## Abstract

Freezing-induced water migration and groundwater level decline are widely observed in regions with shallow water table, but many existing studies trying to quantify freezing-induced groundwater migration do not account for water level fluctuations induced by freezing and thawing. Here, detailed field observations of liquid soil water content and groundwater level fluctuations at a site in the Ordos Plateau, China are combined with numerical modeling to show groundwater and soil water dynamics controlled by wintertime atmospheric conditions and topographically-driven lateral groundwater inflow. By comparing simulation results with and without lateral groundwater inflow, we find lateral groundwater inflow leads to an alleviated freezing-induced water level decline and enhanced freezing-induced water migration. At the field site with a lateral groundwater inflow rate of 1.03 mm/d, compared with the case without lateral groundwater inflow, the water level decline decreases from 40 cm to 15 cm, and the increased total water content in the frozen zone enhances from 0.071 to 0.106. By calculating the budget of groundwater, the mean upward flux of freezing-induced groundwater loss is 1.46 mm/d for 93 days, and the mean flux of thawing-induced groundwater gain is as high as 3.94 mm/d for 32 days. The study enhances our understanding of the mechanisms controlling water redistribution between saturated and unsaturated zones and the water budget in the freezing-thawing cycle. The fluxes of groundwater loss and gain in the freezing and thawing stages obtained in the current study can be useful for future studies on two- or three-dimensional transient groundwater flow in semi-arid regions with seasonally frozen soils.

## 1 Introduction

30 Frozen soils have great impacts on many hydrological, hydrogeological processes and ecological processes (Nelson, 2003;Kurylyk et al., 2014;Schuur et al., 2015;Walvoord and Kurylyk, 2016;Evans et al., 2018;Zhang et al., 2020). In fact, frozen soils can be divided into permafrost and seasonally frozen soils, which underlie approximately 26% and 24%, respectively, of the Northern Hemisphere exposed land surface (Zhang et al., 2003;Dobinski, 2011;Evans and Ge, 2017). The behaviors of subsurface water flow and storage in seasonally frozen soils are distinct from both colder regions with permafrost and warmer regions with insignificant frozen soil (Ireson et al., 2013). Understanding the effects of soil freezing and thawing on subsurface water flow and storage is a necessary path for better water resources management in (semi-)arid regions with occurrence of seasonally frozen soils (Yu et al., 2020).

40 In seasonally frozen regions, by blocking pores and reducing hydraulic conductivity, soil freezing could lead to decreased infiltration (van der Kamp et al., 2003;Iwata et al., 2008;Demand et al., 2019) and limited surface evaporation (Kaneko et al., 2006;Wu et al., 2016). Soil freezing also generated cryosuction (Williams and Smith, 1989;Hohmann, 1997;Yu et al., 2018), which causes migration of water from the unfrozen zone to the freezing front and further decrease the hydraulic conductivity of frozen soils. By assuming that freezing-induced water migration is restricted within the shallow part of unsaturated zone which is far away from the water table, many 45 numerical studies deployed a free drainage lower boundary condition and examined the effects of freezing-induced water redistribution on infiltration and runoff (Cherkauer and Lettenmaier, 1999;Okkonen et al., 2017;Zhang et al., 2017). In fact, freezing-induced water movement is not restricted within the unsaturated zone, and water could be migrated from the saturated zone through the unsaturated zone to the freezing front (Harlan, 1973;van der Kamp, 1992;Ireson et al., 2013). Since the 1950s, there are many field observations of 50 freezing-induced groundwater level decline (Drescher, 1955;Schneider, 1961;Stähli et al., 1999;Daniel and Staricka, 2000;van der Kamp et al., 2003;Ireson et al., 2013;Zhang et al., 2019), which are closely related to shallow groundwater in topographic lows (Gleeson et al., 2011;Fan et al., 2013). Unfortunately, numerical research on freezing-induced water redistribution that satisfactorily considers freezing-induced groundwater level decline is limited, which restricts quantitative understanding of water budgets in the freezing/thawing cycle.

55 To understand the effects of soil freezing on hydrogeological and ecohydrological processes and engineering problems, a key knowledge is the amount of freezing-induced water migration from the saturated zone to the frozen zone. Freezing-induced water migration from the saturated zone to the freezing front would

necessarily strengthen the possibility of frost heave (Chamberlain, 1981;Bronfenbrener and Bronfenbrener, 2010;Rui et al., 2019). During the thawing stage, accumulation of thawed water above the frozen zone would  
60 accelerate soil evaporation (Fetzer et al., 2017;Vanderborgh et al., 2017;Li et al., 2020), which is critical to soil salinization (Liu et al., 2009;Lopez et al., 2010;Bechtold et al., 2011). In some previous experimental and numerical studies, freezing-induced water migration from groundwater to the frozen zone was obtained by assuming a fixed water table (Shoop and Bigl, 1997;Hansson and Lundin, 2006;Alkhaier et al., 2012;Chen et al., 2019). In fact, a fixed water table lower boundary condition is an over-simplified representation of groundwater  
65 conditions (Carrera-Hernández et al., 2012), which implies that loss of groundwater can be replenished instantaneously. It has been found that a fixed water table would overestimate evaporation-induced groundwater loss (Zhu et al., 2010;Zhao et al., 2020). However, the degree of overestimation of freezing-induced groundwater migration by using a fixed head lower boundary condition remains unknown.

As initially proposed by Hubert (1940) and Tóth (1962), lateral groundwater flow is ubiquitous in regions  
70 with undulating topography and water table. Although wintertime water table fluctuations caused by freezing and thawing have been widely recognized (Willis et al., 1964;van der Kamp et al., 2003;Zhang et al., 2019), the simultaneous contribution of lateral groundwater flow to wintertime water table fluctuations received little attention. Ireson et al. (2013) found the wintertime water table recessions in their two study sites in the Canadian prairies were partly due to lateral groundwater outflow, while Jiang et al. (2017) found the pattern of wintertime  
75 water table fall-rise in their study site in the Ordos Plateau, China was also influenced by lateral groundwater inflow. Therefore, the wintertime water table dynamics is not prior known, but is a function of both atmospheric conditions and lateral groundwater inflow/outflow and should be a part of model output. To obtain a clear understanding of wintertime water migration in regions with shallow groundwater, it is appealing to numerically combine hydrological processes in both saturated and unsaturated zones, including topographically-driven lateral  
80 flow in the saturated zone, freezing-induced water migration from the saturated to the unsaturated zone, and thawing-induced water movement. In the current study, the field site reported in Jiang et al. (2017), which has shallow water table and lateral groundwater inflow, is used to numerically examine the interactions of soil water and groundwater and calculate the water budget during the freezing-thawing cycle.

