ext}}{Q_{ext}} \right) \quad (14)$$

Formatted: Space Before: 0 pt, After: 0 pt

where $L_{L,t,p}$ and $L_{U,t,p}$ are the lower and upper boundary values of the extreme flow CI, T is the sum of time steps, Q_{ext} is the observed extreme flow at time step t , NQ_{ext} is the number of extreme peak flow observations which fall within the extreme flow CI. The shape of the 95% CI is governed by the value of PCI; if PCI is closer to 0.95 more of the observed time series extremes fall in the confidence interval band.

2.5 Flood frequency analysis

Numerous extreme value distributions can be deployed to estimate the frequencies of high flows. For example, the Log-Pearson III distribution is very popular in the USA and Australia for infrastructure design (Griffis & Stedinger, 2007), the General Extreme Value and Pearson Type III distributions are widely used in Europe (Madsen et al., 2013), while the Wakeby and Log-Normal distributions have been frequently used in Asia (Chen et al., 2012). However, a single distribution model may not be able to capture the entire temporal and spatial variability of hydrological extremes. Therefore, we employ three common distribution types (LogN, LoglogisticLN, Log-logistic and GEV) with Maximum Likelihood parameter estimator (MLE) for flood frequency curve development. MLE estimates the distribution parameters by optimising the likelihood function of the cumulative probability distribution density, and its reliability is evaluated using the standard error of the estimated parameters. These distributions were fitted to the annual maximum daily peak ~~flow~~flows in each study catchment. In Equations 15–17 14–16, the respective probability density function (PDF) of each distribution is presented. The ~~GEVLog-Normal~~ and Log-logistic models have ~~threetwo~~ parameters, while the ~~Log-Normal~~GEV distribution has ~~twethree~~ parameters:

$$\text{Log-Normal (LN)} \quad f(x) = \frac{\exp\left(-\frac{1}{2}\left(\frac{\ln x - \mu}{\sigma}\right)^2\right)}{x\sigma\sqrt{2\pi}} \quad \sigma, \mu (\sigma > 0) \quad (1514)$$

$$\text{Log Logistic (LogL)} \quad f(x) = \frac{\beta\left(\frac{x}{\sigma}\right)^{\beta-1}}{\alpha\left[1+\left(\frac{x}{\sigma}\right)^\beta\right]^2} \frac{\mu\left(\frac{x}{\sigma}\right)^{\mu-1}}{\sigma\left[1+\left(\frac{x}{\sigma}\right)^\mu\right]^2} \quad (1615)$$

$$\text{GEV} \quad f(x) = \begin{cases} \frac{1}{\sigma} \exp\left(-\left(1+kz\right)^{\frac{1}{k}}\right) \left(1+kz\right)^{-\frac{1}{k}} k \neq 0 \\ \frac{1}{\sigma} \exp(-z - \exp(-z)) k = 0 \end{cases} \begin{cases} \frac{1}{\sigma} \exp\left(-\left(1+k\left(\frac{x-\mu}{\sigma}\right)\right)^{\frac{1}{k}}\right) \left(1+k\left(\frac{x-\mu}{\sigma}\right)\right)^{-\frac{1}{k}} k \neq 0 \\ \frac{1}{\sigma} \exp\left(-\left(\frac{x-\mu}{\sigma}\right) - \exp\left(-\left(\frac{x-\mu}{\sigma}\right)\right)\right) k = 0 \end{cases} \quad K, \sigma, \mu (\sigma > 0) \quad (1716)$$

Where, σ is the scale parameter, β , μ is location and k is the shape parameter and k is the location parameter.

2.6 Uncertainty ~~estimation and decomposition and estimation~~

335 We used two approaches to uncertainty analysis in future flood hazard. First is the additive chain approach which is similar to sensitivity analysis, whereby the main goal is to assess components of the modelling chain independently. Second, we used ANOVA to separate the variance contribution of each component of the modelling chain and their interaction. Unlike the former (sensitivity approach), it helps us to understand the interaction of factors and their main variables.

2.6.1 Additive chain approach

340 We examine the relative contribution of four key components of the modelling chain to the projected uncertainty in future flood ~~risk~~hazard. These are climate models (CM), bias correction techniques (BC), hydrological model parameters (HP) and flood frequency distribution models (FF). ~~For uncertainty decomposition, we~~We only use a single SSP scenario (here ~~SSP3~~SSP370) in our evaluation of the uncertainty cascade, with the assumption that different studies will be interested in quantifying flood ~~risk~~hazard for different emissions outcomes separately. ~~Unlike~~

345 Overall uncertainty is estimated based on the additive ~~or multiplicative~~chain method, while decomposition of the contribution of different sources of uncertainty and their interactions is evaluated using ANOVA. The uncertainty in future flood hazard can be defined as the total uncertainty resulting from the components (s) of the modelling chain considered – here four components s1 to s4 (CM, BC, HP and FF). Initially we define the cumulative uncertainty for each component (s) of the modelling chain denoted by $U^{cum}(X_1, \dots, X_s)$ and conditional probability as $U(q_{x_{s+1}, \dots, x_s})$. The uncertainty in our
350 modelling chain is characterized as the total variance in the flood quantile generated from each of the four components evaluated, with total uncertainty defined as:

$$U^{cum}(x_1, \dots, x_s) = \frac{1}{\pi_{j=s+1}^{n_j}} \sum_{x_{s+1} \in x_{s+1}} \dots \sum_{x_s \in x_s} U(q_{x_{s+1}, \dots, x_s}) \quad (17)$$

355 This uncertainty quantification method keeps summing as the number of components (s) of the modelling chain increases. Therefore, the uncertainty of a particular step along the modelling chain e.g. s=4, denoted by $U^{cum}(X_s)$, can be described as:

$$U^{cum}(X_s) = U^{cum}(X_1, \dots, X_s) - U^{cum}(X_1, \dots, X_{s-1}) \quad (18)$$

360 Note that uncertainty of each component of the chain is a magnitude of contribution to the total uncertainty so that the sum of uncertainties of individual sources is always equal to the cumulated uncertainty $U^{cum}(X_1, \dots, X_s)$.

2.6.2 ANOVA approach

365 Unlike single chain based additive approaches to uncertainty estimation, ANOVA can decompose the aggregated source of uncertainty into individual components and their interaction using specific extreme flow indices (Meresa & Romanowicz, 2017). We develop a hypothesis test using an ANOVA model that can identify the effect of each component (CM, BC, HP, FF) in the model chain to the total variance of the extreme index (Y). According to n-way ANOVA principles, the model splits the total sum of squares (SST) into the sum of squares (SS) of the main variables and their interactions as follows:

$$SST = \sum_{i=1}^{NCM=12} \sum_{j=1}^{NBC=5} \sum_{k=1}^{NHP=300} \sum_{l=1}^{NFF=3} (Y_{ijkl} - \bar{Y})^2 \quad (1819)$$

370 Where Y_{ijkl} is estimated flood magnitude considering $i=12$ climate models, $j=5$ bias correction methods, $k=300$ hydrological parameter sets, $l=3$ extreme frequency distributions, and \bar{Y} is the mean of all variables. SST is the grand square deviation of the main and interacting variables. Further, the deviation in SST is split into the-individual and interacting components to explore their effect on the aggregated extreme flood frequency indices as follows:

$$SST = SS_{CM} + SS_{BC} + SS_{HP} + SS_{FF} + SS_{CMBC} + SS_{CMHP} + SS_{CMFF} + SS_{BCHP} + SS_{BCFF} + SS_{HPFF} \quad (1920)$$

375 where SS_{CM} is the sum of standard errors of climate models, SS_{BC} is the sum of standard errors of bias correction methods, SS_{HP} the sum of standard errors of hydrological parameters and SS_{FF} is the sum of the standard errors of flood frequency. In examining combined effects, SS_{CMBC} is the sum of standard errors of climate models and bias correction methods, SS_{CMFF} the sum of standard errors of climate models and extreme frequency, and SS_{BCHP} is the sum of standard errors of bias correction methods and hydrological parameters.

380 **3-Results**

3.1 Evaluation of bias correction techniques

The annual maximum daily precipitation series from 12 GCMs were evaluated against observations for each catchment during the period 1976-2005 (reference period). RR, MAE, PBIAS and RMSE results for each catchment are presented in Figure 3 and Figure S1. Following bias correction, results indicate an improvement of the GCMs in reproducing observed annual maximum precipitation. However, the performance of each bias correction method is not uniform for all catchments and GCMs. MAE values range from 0 to 195, RMSE 0 to 40, PBIAS -65 to 40, and RRR ranges from -0.40 to 0.50. Overall, the distribution based bias correction methods performed better in reproducing observed maximum precipitation in these catchments. The smallest PBIAS is observed in the Boyne catchment and largest in the Newport catchment. The BC-CCSM and ACCES CM2 climate models show high RR (0.4) in the Slaney catchment using DGQM, SGQM and BSM. Whereas GFDL and MPIESM-LR climate models indicates lower performance in correcting precipitation using all bias correction methods. Figure 4 shows the raw GCM outputs together with the results of the five bias correction methods applied to the CMP6 ensemble in simulating monthlythe maximum daily precipitation in each month for each catchment. The corrected monthly precipitation gives a wider spread in winter months (except DGQM and EQM techniques), relative to summer months.

395 However, the ensemble spread is dependent on the bias correction method. DGQM and EQM methods result in a relatively narrower spread ~~in monthly simulations~~, whereas SGQM, BSM and CF return a wide range of simulations (Figure 4).

400 The influence of each bias correction method on the magnitude of simulated changes in annual maximum daily precipitation for the 2050s (2040-2069) and 2080s (2070-2099) (relative to reference period: 1976-2005) was evaluated for each GCM SSP combination (Figure 5). Simulated changes from the same 12 GCMs using different bias correction approaches show substantial differences in the magnitude of changes in annual maximum precipitation. Generally, projected changes are smaller in the Slaney and Boyne using DG methods, whereas the changes in the Blackwater and Newport are smaller using EQ and SG. There is also a linear relationship between the annual maximum precipitation changes suggested for the 2050s and 2080s, for most bias correction techniques and catchments, indicating a positive trend in the magnitude of changes with time (Figure 5). However, we note that there is greater scatter for EQM relative to other bias correction techniques and in the Blackwater catchment relative to other catchments. We also note that the magnitude of change in annual maximum daily precipitation tends to be higher for SSP5SSP585 than for SSP3SSP370 and SSP4SSP126 and slightly higher in the Slaney and Newport catchments, relative to the Boyne and Blackwater. Changes in annual maximum daily precipitation for SSP126 are smaller than those simulated for SSP370 and SSP585 due to the lower radiative forcing and socio-economic impact associated with SSP126 relative to other scenarios.

410 ~~A similar evaluation was undertaken for mean annual air temperature for each catchment. Figure 6 shows the bias corrected projected mean annual temperature for each catchment under each GCM/SSP combination, together with the ensemble median for each SSP. The selected catchments show continuous warming during the 21st century. The ensemble mean changes for SSP1, SSP3, and SSP5 scenarios are projected to be 10–12°C, 11–13.3°C, and 12–15°C, respectively by the end of the century. The spread at the end of 21st century is somewhat wider than the earlier periods. Bias correction results for precipitation are shown in Figure S2 and for temperature in Figure S3.~~

3.2 Hydrological modelling and parameter uncertainty evaluation

420 ~~Using the GR4J hydrological model, 30,000~~The GLUE procedure was used to identify a set of model parameters that offer acceptable performance. Thirty thousand parameter sets were randomly generated from uniform distributions with the NSE objective function threshold ~~set to of~~ > 0.5, calculated from daily mean flows used to identify behavioural parameter sets. ~~Figure 7 shows the seasonal maximum flow~~To produce future simulations derived, we employ the top 300 behavioural parameter sets. Figure S3 shows the variation in model parameter values and NSE for each GR4J model parameter and catchment. The majority of parameters show clearly identified peaks for each catchment, particularly the parameters X2, X3 and X4. The only parameter to show a lack of identifiability is the X1 parameter (the production storage capacity) in the Newport catchment. This is the smallest of the four catchments and displays large variability in topography, landcover

Formatted: Font: 12 pt

(forestry) and has a lake present in the catchment. Figure 6 shows the ability of the GR4J model to simulate the maximum daily flows in each month using behavioural sets relative to observations for the years 1976-2005, together with the 90% percent confidence intervals of the simulations. ~~Monthly maximum simulations~~ Simulations successfully capture the observations, which mostly fall within the 95% ~~and 5% percent~~ confidence interval, except in the Boyne catchment, where a portion of the observed maximum flow time series fall outside of the simulated confidence interval. We note that the Boyne catchment has undergone significant arterial drainage works, which is likely to result in higher peak flows (Harrigan et al., 2014) in the observations relative to the model simulated values. GR4J achieved the best fit in the 95% CI modelling discharge in the Newport catchment. Overall, the model was able to capture winter flows well in all catchments, particularly winter peak flow simulations. The biggest discrepancies were observed in modelled flows during late summer, with poorer performance likely associated with use of the NSE objective function which is more sensitive to the large peak values than lower flows in summer.

Ensemble median projections of monthly maximum flow derived from 12 GCMs under SSP3 and 5 bias correction techniques for each catchment for the period 1976 to 2100 are shown in Figure 8. Increases are largest during the winter and early spring months in the Blackwater and Newport catchments, with maximum flow increasing from 17 m³/s to 25 m³/s during winter in the Newport catchment, and from 120 m³/s to 160 m³/s in the Blackwater. Also, the projected flows during late autumn and early summer periods shows the same trend and uniform pattern, with a maximum flow rate of about 35 m³/s for the Blackwater, 5 m³/s for Newport, 40 m³/s for the Boyne and 15 m³/s for the Slaney.

We examined the uncertainty associated with model parameters for different GCMs and future time periods. Figure 7 shows the simulated annual maximum daily flow for the reference and each future time period using the 300 GR4J behavioural parameter sets forced with 12 GCMs bias corrected using DGQM. It is evident that the uncertainty associated with hydrological model parameters is not static and varies depending on climate model, catchment and future time period. The importance of hydrological model uncertainty tends to be greatest for climate models that project the largest magnitude of change indicating that the changing characteristics of precipitation (e.g. mean and variability) have a large bearing on the importance of hydrological model uncertainty. It is also likely that different bias correction techniques interact with parameter uncertainty. The uncertainties associated with hydrological model parameters tend to be greatest for the 2080s (black lines in Figure 7), and for the Boyne and Slaney catchments.

Percent changes in maximum annual daily flow simulated using ~~each of the behavioural parameter sets~~, 12 GCMs bias corrected by each of the five methods, together with the raw simulations are presented in Figure 9. A clear increase in the annual maximum flow is suggested using DGQM, SGQM, CF, EQM and BSM, however, the magnitude of simulated increases differs depending on bias correction approach and are not uniform across the selected catchments. Overall, distribution based bias correction models give smaller changes in annual maximum flow time series. This indicates that wet-day frequency correction

is very important for understanding future annual maximum flow projections. Annual maximum flow changes using EQM gives a higher spread range and uncertainty: in each catchment, while the change factor method produces the most modest changes. Changes in annual maximum flow are smallest in the Boyne catchment and largest in the Newport Blackwater, which is notable as the catchment with largest groundwater storage. Changes in annual maximum flow are more constrained under SSP3 and SSP5, SSP126 than SSP4, SSP370 and SSP585, however differences between SSPs are modest and uncertainty ranges of changes in annual maximum flow are considerable for each (Figure 98).