## 2 Methods

### 85 2.1 Study area and conceptual model

The Ordos Plateau in Northwestern China is one of the most intensively studied groundwater basins due to its

dependence on groundwater (Hou et al., 2010; Jiang et al., 2018). The main aquifer is the thick Cretaceous sandstone, which is overlain by thin Quaternary sediments. Due to the spatially undulating topography and low permeability of the sandstone aquifer, water table undulation is a subdued replica of the topography and regional  
90 groundwater generally flows laterally from topographic highs to topographic lows of a catchment. In a specific catchment, as a result of the occurrence of a small lake in topographic lows and the contribution of lateral groundwater flow from topographic highs, water table is shallow in topographic lows near the lake.

The Ordos Plateau has a semi-arid and cold climate. According to the meteorological data in the Otak station from 1955 to 2016 (data from China Meteorological Data Service Center, available at <http://data.cma.cn>),  
95 the annual mean precipitation is 265 mm and the annual mean evaporation is 1370 mm. The average monthly temperature decreases from -1.5 °C in November to -10.4 °C in January and increases from -6.4 °C in February to 0.9 °C in March, therefore, the period from late November to late March corresponds to the freezing-thawing cycle. Groundwater level declines induced by evapotranspiration in the summer and by freezing in the winter have been reported in some sites with shallow groundwater (Jiang et al., 2017; Zhang et al., 2019). The  
100 relationship between groundwater, soil water and the summertime atmospheric conditions, i.e., infiltration and evapotranspiration, has been numerically coupled by some researchers (Chen et al., 2019; Zhao et al., 2020). However, there is no numerical study on how groundwater and soil water dynamics respond to wintertime atmospheric conditions.

The Wudu Lake catchment is one of the small catchments located to the southeast of the first-order water  
105 divide of the Ordos Plateau. The distribution of water table elevations in the Wudu lake catchment can be found in Jiang et al. (2018) while the zone of flowing wells, i.e., with higher hydraulic head than the topography, can be found in Wang et al. (2015). There is a monitoring site of soil water content and groundwater level in the topographic lows of this catchment. The occurrence of several flowing wells near the monitoring site indicates that the site belongs to the discharge area and could receive lateral groundwater flow from topographic highs. The  
110 water table depths are recorded by using water level loggers in a shallow well with a depth of 10 m while the temperatures and liquid water content in the Quaternary deposits are recorded by using 5TM sensors produced by Decagon Devices at 8 depths (at around 10 cm, 20 cm, 30 cm, 50 cm, 70 cm, 90 cm, 110 cm, 150 cm). As shown in Fig. 1, water table depth increases from 115 cm on 28 NOV 2015 to 143 cm on 29 JAN 2016, which is a direct result of freezing-induced water migration from groundwater to the freezing front.

115 At the monitoring site, lateral groundwater flow had been found to be an indispensable component of groundwater budget (Jiang et al., 2017). Fig. 2 shows the control of main hydrological and hydrogeological

processes on groundwater level during the freezing-thawing cycle. The processes leading to water level decline include water migration induced by freezing and evaporation due to the dry climate, and the processes leading to water level rise is lateral groundwater flow throughout the cycle and infiltration of thawed water during the  
120 thawing stage.

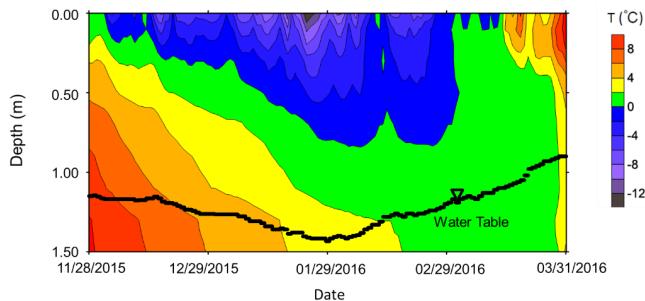

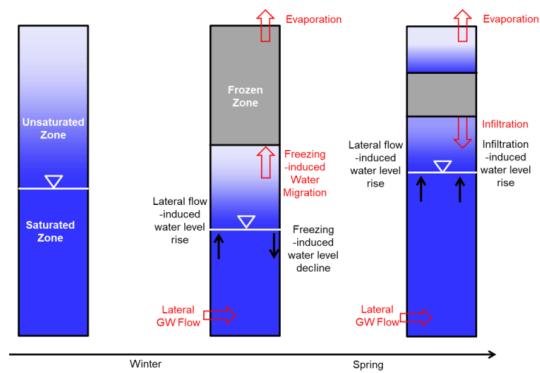

Figure 1. The contour map showing the change of soil temperature at the study site during the freezing-thawing cycle. Also shown is the fluctuating groundwater level monitored at the study site.

125 Figure 2 The conceptual models of hydrological processes and groundwater regime in semi-arid regions during the seasonally freezing and thawing stages.