3.3 Flood hazard quantile projections under varying climate conditions

To evaluate changes in flood frequency we use the Akaike Information Criteria (AIC) to identify the best fitting distribution type in the reference period and observed time series for each GCM projection and catchment. Figure 10 Figure 9 shows the estimated flood quantile values at different return periods (from 2 year to 100 year) using GEV, LogNLN and LogL distribution models, and associated 95% confidence intervals from 12 GCMs (under SSP3, SSP370 scenario) bias corrected using the DGQM method over the full simulation period (1976-2100). Overall, the LogL, LogN distribution returned the smallest changes in flood quantiles, quantile magnitude and the narrowest uncertainty band, while the estimated quantile values using LogL tend to be the largest across each catchment. The GEV distribution gives the largest uncertainty ranges in flood quantiles in all catchments (Figure 109).

Flood quantile changes Percent changes in flood quantiles for return periods ranging from 10 to 50 years were also evaluated for each future period under SSP3, SSP370 using the ensemble mean of three distribution types fitted to the median GR4J simulation combining all GCMs and bias correction methods (Figure 10); and Figure flood Figure S4 shows quantile using GEV distribution fitted to the median GR4J simulation combining all GCMs and DGQM bias correction methods, method (Figure 11 and Figure S4). Each catchment shows a significant increase in the magnitude of flood quantiles, magnitudes, quantiles in the future. Overall, changes in flood quantiles are consistent with changes in annual maxima daily flow. However, future flood quantile changes are not the same across catchments and differences exist based on bias correction methods employed. The frequency of the larger return period flood (100-year flood) increases to higher than once in 20 years. The smallest changes (0-15%) in flood quantiles are observed in the Slaney using DGQM, the Boyne using SGQM and DGQM, Newport using CF and EQM, and in the Blackwater using CF. For the 100-year flood, the The largest changes in magnitude (50-200%) are noted using EQM in the selected catchments. By comparison, the other bias correction methods are consistent and indicate changes of between 30-50% in the Slaney and Boyne, and 50-100% in Blackwater and Newport in the future. Overall, the Slaney catchment shows smaller relative change in flood quantiles (0-20%) at different return periods using BSM, SGQM and CF, similarly using the DGQM projected changes range from 0-15%. Moreover, changes in extreme flood quantiles do not increase linearly from the across all catchments are found using the BSM bias correction method, where in the Blackwater catchment increases of over 90 percent are found for the 50-year return period in the 2050s to and 2080s. In almost all catchments and combinations of Other bias correction techniques changes are greater in the return more modest increases. Changes in flood

495 quantiles estimated using the CF and DGQM approaches show larger changes in the 2050s than relative to the 2080s under
SSP3-in the Blackwater. Indeed, the CF method shows the most modest changes in all quantiles for the 2080s relative to other
time periods across all catchments. In the Slaney most bias correction methods show only small changes in flood quantiles
between time periods, the exception being EQM which shows substantial increases in each flood quantile moving across each
time-period. The EQM method tends to show the greatest increases in magnitude for higher quantile floods, with largest percent
500 reductions in the magnitude of higher frequency floods, a characteristic not reported using other bias correction techniques.

Formatted: Not Highlight

3.4 Uncertainty estimation and decomposition for flood ~~hazard~~ quantile estimation

The magnitude of each of the four sources of uncertainty on flood ~~risk~~ hazard estimation was estimated first based on the additive chain principle to reveal their contribution to the overall uncertainty in projected changes. Projections from each of 12 climate models were iteratively passed through five bias correction techniques and used to force the GR4J model using behavioural parameters sets, before fitting each of the three frequency distributions to estimate future flood hazard. ~~Figure 12~~
505 ~~Therefore, for the spread for climate models was evaluated by varying simulations using each of the 12 GCMs while using a single bias correction technique, median hydrological model parameter set and a single flood frequency distribution. Figure 11~~
~~presents the integrative range of this cascade of uncertainty in estimating return period floods for each catchment using data spanning the years 1976-2100. The dominant source of uncertainty differs from catchment to catchment. Climate models, flood frequency distribution and bias correction techniques tend to be the dominant contributing source of uncertainty in estimating flood quantiles. In~~
510 ~~Using this one at a time approach to evaluating uncertainties in flood quantiles, in~~ the Newport and Blackwater catchments climate model projections present the dominant source of uncertainty, particularly for higher flood quantiles. Notably the relative magnitude of uncertainty in the smaller flood quantiles in the Blackwater catchment is different than for larger flood quantiles, with the extreme value distribution becoming dominant at lower flood quantiles. The largest
515 source of uncertainty in the Slaney is derived from the use of different frequency distribution models. For the Boyne catchment the bias correction methods contribute more to the total uncertainty. Therefore, the various steps in the modelling chain contribute differently in each catchment to total uncertainty in future flood ~~risk~~ hazard estimation and in some catchments vary depending on the flood quantile of interest (Figure ~~12~~ 11).

520 While additive chains may be useful for evaluating individual components of uncertainty, they do not allow identification of the interactive components of the uncertainty cascade. We use ANOVA to decompose the contribution of individual sources of uncertainty and their interaction in contributing to the total uncertainty in future flood hazard (Figure ~~12~~ 12). We evaluate changes in 10-year, 50-year and 100-year return period flood for the 2080s (2070-2099) relative to the reference period (1976-2005). The decomposition of uncertainty is based on the variance in changes of flood quantile values and calculated out of 100
525 percent, i.e. the sum of all sources is equal to 100. The contribution of each source of uncertainty is not uniform across the selected catchments (Figure ~~12~~ 12). Taking the example of the magnitude of the 100-year flood (Figure ~~12~~ 12 outer band),

future flood hazard in the Blackwater catchment for the 2080s is highly sensitive to the climate model used (36.5% of total uncertainty in 100-year flood) and respective bias correction methods (20% of total uncertainty). By contrast, future flood frequency in the Boyne is more sensitive to bias correction methods (30.0%) and extreme value distribution (25.5%) employed.

530 In the Boyne catchment, the climate model ensemble accounts for less than one quarter (22.5%) of the uncertainty in simulations of the 100-year flood by the 2080s and is comparable in magnitude to the interactive components of the cascade. In the Newport catchment the use of different extreme value distributions (36.3%) presents the largest component of uncertainty, followed by the climate model ensemble. The results of ANOVA analysis also confirm that the uncertainty resultant from the interaction of the key sources considered is not negligible and also varies on a catchment basis. In the Slaney and Blackwater catchments the interaction of various uncertainty components accounts for 16.8% and 16% of the total uncertainty in estimates of the 100-year flood by the 2080s. By contrast, interactive components in the Newport and Boyne catchments account for approximately one quarter of the uncertainty range (25.2% in the Newport and 22% in the Boyne). Overall, hydrological parameter uncertainty is the least dominant source of uncertainty in future flood frequency estimates across each catchment (Figure 4211 and Figure 4312). For estimates of the 100-year flood in the 2080s (Figure 4312 outer band), hydrological model parameter uncertainty is typically 5% of the total uncertainty, reaching up to 9% in the Boyne. Furthermore, the contribution of each of the main components of uncertainty and their interactions to total uncertainty is broadly similar for the different return periods considered for our analysis of the 2080s (Figure 4312).

4. Discussion

545 We examined future flood risk changes in flooding for four catchments in Ireland, including within our modelling chain the uncertainties derived from 12 CMIP6 GCMs, 5 commonly used bias correction techniques, hydrological model parameters and three flood frequency distributions. We found that maximum precipitation and mean air temperature in all catchments are projected to increase over the coming decades, however changes are not uniform across catchments. The largest change in annual maximum precipitation was found for the Newport catchment, with ensemble median increases becoming progressively larger for the 2020s, 2050s and 2080s (27%, 40%, 60%, respectively). In the Slaney catchment, increases in annual maximum precipitation between the 2050s and 2080s are not statistically significant. In the Blackwater catchment, most of the climate models indicate a positive change but these have a wide range of uncertainty relative to other catchments (from 0 to 55% in 2050s and 0 to 60% in 2080s). We find projected changes in flood magnitudes to be broadly proportional to changes in maximum precipitation in all catchments. Projected changes in flood magnitude are higher using the SSP4SSP585 and SSP5lower using SSP126 climate scenarios, whereas the SSP3 results in more modest flood increases. Overall changes in precipitation and air temperature are broadly consistent with previous findings using CMIP5 (Broderick et al., 2019) in Ireland.

560 Our findings demonstrate the large uncertainties associated with projected flood magnitudes, with climate change. Over recent years much research has sought to explore the dominant sources of uncertainty in climate change impact assessments. ~~For instance, Bastola et al. (2011b) identify hydrological model uncertainty as important in previous assessment of change in flood risk, others have identified climate models as being the dominant source (e.g. Similar studies have identified climate models as being the dominant source (e.g. Sulis et al., 2012; Sulis et al., 2012; Hattermann et al., 2018). Mizukami et al. (2016) rank hydrological model structure of greater importance than bias correction approaches in US catchments. However, our findings call into question the ability to generalise the most important components of the cascade of uncertainty in assessing future flood risk across catchments. Using variance decomposition to partition the components of the modelling chain employed, together with their interactions, we show that the dominant sources of uncertainty in assessing climate change impacts on future floods differ on a catchment-by-catchment basis. In two of our study catchments~~ Indeed (Addor et al. (2014) highlight that there seems to be a general agreement in the literature on the dominant contribution of climate models to the uncertainty in discharge projections. On the contrary, our findings demonstrate the challenges of generalising about the dominant components of the cascade of uncertainty at the catchment scale. Using both additive chains and variance decomposition to examine components of the modelling chain employed, our results show that not only does the contribution and importance of different components of the modelling chain vary across catchments, but that the dominant source of uncertainty can be completely different. Moreover, the dominant sources of uncertainty vary depending on which approach is used to evaluate uncertainty. Using additive chains, in two of our study catchments, the climate model ensemble was the dominant source of uncertainty, as was expected. However, for the other two catchments, namely the Boyne and the Slaney, the extreme value distribution employed for flood frequency analysis and the bias correction method used to adjust raw GCM output contribute greater uncertainty to future flood risk than the ensemble of GCMs employed. Across all catchments the uncertainty in future hydrological model parameters is the smallest component of total uncertainty, while Using variance decomposition that allows for the interaction of components of the modelling chain to be evaluated and quantified offers a fuller assessment of uncertainty. Our result show that in the Slaney and Blackwater catchments the climate model ensemble used dominated the cascade of uncertainty. In the Slaney, the second most important component is the bias correction technique used, while in the Blackwater the frequency distribution model comes second. In the Newport catchment the flood frequency distribution model used ranks as the most important component of the cascade of uncertainty, followed by the climate model ensemble. Finally, in Boyne catchment, the climate model ensemble ranks as only the third most important component of the uncertainty cascade in simulating flood quantiles, with the bias correction methods coming first and the flood frequency distribution second.

590 We hypothesise how catchment characteristics may influence the dominant components of the cascade of uncertainty in each catchment. The Slaney and Blackwater where climate models dominate are among the largest in our sample with groundwater contributing significantly to runoff in both. In the Blackwater catchment topography has a large bearing on flood response time within the catchment with flood peaks moving more rapidly from elevated sub-catchments into the main channel and may be a reason as to why the flood frequency model ranks as the second dominant component in the cascade of uncertainty. The

595 Slaney catchment drains the southern component of the Wicklow mountains before reaching shallower elevations as it flows
south through Carlow and Wexford. The variation in topography and hence precipitation from upper to lower reaches may be
a reason as to why bias correction methods emerge as the second most important component of the uncertainty cascade in this
catchment. The Newport catchment is the smallest in our sample with flood response influenced more strongly by varied land
use cover (forestry) and the presence of a lake in the upper reaches of the catchment. The flood frequency distribution
dominates the cascade, followed by the climate model ensemble used. Finally, the Boyne catchment has been heavily
600 influenced by arterial drainage works, resulting in the insertion of field drains and the deepening and widening of the river
channel (Harrigan et al., 2014). These interventions have resulted in a faster rainfall runoff response. In the Boyne catchment
therefore, projected changes in future rainfall are likely to have a more direct bearing on the flood response, with uncertainty
in bias correction and the flood frequency distribution dominating the cascade of uncertainty.

605 Across each of our catchments and in the context of the modelling chain employed, the uncertainty from hydrological model
parameters is the smallest component of total uncertainty in the estimation of future flood hazard magnitude. Bastola et al.
(2011a; 2011 b) identify hydrological model uncertainty as important in a previous assessment of change in flood risk, while
Mizukami et al. (2016) rank hydrological model uncertainty of greater importance than bias correction approaches in US
catchments. We note that we do not consider hydrological model structure uncertainty in our modelling chain and that our
610 decision to select only the top 300 behavioural parameter sets, rather than all those identified may be a factor here. This
highlights how subjective decisions in the application of hydrological models may have important implications for the
uncertainty in future projections (Melsen et al., 2019). We also find that the contribution to total uncertainty from the
interaction of components within the modelling chain is substantial – up to one quarter of the uncertainty range considered in
two catchments.

615 ~~While our sample is small, results suggest that rather than being the same across catchments, the dominant sources of~~
~~uncertainty in future flood quantiles are catchment dependent. While uncertainty decomposition may be useful in helping~~
~~scientists navigate the cascade of uncertainty by prioritising the key components of the uncertainty cascade to sample (Clark~~
620 ~~et al., 2016) for a particular catchment, our small sample makes it difficult to determine how catchment characteristics may be~~
~~informative in identifying the dominant sources of uncertainty a priori. There are some indications that catchment properties~~
~~and the characteristics of observed precipitation may influence which uncertainties may dominate.~~ Vetter et al. (2017) used
variance decomposition to examine the contribution of modelling chains (GCM, emissions scenario (in the form of
Representative Concentration Pathways (RCPs)) and hydrological model) to total uncertainty in different parts of the flow
regime. In their study they examine 12 large catchments globally. While Vetter et al. (2017) highlight the dominance of GCMs
625 in total uncertainty across many catchments they highlight that the share of emissions scenario and hydrological model
contributions to overall uncertainty can differ between catchments. Similar to our findings, Vetter et al. (2017) highlight the
importance of interacting components of the modelling chain employed. ~~The possibility that dominant sources of uncertainty~~

630 differ on a catchment by catchment basis presents challenges for both top-down and bottom-up approaches to climate change adaptation. Top-down approaches must a priori decide on the components of the modelling chain to include. Including all relevant components is a very resource-expensive task (Smith et al., 2018) and it may not be apparent at the outset which components of modelling chain to include for specific catchments. For bottom-up approaches, such as the scenario neutral method (Broderick et al., 2019), the modeller is forced to choose which aspects of uncertainty to prioritise in assessing sensitivity to future changes. Again, this may not be apparent a priori. Moreover, the findings of Dobler et al. (2012) suggest that the dominant components of the modelling chain may further vary depending on which part of the flow regime (low, mean, high flows) is of interest. They highlight, for example, that the importance of bias correction approaches to the overall uncertainty in hydrological response increases for high flows. Our analysis of flood magnitudes for different return periods using all data from 1976-2100 suggests that the dominant source of uncertainty may also vary based on the return period of interest.