## 2.2. The SHAW model

The Simultaneous Heat and Water (SHAW) model (Flerchinger and Saxton, 1989) is one of the most robust models for freezing-induced water migration (Hayhoe, 1994; DeGaetano et al., 2001; Kahimba et al., 2009; Zhang  
130 et al., 2017). The contributions of liquid water, ice, and vapor contents have been considered in the water balance equation, and the contributions of heat conduction, phase change, liquid flow, and vapor gas diffusion have been considered in the energy balance equation (Li et al., 2010). Because water flow in the unsaturated zone is predominantly vertical (Stephens, 1996; Romano et al., 1998; Van Dam and Feddes, 2000), the SHAW model only

accounts for the effects of soil freezing and thawing on water redistribution within a one-dimensional (1D) soil  
 135 column. Moreover, by adding a source term in the water balance equation, it has the ability to account for the contribution of lateral groundwater flow to water level in the soil column. Therefore, the SHAW model is suitable to couple the groundwater dynamics with soil water dynamics during the freezing-thawing cycle as observed in our field site.

Considering convective heat transfer by liquid, latent heat transfer by ice and latent heat transfer by vapor,  
 140 the energy balance equation in the soil matrix is expressed as

$$C_s \frac{\partial T}{\partial t} - \rho_i L_f \frac{\partial \theta_i}{\partial t} = \frac{\partial}{\partial z} \left[ k_T \frac{\partial T}{\partial z} \right] - \rho_i c_i \frac{\partial q_i T}{\partial z} - L_v \left[ \frac{\partial q_v}{\partial z} + \frac{\partial \rho_v}{\partial t} \right] \quad (1)$$

where  $T$  is temperature [ $\Theta$ ],  $\theta_i$  is volumetric ice content [-],  $z$  is soil depth [L],  $t$  is time [T],  $\rho_i$ ,  $\rho_l$  and  $\rho_v$  are densities of ice, liquid water and vapor [ $M\ L^{-3}$ ], respectively,  $L_f$  and  $L_v$  are latent heat of fusion and vaporization [ $L^2\ T^{-2}$ ], respectively,  $q_i$  is liquid water flux [ $L\ T^{-1}$ ],  $q_v$  is water vapor flux [ $M\ L^{-2}\ T^{-1}$ ],  $c_i$  is specific heat capacity of water [ $L^2\ T^{-2}\ \Theta^{-1}$ ],  $C_s$  is volumetric heat capacity of soil [ $M\ L^{-2}\ T^{-2}\ \Theta^{-1}$ ], and  $k_T$  is thermal conductivity of soil [ $M\ L^2\ T^{-3}\ \Theta^{-1}$ ]. Calculation of  $C_s$  and  $k_T$  can be found in Flerchinger and Saxton (1989) and is not reproduced here.  
 145

By considering ice content change and vapor flux, the water balance equation is written as

$$\frac{\partial \theta_l}{\partial t} + \frac{\rho_i}{\rho_l} \frac{\partial \theta_i}{\partial t} = \frac{\partial}{\partial z} \left[ K \left( \frac{\partial \psi}{\partial z} + 1 \right) \right] + \frac{1}{\rho_l} \frac{\partial q_v}{\partial z} + U \quad (2)$$

where  $\theta_l$  is liquid water content [-],  $K$  is hydraulic conductivity [ $L\ T^{-1}$ ],  $\psi$  is soil matric potential [L], and  $U$  is a source/sink term for water flux [ $T^{-1}$ ]. Soil water characteristic curves, which describe the relationship between soil matric potential and liquid water content, are defined for both unfrozen and frozen soils. Here, the van Genuchten equation (van Genuchten, 1980) is selected, which is written as

$$\frac{\theta_l - \theta_r}{\theta_s - \theta_r} = \left( 1 + |\alpha \psi|^n \right)^{-m} \quad (3)$$

where  $\theta_s$  and  $\theta_r$  are saturated and residual water content [-],  $\alpha$  [ $L^{-1}$ ],  $n$  [-] and  $m$  [-] are empirical parameters.  $\alpha$   
 155 equals the inverse of the air-entry value,  $n$  is a pore-size distribution index and  $m=1-1/n$ . In the frozen zone, due to the co-existence of liquid water and ice, matric potential is strongly dependent on temperature, and the matric potential is obtained by the following equation (Fuchs et al., 1978):

$$\psi = \frac{L_f}{g} \frac{T}{T + 273.15} \quad (4)$$

where  $g$  is the acceleration of gravity [ $L\ T^{-2}$ ]. Eq. (4) indicates that as the negative temperature increases, the soil  
 160 suction also increases (matric potential becomes more negative).

The hydraulic conductivity of the unfrozen zone is computed by

$$K = K_s S_e^l \left[ 1 - \left( 1 - S_e^{1/m} \right)^m \right]^2 \quad (5)$$

where  $K_s$  is the saturated hydraulic conductivity [ $\text{L T}^{-1}$ ],  $S_e$  [-] is the effective saturation calculated by  $(\theta_l - \theta_r) / (\theta_s - \theta_r)$ , and  $l$  [-] is a pore-connectivity parameter which is assumed to be 0.5 in the original work of 165 (Mualem, 1976). Note that in the saturated unfrozen zone,  $K$  equals  $K_s$ , but in the unsaturated unfrozen zone,  $K$  equals unsaturated hydraulic conductivity ( $K_u$ ). In the frozen zone, due to occupation of ice in the pores, the unsaturated hydraulic conductivity computed from Eq. (5) is reduced linearly with ice content and is assumed to be zero when the porosity is decreased to 0.13 (Flerchinger, 2000).

### 2.3. Model inputs

170 In the following, based on the conceptual model shown in Figure 2, we use SHAW to couple soil water and groundwater dynamics in a 1D soil column during the freezing-thawing cycle from 28 NOV 2015 to 1 APR 2016, as such to understand how the coupled unsaturated-saturated processes respond to wintertime atmospheric conditions. To ensure that the lateral groundwater inflow occurs within the saturated zone, the length of the 1D soil column is set to be 155 cm. The model domain is uniformly divided into 31 layers, which results in 32 nodes.

175 The top node has an atmospheric boundary condition, while the bottom node has a zero-flux and specified-temperature. Following Flerchinger (2000), the occurrence of lateral groundwater flow is realized by setting a specified hydraulic gradient at the 31<sup>st</sup> node. The fluctuation of groundwater level is an outcome of wintertime atmospheric conditions and lateral groundwater flow, while the fluctuations of soil water content are controlled by both wintertime atmospheric conditions and groundwater dynamics.