640 Our results show the value of ANOVA-based methods for examining and visualising the relative contribution of uncertainties within the modelling chain considered. In our example we used the planning horizon of the 2080s to decompose uncertainties. In addition, the use of ANOVA techniques to quantify uncertainty may offer insight into where effort to reduce uncertainty may be most fruitful (Clark et al., 2016). In all catchments the magnitude of change in flood events is heavily dependent on the approach to bias correction. Across all catchments EQM performs the poorest at matching precipitation quantiles during the historical period. All other methods considered show consistent performance except in the Blackwater catchment. This is likely due to long positive tail of the precipitation distribution and intensity characteristics in the Blackwater. On the whole, distribution-based methods tend to be most consistent across the selected catchments and also have relatively smaller spread. Therefore, the DGQM or SGQM method (s) are promising for future risk evaluation and minimizing uncertainty.

650 Given the importance of uncertainty quantification in adapting to climate change it should be a priority for future work to examine how the dominant components of uncertainty in modelling chains relate to catchment characteristics. While our study of four catchments is limited in this regard, there is evidence that catchment characteristics, which provide insight into the processes governing the rainfall-runoff response, may also play a role in determining the components of the modelling chain that dominate uncertainties in future flood projections. The Newport catchment is the smallest of our sample (146 Km²) and is an elevated catchment with a flashy response to rainfall. The shorter time of concentration and linear precipitation-runoff relationship mean that this catchment is highly sensitive to changes in extreme precipitation with uncertainty in flood frequency distribution and bias correction accounting for over half of the total uncertainty in the projected 100-year flood in the 2080s. The Boyne catchment has been subject to significant arterial drainage works which have resulted in a faster rainfall-runoff response and elevated high flows (Harrigan et al., 2020; Berghuijs et al., 2019). Our findings suggest that bias correction and flood frequency distribution are the dominant sources of uncertainty in the projected 100-year flood by the 2080s in this catchment. In the Blackwater and Slaney catchments groundwater contributes significantly to runoff and the catchments are

larger with typically well drained soils. In both catchments the climate model ensemble represents the dominant source of uncertainty.

665 As our study has shown, the evaluation of uncertainties and their interaction in future flood risk assessment with climate change is a critical step in understanding future impacts and informing adaptation decision making. However, results depend on the modelling chain employed. The work presented here is illustrative rather than exhaustive. We do not, for example, include uncertainties in future flood estimates derived from different hydrological model structures, nor do we evaluate the transferability of parameter sets to represent future rainfall runoff response (e.g. Broderick et al. 2016). We also assume that flood processes remain stationary within the 30-year windows used to evaluate changes, while we also assume that other factors that can influence rainfall runoff response, such as land use change, remain unchanged from the calibration period used to train our hydrological models.

675 **5. Conclusions**

This study evaluates changes in future flood magnitude with climate change for four Irish catchments using a modelling chain incorporating 12 GCMs comprising the CMIP6 ensemble, 5 bias correction techniques, hydrological model parameter uncertainty and the use of extreme value distributions. Our findings suggest increasing flood risk

680 As our study has shown, the evaluation of uncertainties and their interaction in future flood risk assessment with climate change is a critical step in understanding future impacts and informing adaptation decision making. However, results depend on the modelling chain employed and the method used to quantify uncertainties. Given the possibility of examining interactive components of modelling chain, we recommend the use of ANOVA based techniques to decompose the cascade of uncertainty. We highlight however that our modelling chain is not complete and that the work presented here is illustrative rather than exhaustive. We do not, for example, include uncertainties in future flood estimates derived from different hydrological model structures with previous work, as indicated above, showing that hydrological model structure and complexity may be an important component of future uncertainties. Other potential sources of hydrological model uncertainty are also omitted. For example, we did not evaluate the transferability of parameter sets to represent future rainfall runoff response (e.g. Broderick et al. 2016), nor did we evaluate the influence that selection of different objective functions may have on the identification of behavioural parameter sets. Westerberg et al. (2020) also highlight the potential importance of uncertainty in the discharge data used to calibrate hydrological models. In assessing different flood quantiles, we use only 30 years of annual maxima to extrapolate to return periods outside our record length. Such extrapolations should be treated cautiously but are prevalent in many studies (e.g. Alison L. Kay et al., 2006; Lawrence, 2020; Meresa and Romanowicz, 2017) while rarer floods are also associated with design standards (e.g. 100-year flood) and therefore of interest to decision makers. We also assume that flood processes remain stationary within the 30-year windows used to evaluate changes, while other factors that can influence rainfall runoff response, such as land use change, remain unchanged from the calibration period used to train our hydrological models.

5. Conclusions

This study evaluates changes in future flood magnitude with climate change for four Irish catchments using a modelling chain incorporating 12 GCMs comprising the CMIP6 ensemble, 5 bias correction techniques, hydrological model parameter uncertainty and the use of extreme value distributions. Our findings suggest increasing flood hazards over the coming decades in all catchments, with changes in flooding largely consistent with changes in maximum precipitation. However, uncertainties in future flood changes are large and increase with time and flood quantile. Using ANOVA, we decompose uncertainties in future flood quantiles to examine how individual components of theour modelling chain and their interactions contribute to overall uncertainty. Our results show thathow the dominant sources of uncertainty may vary on a catchment basis, ealling into questionhighlighting the abilityinability to generalise on the dominant components of uncertainty across catchments, even in a relatively small domain like Ireland. Across all four catchments the climate models, bias eorrelationcorrection methods and the extreme value distributions used to evaluate flood return periods were differentially dominant, while the uncertainty derived from the interaction of various components was substantial in all catchments. Hydrological model parameter uncertainty was the least important component. Our work shows the value of ANOVA methods in visualising and quantifying the uncertainty cascade at a catchment level which will be helpful in navigating the uncertainties associated with future flood risk for better adaptation decision making. While our sample is small, there is evidence that the dominant components of uncertainty in future flood risk may be related to catchment characteristics. FutureWe therefore recommend that future work seeks to better understand the link between the key components of the cascade of uncertainty and catchment characteristics is therefore recommended. Ability to do so would offer considerable advantages in knowing a-priori which sources of uncertainty should be targeted as priority.

960 **Figure 3** Comparison of corrected annual maximum daily precipitation using five bias correction methods and observed annual maximum precipitation using a) Pearson correlation coefficient (RR), b) Percent Bias (PBIAS) and c) Mean Absolute Error (MAE). The y-axis indicates each of 12 CMIP6 climate models and the x-axis represents each of 5 climate bias correction method.

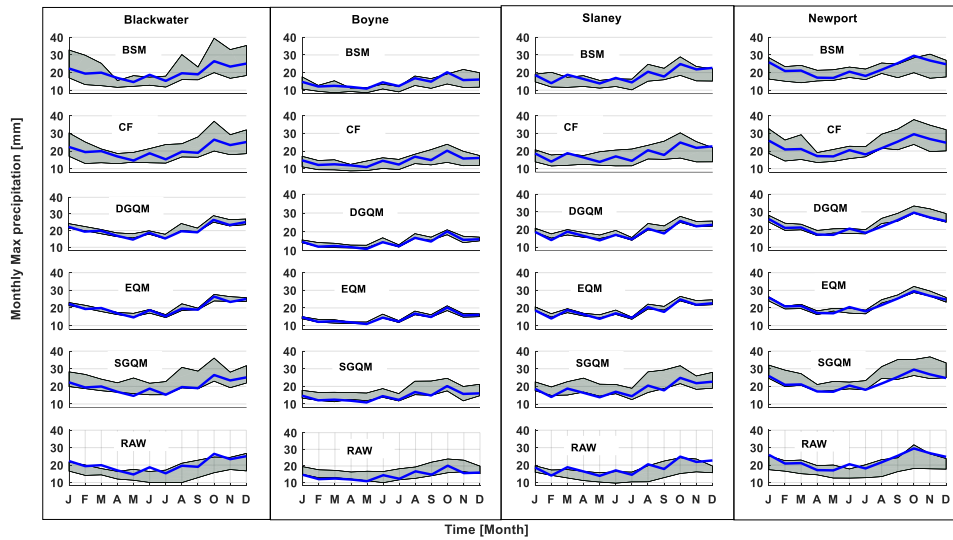

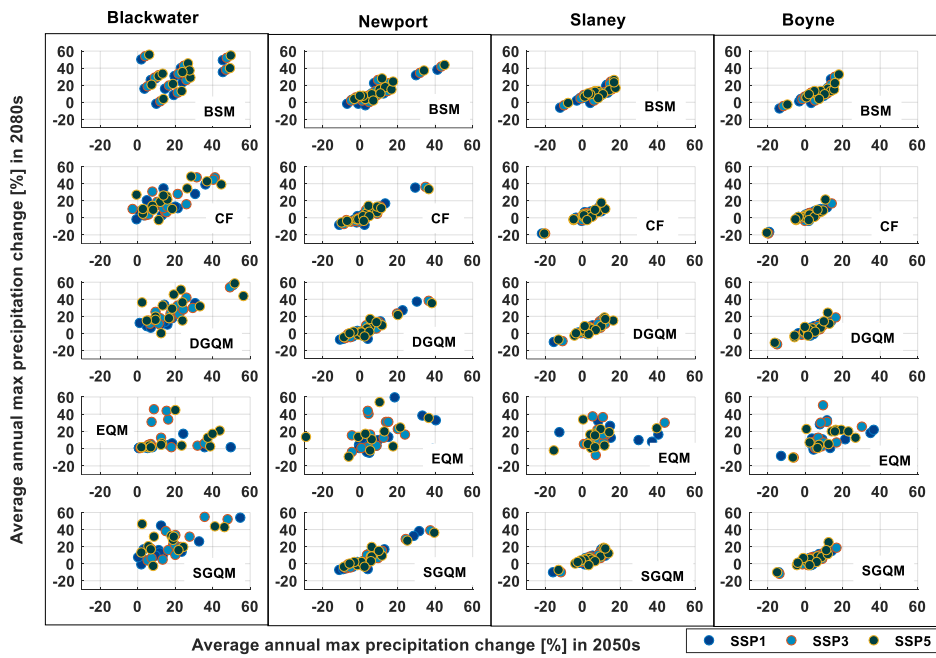

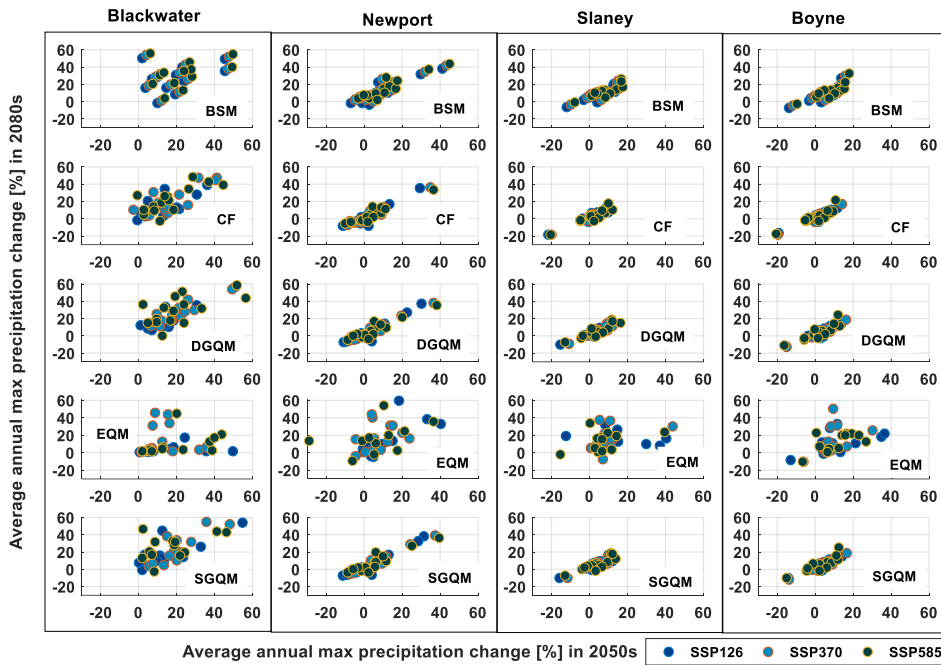

Figure 4 Comparison of raw and bias corrected simulations from 12 CMIP6 GCMs with observed monthly-maximum daily precipitation in each month for each of our four study catchments. Each row presents results of one of five bias correction techniques (top row - Birnbaum Distribution (BSM), second row-Change Factors (CF), third row- Double Quantile Mapping using Gamma Distribution (DGQM), fourth row-Empirical Quantile Mapping using Simple Interpolation (EQM), fifth row-Single Quantile Mapping using Gamma Distribution (SGQM), and the last row is the raw GCMs output). In each panel the grey shaded region represents the spread of 12 GCM simulations, with blue line being the observed monthly-maximum precipitation.

980 **Figure 5.** Scatter plots of change in maximum annual daily precipitation as simulated by 12 CMIP6 GCMs (each circle dot) corrected using each of the five bias correction techniques for three SSP scenarios for the 2050s (2040-2069) and 2080s (2070-2099). The dark blue circle represents SSP1SSP126, light blue represents SSP3SSP370 and dark green represents SSP5SSP585.