180 The inputs for the atmospheric boundary condition include maximum air temperature, minimum air temperature, wind speed, precipitation, solar radiation and dew-point temperature. The first four parameters available from the observations at the Otak meteorological stations, the parameter of solar radiation is calculated by the Angström-Prescott equation (Yorukoglu and Celik, 2006) based on the sunshine duration (data available from China Meteorological Data Service Center), and the dew-point temperature is calculated by the 185 Hyland-Wexler equation (Wexler et al., 1983) based on relative humidity, maximum air temperature and minimum air temperature. Fig. 3 shows the maximum and minimum air temperatures, dew-point temperature and precipitation. The inputs for the lower boundary condition at the bottom include a zero hydraulic conductivity to insure a no-flux boundary condition, and the daily averaged soil temperature measured at approximately corresponding depth for the specified-temperature boundary condition. The model spin-up is run for 30 days 190 before the start of freezing time (28 NOV 2015) to reach a quasi-steady state. The initial conditions of soil water

content and soil temperature for spin-up are determined based on measured values on 29 OCT 2015.

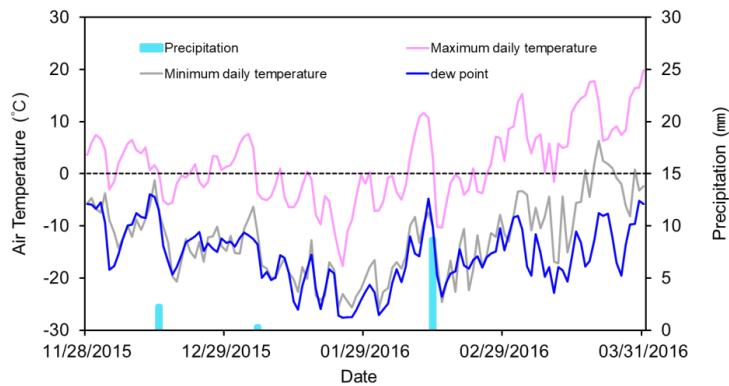

Figure 3 the maximum daily air temperature, the minimum air temperature, dew-point temperature and precipitation during the freezing-thawing cycle from 28 NOV 2015 to 1 APR 2016.

195

Although soil samples from all depths belong to sand or loamy sand, soil texture differs in the profile. The percentage of clay ranges between 5 and 8% in the layer between 70 and 100 cm, and between 1 and 4% in other depths (Zhao et al., 2020). Therefore, the model domain is divided into three layers. The parameters for the van Genuchten (1980) and Mualem (1976) models obtained by Zhao et al. (2020) are further calibrated, which are 200 shown in Table 1. As shown in Table 2, the further calibrated parameters result in much lower RMSEs. Based on the possible range of lateral flow rate varying between 0.96 and 1.16 mm/d (Jiang et al., 2017), the lateral inflow rate is calibrated to be 1.03 mm/d, which leads to the lowest RMSE of water table depth. This base case is denoted as Scenario A in Sect. 3.2.

To examine the role of soil heterogeneity in freezing-induced water migration, in Scenario B, we assume 205 the whole soil column has the same soil texture as that of 0 cm to 70 cm, and all other conditions are kept unchanged as Scenario A. By setting the lateral inflow rate to be zero, Scenario A changes into Scenario C and Scenario B changes into Scenario D. Because the disappearance of lateral groundwater inflow would lead to much deeper water table depth, the length of the 1D soil column in Scenarios C and D is extended to 200 cm. In Scenario C, the layer from 155 cm to 200 cm is assumed to have the same soil texture as that from 100 cm to 155 cm. Because there is no temperature measurement at 200 cm, the temperature at the lower boundary is estimated 210 by the method proposed by Hirota (2002), which is based on heat conduction and energy balance.

Table 1 Calibrated hydraulic parameters for the van Genuchten (1980) and Mualem (1976) models

Depth (m)	$\theta_r$ ( $\text{m}^3 \text{ m}^{-3}$ )	$\theta_s$ ( $\text{m}^3 \text{ m}^{-3}$ )	$\alpha$ ( $\text{m}^{-1}$ )	$n$ (-)	$K_s$ ( $\text{m d}^{-1}$ )