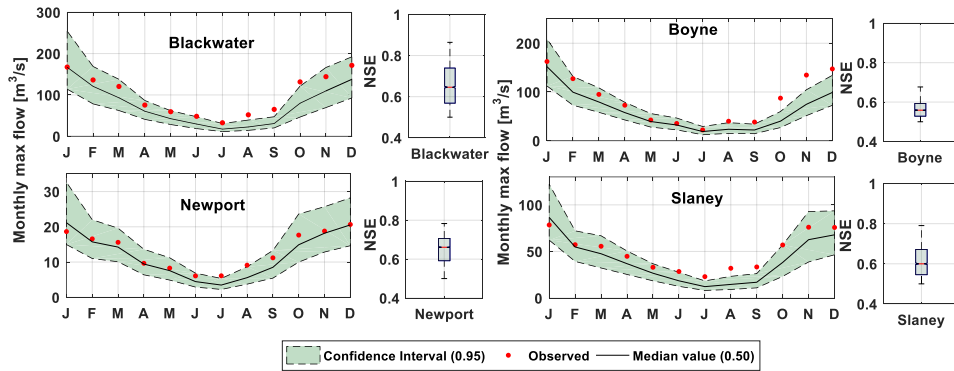

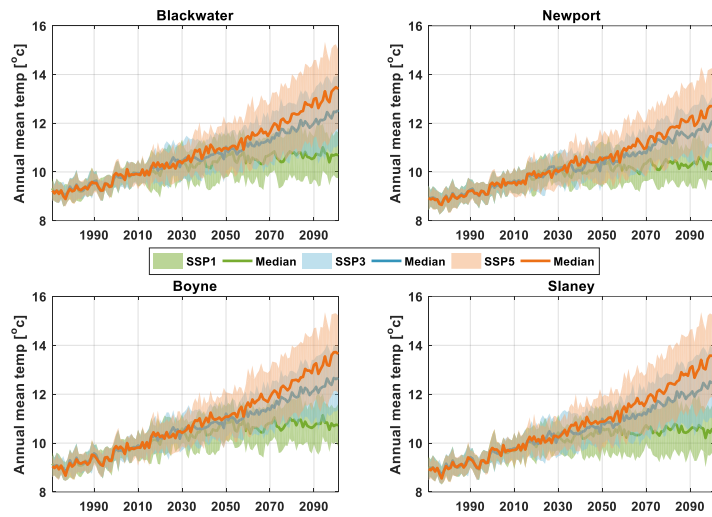

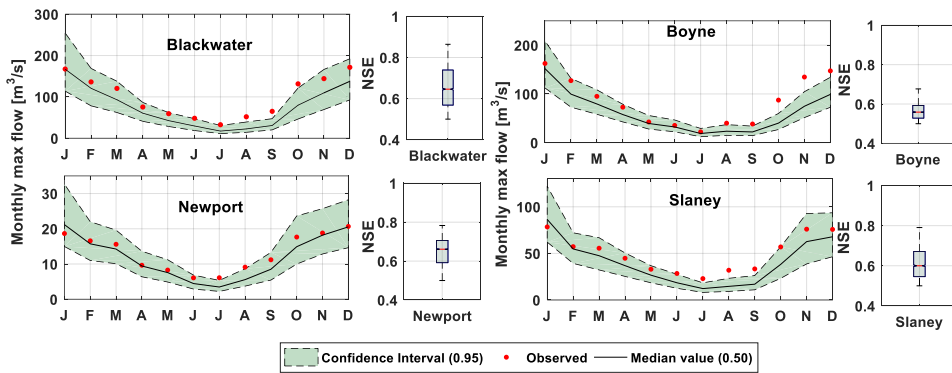

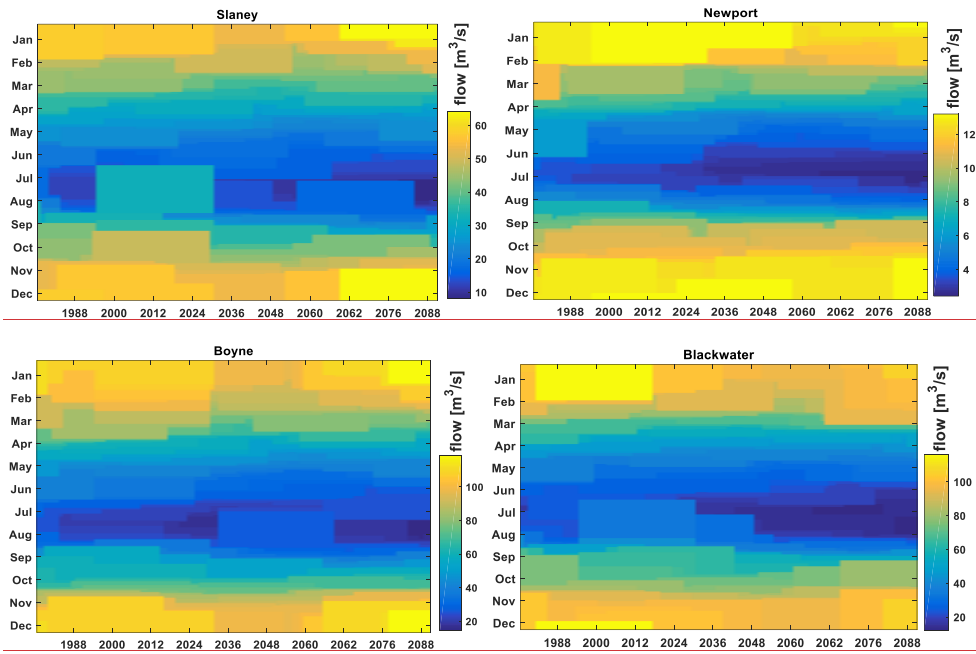

Figure 6. Ensemble of bias corrected simulations of annual mean air temperature (temp) from 12 CMIP6 GCMs for each catchment for the period 1976-2100. Orange, blue and green shaded areas represent the spread of GCM simulations forced using SSP1, SSP3 and SSP5, respectively. The solid lines represent the median of the 12 GCMs for each SSP scenario.

990 **Figure 7.** Observed and simulated monthly maximum daily flows (m^3/s) using GR4J behavioural parameter sets for the
 reference period (1976-2005). The black line and shaded area represent the median and 95 percent confidence interval of
 simulated flows, respectively, the red dot represents observed monthly maxima observations. Boxplots show the spread in
 NSE scores for behavioural parameters sets in each catchment.

995

Figure 7. Hydrological model parameter uncertainty in simulating the annual maximum daily monthly maximum flow (m^3/s) projections for 1976-2100 in each catchment as simulated using 12 CMIP6 GCMs, the five bias correction techniques and the best 300 parameter sets of the hydrological model for each climate model for the reference period (red), the 2020s (green), 2050s (blue) and 2080s (black) under SSP370 scenario and DGQM bias correction method.

Formatted: Tab stops: Not at 15.13 cm

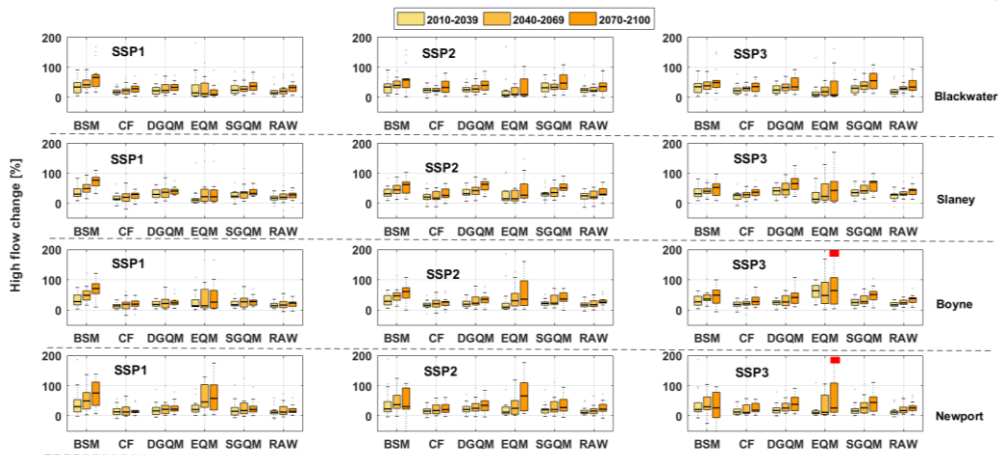

Figure 9.