### 3 Results and discussion

#### 3.1 Field data showing freezing-induced water migration and water level decline

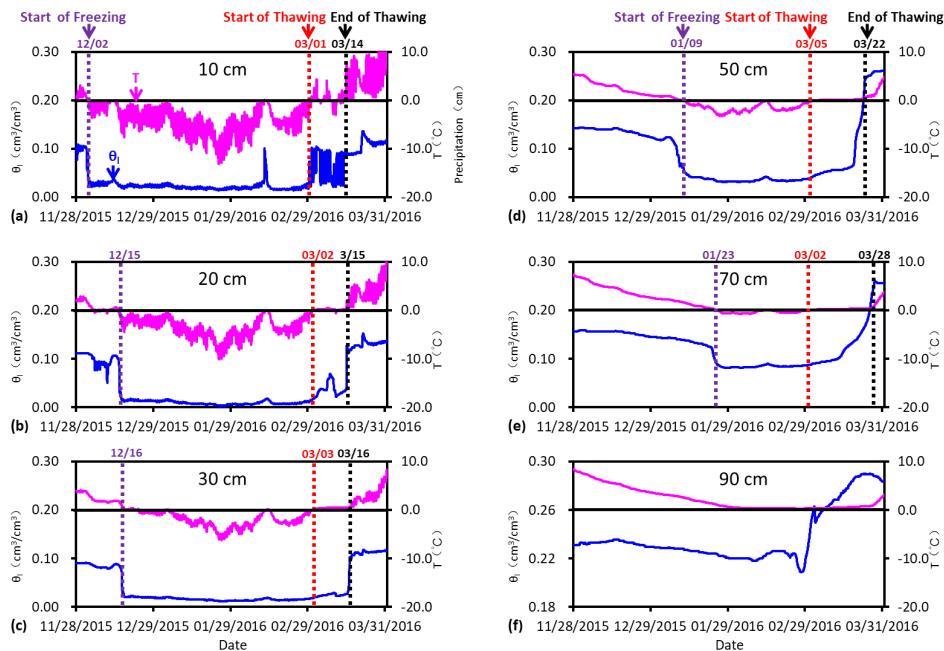

During the freezing stage from 28 NOV 2015 to 29 FEB 2016, there is a general trend of deepening frost depth (Fig. 1). The dates of the start of freezing, i.e., when soil temperature drops to 0 °C, at 10 cm, 20 cm, 30 cm, 50 cm, and 70 cm are 02 DEC, 15 DEC, 16 DEC, 9 JAN and 23 JAN, respectively (Fig. 4). At 10 cm, 20 cm and 30 cm below surface, there is a sharp decrease in liquid water content when the soil temperature drops to 0 °C, while at 50 cm and 70 cm below surface, due to freezing-induced water migration toward the freezing front, there is a gradual decrease in liquid water content before reaching a temperature of 0 °C. At 90 cm below surface, probably because the freezing front is close enough to the sensor, although the temperature at the sensor does not reach 0 °C, there is a significant decrease in liquid water content on 29 FEB due to freezing-induced water migration. Therefore, the relationship between temperature and liquid water content recorded by 5TM sensors, which are based on the frequency domain reflectometer (FDR) method, well reflects the effect of freezing on liquid water content.

Due to the rising air temperature in spring, soil temperature at 10 cm increased from below 0 °C to above 0 °C on 1 MAR, which is considered to be the start of the thawing stage in the current study. Because the water level is highest on 1 APR as a result of the downward infiltration of thawed water, 1 APR is considered to be the end of the thawing period. For the four sensors at 10 cm, 20 cm, 30 cm and 50 cm, the start dates of thawing

stage are 1 MAR, 2 MAR, 3 MAR, and 5 MAR, while for the sensor at 70 cm, the start date of thawing stage is 2 MAR, implying the occurrence of bi-directional thawing. Different from the quick response of soil temperature to freezing, the response of soil temperature to thawing is a slow process. For the 3 sensors at 10 cm, 20 cm and 30 cm, the duration from start to end of thawing is 13 days, while for the 2 sensors at 50 cm and 70 cm, the durations from start to end of thawing are 18 days and 26 days, respectively. The thawing of frozen soil is accompanied by a trend of increasing liquid water content. The liquid water content at the end of thawing is much higher than that before freezing, indicating the contribution of freezing-induced water gain.

235

240

Figure 4 The observed hourly liquid water content and soil temperatures during the freezing-thawing cycle from 28 NOV 2015 to 1 APR 2016.

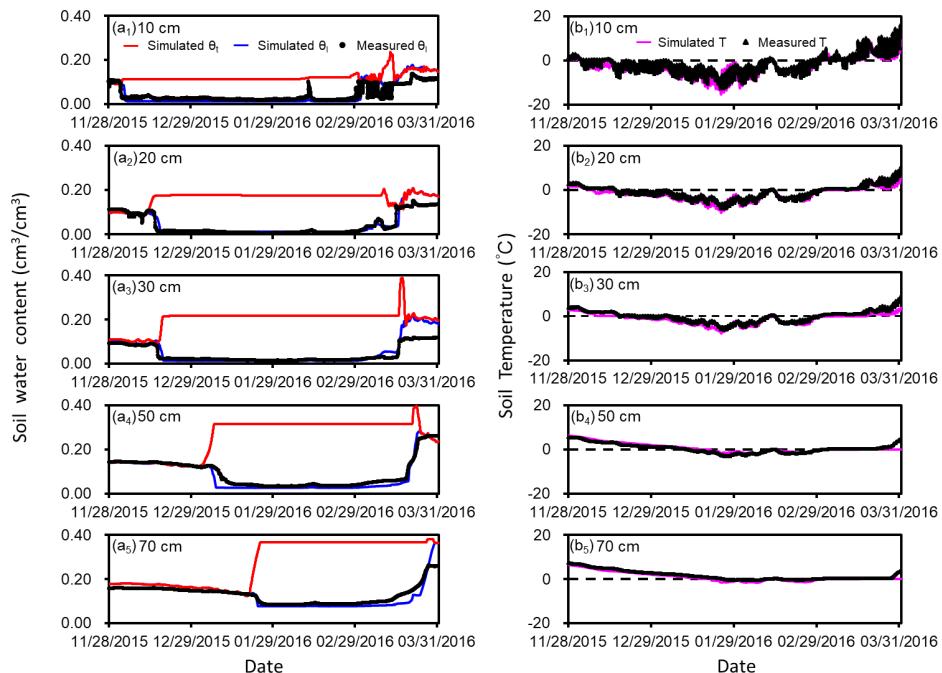

As shown in Fig. 1, water table depths on 28 NOV and 1 APR are 115 cm and 90 cm, respectively. Because 245 snowfall in winter is limited, the much higher water level at the end of thawing stage is mainly due to the occurrence of lateral groundwater inflow as reported in Jiang et al. (2017). The lowest water level equaling 143 cm below surface occurs on 29 JAN. From 29 JAN, there is a trend of rising water level, which is one month earlier than the occurrence of thawed water infiltration during the thawing stage. This phenomenon can also be attributed to lateral groundwater inflow. The occurrence of lateral groundwater inflow also alleviated the

250 magnitude of freezing-induced groundwater level decline from 28 NOV to 29 JAN, i.e., freezing-induced groundwater level decline should be greater than 28 cm. To quantify the water budget during the freezing/thawing cycle, the abovementioned model is constructed to determine the fluxes of freezing-induced migration, lateral groundwater flow, infiltration and soil evaporation.

### 3.2 Freezing-induced water redistribution: the effect of lateral groundwater flow and soil heterogeneity

255 Based on the parameters of van Genuchten (1980) and Mualem (1976) equation listed in Table 1, and the lateral flow rate of 1.03 mm/d, there are good fits between simulated and measured liquid water content in the frozen zone, and also for soil temperature (Fig. 5) and water level (Fig. 6a). Fig. 5 also shows the simulated total water content, which coincides with liquid water content before freezing, but increases rapidly due to freezing-induced water migration from the underlying soil and finally maintains at a stable value corresponding  
260 to the completely frozen state. In the frozen zone, the magnitude of increase in total water content increases from the shallow to the deep (Fig.5 and 6a), indicating that the distance to the water table not only controls the initial liquid water content, but also the amount of freezing-induced water gain from underlying soils.

265 Figure 5 The observed and simulated liquid water content and simulated total water content ( $\theta_i$ ) (a<sub>1</sub>-a<sub>5</sub>) and soil temperature (b<sub>1</sub>-b<sub>5</sub>) at the 5 different depths within the frozen zone during the freezing-thawing cycle.

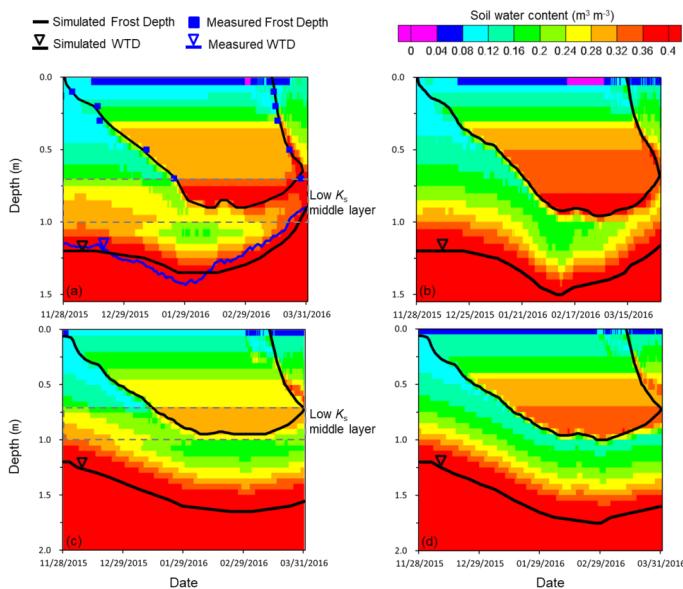

Figure 6 The frost depth, groundwater level and total water content under the four scenarios. (a) Scenario A, heterogeneous soil profile with a lateral flow rate of 1.03 mm/d; (b) Scenario B, homogeneous soil profile with a lateral flow rate of 1.03 mm/d; (c) Scenario C, heterogeneous soil profile without lateral inflow; (d) Scenario D, homogeneous soil profile without lateral inflow.

270

Soil texture and the corresponding hydraulic conductivity are also factors controlling the flux of freezing-induced water migration through the unfrozen zone. Because the soil texture in the layer from 70 cm to 100 cm is slightly different from overlying and underlying soils, we compare the distribution of total water content under the homogeneous case (Scenario B, Fig. 6b) with that of the base case (Scenario A, Fig. 6a). We find the low  $K_s$  of the middle layer restricts water migration into the part of frozen zone overlying the middle layer. As shown in Table 3, the increase of total water content in the frozen zone is 0.126 for Scenario B (corresponding to an increased water storage of 119.7 mm), and is 0.106 for Scenario A (corresponding to an increased water storage of 96.1 mm). Scenario A also has a smaller magnitude of freezing-induced water table decline (Table 3). Moreover, due to the ability of clay to retain more water, before late January when the frost depth is still away from the middle layer, the middle layer shown in Fig. 6a has more liquid water than that shown in Fig. 6b; from late January to late February when the freezing front in Fig. 6a is shallower than the bottom of the middle layer, the unfrozen part of the middle layer also has higher water content than the underlying soil.

275

280

285

Table 3 A comparison of water table decline ( $\Delta$ WTD), frost depth (FD), and water gain in the frozen zone under different groundwater conditions.

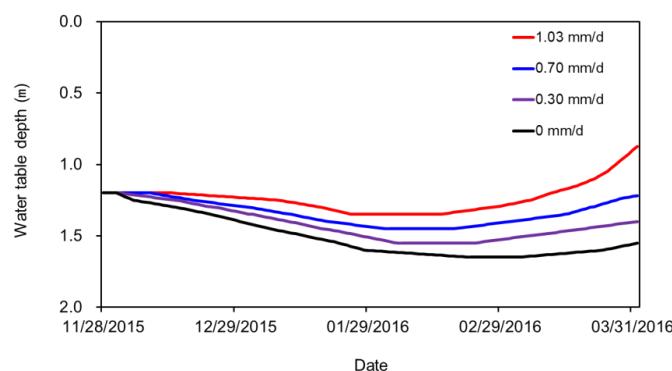

Groundwater conditions	Heterogeneous (low $K_s$ middle layer)				Homogeneous					
	$\Delta$ WTD (mm)	FD (cm)	$\Delta S_{FZ}$ (mm)	$\Delta$ TWC	Mean TWC	$\Delta$ WTD (mm)	FD (cm)	$\Delta S_{FZ}$ (mm)	$\Delta$ TWC	Mean TWC
	Fixed WTD=1.2 m	0	90	114.5	0.127	0.283	0	95	142.8	0.150
LFR=1.03 mm/d	15	90	96.1	0.106	0.265	30	95	119.7	0.126	0.282
LFR=0 mm/d	40	95	67.3	0.071	0.236	55	100	94.1	0.094	0.256

$\Delta S_{FZ}$  represents increased water storage in the frozen zone,  $\Delta$ TWC represents increased total water content in the frozen zone, and Mean TWC represents the mean total water content in the frozen zone at the state of completely frozen.