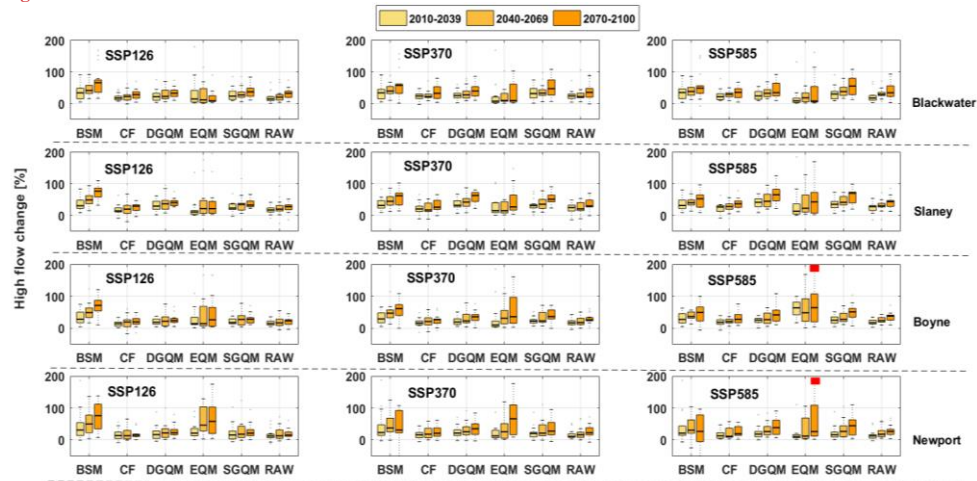

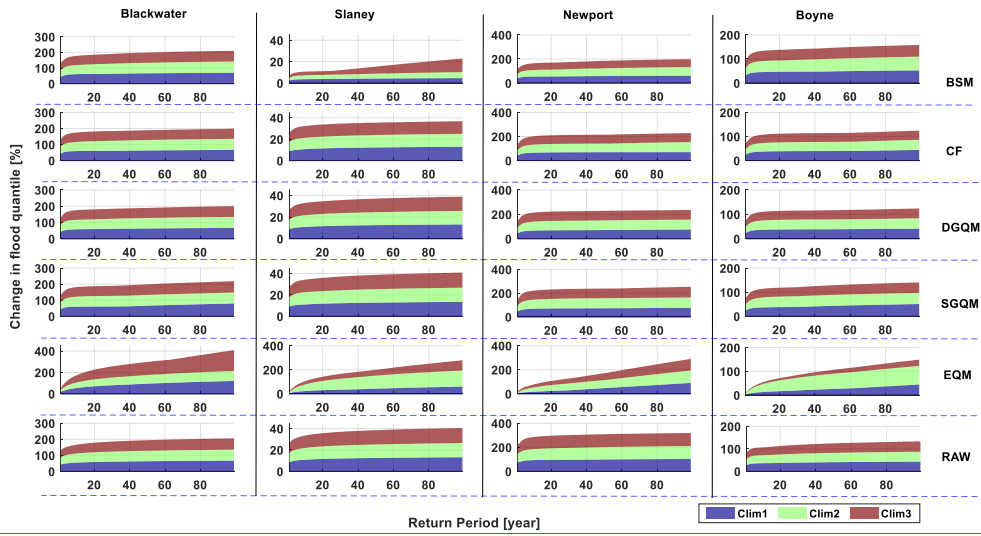

Figure 8. Matrix of projected percent changes in annual maximum river daily flow for the 2020s (2010-2039), 2050s (2040-2069), and 2080s (2070-2099) for *SSP1*, *SSP3*, *SSP126*, *SSP370* and *SSP5*, *SSP585* in each catchment with respect to the reference period (1976-2005). Each box plot represents the spread of 12 GCMs for each of the five bias correction techniques

1015 as simulated using behavioural model parameter sets. Marked for each boxplot are the median and 0.25 and 0.75 quantiles. The red dots are outliers (changes above 200%).

1020 **Figure 109.** Comparison of flood quantiles estimated using three flood distribution models (LogL, GEV and ~~LogN~~LogN) fitted to projected annual maxima series using derived from 12 GCMs bias corrected using the DGQM method. The shaded region indicates the 95% confidence interval of annual maximum projections from 12 GCMs under SSP3SSP370 scenario during over the full projection period (1970-2100 period) in each catchment.

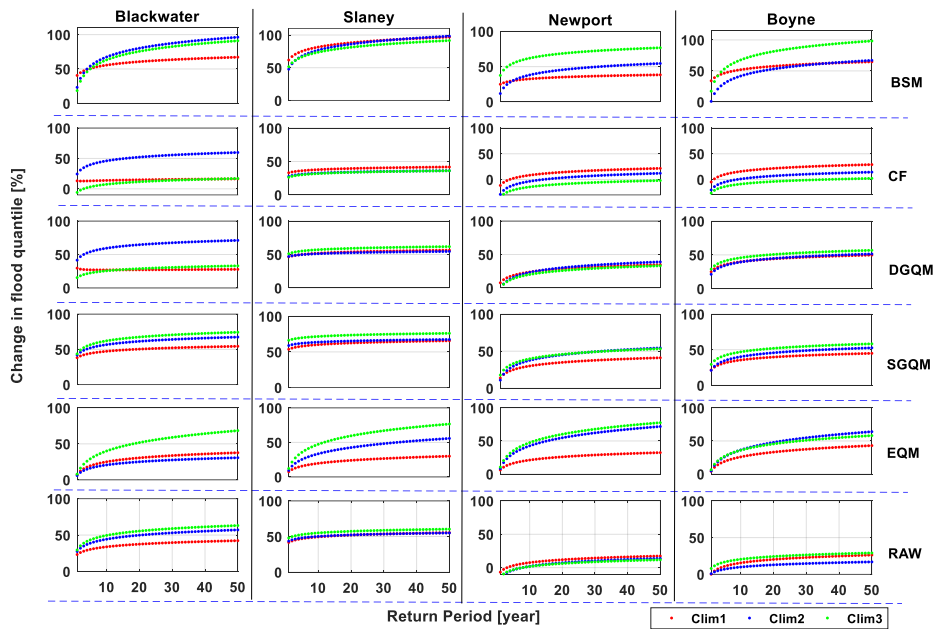

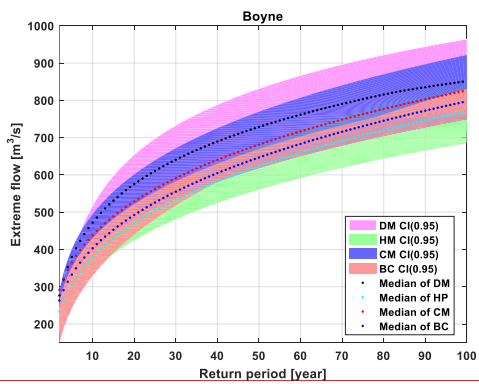

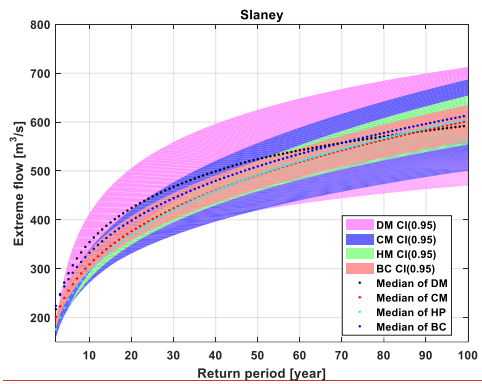

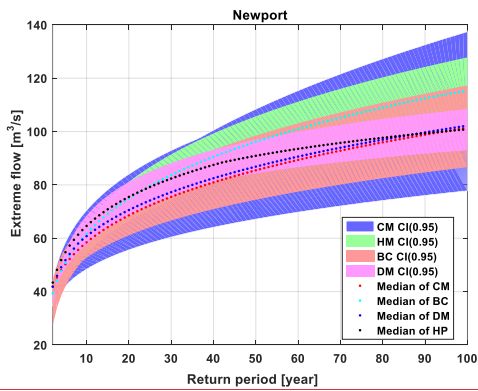

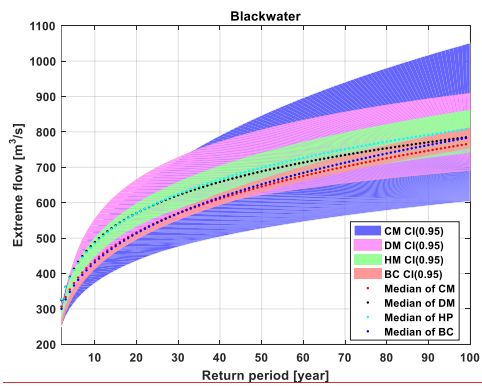

Figure 14-10. Percent changes in extreme flow quantiles using ensemble mean of three distribution types, 12 GCMs and 300 parameter sets in each catchment for the 2020s (clim1-red), 2050s (clim2-blue) and 2080s (clim3-green). Simulated changes are derived using raw (bottom row) and bias corrected (the first four rows) simulations. The shaded region is the spread of 12 climate model and three flood frequency models in the 2020s (blue), 2050s (green) and 2080s (brown) period.

Figure 13.12. Contribution of each component of the modelling chain, together with their interaction, to the range of simulated changes in flood risk magnitude for the 2080s (2070-2099) relative to the reference period (1976-2005). Sources considered include 12 CMIP6 climate models (CM), 5 bias correction techniques (BC), hydrological model parameter uncertainty (HP) and 3 extreme value distribution models (DM). The outermost circle/donut represents the flood quantile change at return period (RP) of 100 years, the middle circle RP of 50 years and innermost circle RP of 10 years for the 2080s. Percent changes are annotated for the outermost circle (100-year flood).