290

Lateral groundwater flow is a component of water budget influencing water level. When there is no lateral groundwater flow, in either the heterogeneous case (Scenario C, Fig. 6c) or the homogeneous case (Scenario D, Fig. 6d), the lowest water level occurs at the end of the freezing stage. By comparing the simulated groundwater level under a series of lateral groundwater inflow rates, we find the occurrence of lateral groundwater inflow alleviates the magnitude of freezing-induced water level decline, and leads to a trend of earlier water level rise before the start of the thawing stage (Fig. 7). Therefore, in the field, the existence of lateral groundwater inflow can be determined by the earlier occurrence of groundwater level rise before the start of the thawing stage. Due to the occurrence of lateral groundwater inflow, the rise in water level from late January to late February also restricts the frost depth to some extent (Table 3).

295

300

Figure 7 The temporal variations of simulated water table depth under different lateral groundwater inflow rates.

The higher water level caused by lateral groundwater flow would be beneficial for freezing-induced water migration towards the freezing front. In the heterogeneous cases, the increase in total water content in the frozen zone is found to be 0.106 in Scenario A, but is only 0.071 in Scenario C without lateral groundwater flow; in the homogeneous cases, the increase in total water content in the frozen zone is found to be 0.126 in Scenario B, but 305 is only 0.094 in Scenario D without lateral groundwater flow (Table 3). Therefore, compared with scenarios without lateral groundwater inflow, the occurrence of lateral groundwater inflow can inevitably lead to an increased freezing-induced water accumulation.

If a fixed head equaling 1.2 m below surface is assigned at the lower boundary, the increase in total water content in the frozen zone is 0.127 for the heterogeneous case, and is 0.150 for the homogeneous case (Table 3). 310 This confirms that a fixed head lower boundary condition would inevitably overestimate freezing-induced water migration. As we pointed out in the Introduction part, a fixed head lower boundary condition implies instantaneously replenishment of groundwater. The results shown in Fig. 7 indicate that an even larger groundwater inflow is needed to maintain a stable water level.

### 3.3 Soil evaporation during the freezing-thawing cycle

315 By comparing model results with and without consideration of the three snowfall events, we find snowfall did not infiltrate into the soil column due to the low permeability of frozen soil and got evaporated directly, implying that soil water evaporation is the only form of water loss leaving the top of the soil column during the freezing-thawing cycle. Therefore, we use the evaporation rate without considering snowfall events to represent actual soil evaporation. Note that although snowfall is not considered, the atmospheric conditions associated with 320 the snowfall event on 13 FEB still result in higher evaporation rate (Fig. 8).

Based on the trend of evaporation rate versus time, we identify three stages of soil water evaporation. Stage I has a trend of decreasing evaporation rate, stage II has a limited evaporation rate, and stage III has a trend of increasing evaporation rate. In both scenarios, the start of stage II corresponds to a frost depth of around 20 cm. In Scenario A, the mean evaporation rates in the three stages are 0.36, 0.18 and 0.59 mm/d, respectively (Fig. 8a), 325 leading to a cumulative evaporation of 32.1 mm; in Scenario B, the mean evaporation rates in the three stages are 0.53, 0.21 and 1.55 mm/d (Fig. 8b), respectively, corresponding to a cumulative evaporation of 55.3 mm. The high evaporation rate in stage III, which is a direct result of accumulation of liquid water during the thawing stage, well explains the occurrence of soil salinization in spring (Liu et al., 2009; Lopez et al., 2010; Bechtold et al., 2011). Similar three stages of temporal evolution of soil evaporation during the freezing-thawing cycle have

330 been reported in several field studies (Kaneko et al., 2006; Wu et al., 2016; Xue et al., 2020).

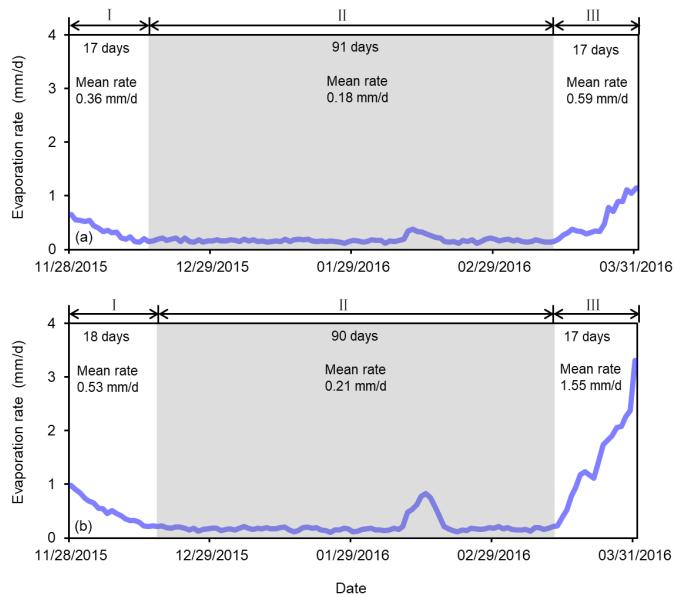

Figure 8 The simulated daily soil evaporation for Scenario A (a) and Scenario B (b). Also shown is the mean evaporation rate for each stage.

335 In subsect. 3.2, based on the difference of total water content between the beginning and the end of the freezing stage, the increased water storage in the frozen zone induced by freezing was calculated to be 96.1 mm for Scenario A, and 119.7 mm for Scenario B. Considering the amount of water loss leaving the soil column due to soil evaporation, the actual cumulative freezing-induced water migration into the frozen zone should be 115.6 mm for Scenario A and 146.0 mm for Scenario B. Therefore, a clear quantification of soil evaporation is critical  
 340 to understanding interactions of soil water and groundwater induced by freezing.

### 3.4 Water budgets during the freezing/thawing cycle

Because almost all snowfall are evaporated without entering the subsurface, soil evaporation and lateral groundwater inflow are the only two processes influencing the balance of water in the soil column. If the freezing/thawing cycle is divided into the freezing stage and the thawing stage, the balance of water in each stage

345 can be written as

$$S_{s0} + S_{u0} + q \cdot \Delta t_F = S_{s1} + S_{u1} + ET_F \cdot \Delta t_F \quad (6a)$$

$$S_{s1} + S_{u1} + q \cdot \Delta t_T = S_{s2} + S_{u2} + ET_T \cdot \Delta t_T \quad (6b)$$

where  $S_{s0}$  [L],  $S_{s1}$  [L] and  $S_{s2}$  [L] are cumulative water storages in the saturated zone at the beginning of freezing stage, at the end of freezing stage (beginning of thawing stage) and at the end of the thawing stage, respectively; 350  $S_{u0}$  [L],  $S_{u1}$  [L] and  $S_{u2}$  [L] are cumulative water storages in the unsaturated zone at the beginning of freezing stage, at the end of freezing stage (beginning of thawing stage) and at the end of the thawing stage, respectively;  $q$  [L/T] is the mean rate of lateral groundwater inflow during the freezing/thawing cycle;  $\Delta t_F$  [T] and  $\Delta t_T$  [T] are the durations of the freezing and thawing stages, respectively;  $ET_F$  [L/T] and  $ET_T$  [L/T] are the mean soil evaporation rates during the freezing and the thawing stages, respectively. The values of each term in Eq. (8) are 355 listed in Table 4.

Table 4 Water budgets during the freezing-thawing cycle

Stage	Duration	$\Delta t$ (d)	Initial $S_s$ (mm)	Initial $S_u$ (mm)	$q \cdot \Delta t$ (mm)	$ET \cdot \Delta t$ (mm)	Final $S_s$ (mm)	Final $S_u$ (mm)
Freezing	28 NOV 2015 - 28 FEB 2016	93	120.9	246.4	95.8	19.5	80.6	362.9
Thawing	29 FEB 2016 - 1 APR 2016	32	80.6	362.9	33.0	12.6	239.6	224.4

Apparently, the groundwater loss during the freezing stage is calculated by  $S_{s0} - S_{s1}$ , which equals 40.3 mm and corresponds to a water table decline of 10 cm. In fact, such a water table decline has been alleviated by 360 the lateral groundwater inflow. The freezing-induced groundwater loss should be calculated by  $S_{s0} - S_{s1} + q \cdot \Delta t_F$ , which equals 136.1 mm. In a groundwater flow model without considering the unsaturated zone, this process can be characterized by a mean upward groundwater flux of 1.46 mm/d with a duration of 93 days at the upper boundary. This is consistent with the dominance of upward flux at the upper boundary in the unfrozen period at the study site (Jiang et al., 2017). Therefore, the current study confirms that shallow groundwater in the discharge 365 area of a semi-arid catchment is dominated by upward flow, which is consistent with the direction of regional groundwater flow in the discharge area (Hubbert, 1940; Toth, 1962).

Similarly, in the thawing stage, groundwater gain from downward infiltration should be calculated by  $S_{s2} - S_{s1} - q \cdot \Delta t_T$ , which equals 126.0 mm. In a groundwater flow model, this process can be characterized by a mean downward groundwater flux of 3.94 mm/d at the upper boundary with a duration of 32 days. As 370 demonstrated in Jiang et al. (2017), in the unfrozen period, the stage from late SEP 2014 to early OCT 2014 (with a duration of 18 days) is the only stage with net infiltration in our study site, and the net downward groundwater flux equals 2.99 mm/d. The current study indicates that the thawing stage has an even larger downward groundwater flux. Therefore, it is interesting to examine the pattern of two-dimensional or three-dimensional

groundwater flow induced by the freezing-thawing cycle by using a fully coupled soil-groundwater freeze-thaw

375 model in the future.

#### 4 Conclusions

Based on field observations of soil temperature, liquid soil water content and groundwater level in the discharge area of a catchment, it was found that the observed temporal variations of wintertime liquid water content and groundwater level are not only controlled by freezing and thawing, but also by lateral groundwater 380 inflow. Therefore, a model is built to examine the responses of soil water and groundwater to wintertime climatic conditions and occurrence of lateral groundwater inflow in the saturated part of the soil column. The calibrated model increases our understanding of water balance as well as freezing-induced water migration during the freezing-thawing cycle.

Our model results showed that almost all snowfall is evaporated without infiltrating into the soil column due 385 to the low permeability of frozen soil. Therefore, soil evaporation is the only form of water loss, while lateral groundwater inflow is the only source of water gain. By comparing models with and without lateral groundwater inflow, we found the occurrence of lateral groundwater inflow led to much smaller magnitude of freezing-induced water level decline, and a trend of rising water level before the start of the thawing stage. Consequently, compared with the case without lateral groundwater inflow, the higher water level due to lateral 390 groundwater inflow resulted in much larger freezing-induced water migration into the frozen zone. We also found the middle layer with lower saturated hydraulic conductivity restricts both evaporation rates and freezing-induced water migration.

Based on the budget of groundwater during the freezing-thawing cycle, the mean flux of freezing-induced groundwater loss in the freezing stage with a duration of three months is 1.46 mm/d, and the mean flux of 395 thawing-induced groundwater gain in the thawing stage with a duration of one month is found to be 3.94 mm/d. As found by Jiang et al. (2017), due to the semi-arid climate, the only stage with net recharge in the unfrozen period is from late September to early October. Therefore, combined with the fluxes obtained by Jiang et al. (2017) for the unfrozen period, the fluxes during the freezing-thawing cycle obtained in the current study can be useful for future transient groundwater flow models to characterize the control of climatic conditions on 400 groundwater flow in semi-arid regions with seasonally freezing and thawing processes.

### Code/Data availability

The numerical models in the current study were built by using the SHAW model (vision 3.0), which is available at <https://www.ars.usda.gov/pacific-west-area/boise-id/watershed-management-research/docs/shaw-model/>.

405 The meteorological data of the Otak station is available from China Meteorological Data Service Center (<http://data.cma.cn>).

The observed soil temperature, liquid water content and water table depth from 28 NOV 2015 to 1 APR 2016 at the field site are available in the supplement document.

### 410 Author contribution

XJ designed the field site and HX was involved in data collection. All authors were involved in data interpretation. XJ and LW developed the initial idea of the current study, and HX established the models with inputs from all coauthors. HX and XJ wrote the manuscript with contributions from YZ.

### 415 Competing interests

The authors declare that they have no conflict of interest.
