**Abstract.** East-African forested mountain regions are vital in generating and supplying water resources to adjacent arid and semi-arid lowlands. However, these ecosystems are under pressure from both climate and land-use changes. This study aimed to analyze the effects of climate and land-use changes on water yield using the Budyko framework conceptual framework as a first-order conceptual framework assuming steady-state for pristine/protected forested areas. For 9-nine selected forested water towers in East Africa, the amount and distribution of water resources and their decadal changes were analyzed. Results show that most areas inside and outside the water towers are under pressure from human influences. Water yield was observed to be more sensitive to climate changes compared to land-use changes within the selected East African water towers themselves. However, for the surrounding lowlands, the effects of land-use changes have had greater impacts on water yield. We conclude that the East-African water towers have seen a strong shift towards wetter conditions, especially in the period of 2011-2019 while at the same time, the potential evapotranspirationatmospheric demand is gradually increasing. Given that majority-most of the water towers were identified as non-resilient to these changes, future water yield is likely to also experience more extreme variations.

**Keywords:** Water towers, Climate changes, Land-use changes, Water yield, Budyko framework

## 1. Introduction

Many mountainous areas act as water towers by generating and supplying water resources runoff and streamflow to adjacent lowlands that would otherwise be much drier. Beyond the supply of water, the elevated water towers maintain high actual evapotranspiration hence playing a key role in regional rainfall recycling (WWF, 2005). Water towers have been defined in various ways. (Viviroli et al., (2007) categorized water towers into four categories types essential, supportive, occasional, and limited water towers based on their contribution to downstream discharge. (Dewi et al., (2017) introduced a quantification criterion for defining water towers as an area that satisfies two conditions: (a) an aridity-humidity index (i.e. a ratio of precipitation to potential evapotranspiration) of above 0.65 and (b) where the aridity-humidity index relative to the elevation is greater than 2.77. (Immerzeel et al., (2020) introduced a global water tower index (WTI), which ranks water towers in terms of their water-supplying role and the downstream dependence of ecosystems and society. (UNEP, (2010) defined water towers as elevated areas of land (generally at least 200 m above the surrounding area) that receive at least 750 mm of rainfall and 250 mm of runoff per year and are significant water sources for populations beyond their immediate delineated boundaries.

What is evident in all definitions is that high elevation and high precipitation are key components that determine the generation of streamflow to the drier lowland areas - an important aspect for arid and semi-arid areas in the East African region. EAC et al. (2016) defined the key water towers based on major rivers in East Africa and delineated 3 major montane forest ecosystems (i) the Albertine Rift, (ii) the Kenyan Highlands and the (iii)

Field Code Changed

Ethiopian Highlands. An area is considered a water tower if it has a high elevation and high precipitation, consequently generating streamflow to lowland areas (Dewi et al., 2017; Immerzeel et al., 2010; Vivioli et al., 2007). Although research on water towers has focused mainly on glaciated mountain chains (Immerzeel et al., 2020) —where the temperature is a key factor in determining water flows from glaciated mountain chains, there is growing awareness that forested mountains can provide similar services (Vivioli and Weingartner, 2004). Mountainous areas in Africa cover approximately 20 % of Africa's surface area and receive-maintain significantly more precipitation rain than adjacent lowlands (UNEP, 2014; EAC et al., 2016). Mountain forests capture, store, purify and release water They capture water, store it, purify it, and release it to lowland areas (UNEP, 2014). The East-African region The East African-region is one of the most mountainous areas of Africa with several peaks above 4,500 meters and hosts the three highest mountains on the continent: Kilimanjaro (5,895 m), Mount Kenya (5,119 m), and the Rwenzori Mountains (5,109 m) (UNEP, 2014). Many of the water towers are of volcanic origin which can be linked to the East-African rift system extensive plate tectonics (Dawson, 2008; Scoon, 2020).

Montane forest ecosystems in the East-African region are classified as water towers due to their high elevations and high humidity, thus generating water yield for adjacent lowland areas (UNEP, 2010).— There is a high dependency on surface water in the East-African region (Jacobs et al., 2018), but rainfall distribution is meager insufficient in most parts of the region, with several areas experiencing frequent occurrence-of severe droughts (Nicholson, 2017). (El Tom, (1972) tested the reliability of rainfall and showed that in the dry areas, the rainfall is highly variable and nearly independent of the mean annual value – affecting rainfed agriculture in the region. Fluctuations of rainfall are evident in both seasonal and decadal time series mainly in the semi-arid zones (Hulme, 1990). Therefore, the forested water towers in the region are therefore important sources of water that sustain environmental and human water demands in the dry lowland areas.

The water towers of East Africa are under pressure from human intensification and climate change (WWF, 2005; Gebrehiwot et al., 2014). According to the Intergovernmental Panel for Climate Change (IPCC) Fifth Assessment Report, the average annual temperature for Africa has risen by at least 0.5 °C during the last 100 years and this is predicted to increase by approximately 3.2 °C by 2080. This will dramatically diminish glaciers in East-African water towers whose surface area has already decreased by 80 % since the 1990s (EAC et al., 2016), affecting runoff and water resources downstream. The East-African montane forest zones continue to be lost to agriculture and other anthropogenic uses. This is mainly attributed to high and increasing population density which is a major driving force of environmental change in the mountainous areas (UNEP, 2014).

Understanding historical climate change and human-induced land-use changes and their impacts on streamflow generation from the forested water towers can explain some of the extreme hydrological events experienced in the adjacent lowlands. This can help inform the role of forested water towers in observed extremities in the lowlands such as floods and hydrological droughts. To the best of our knowledge, there are no studies that have focused on the East-African forested water towers and their ability to generate streamflow under a changing climate and land-use in the East African region. At the regional scale, studies have either focussed on studying forest trends/deforestation (Aleman et al., 2018) or the effects of land-use changes on climate (Otieno and Anyah, 2012). At the river basin scale, studies have focussed on hydrological responses (Hyandyne et al., 2018; Mango et al., 2011; Gabiri et al., 2020).

That said—Guzha et al. (2018) in their review emphasized the importance of forests in streamflow generation in the East African region, with forest degradation leading to increased stream discharges and surface runoff. Moreover—Muthoni et al. (2019), focused on spatial-temporal trends and variability of precipitation within East and Southern Africa. However, there is limited information on the partitioning of the available precipitation into water yield and evapotranspiration from the forested water towers of the East-African region. Given the semi-arid conditions in the lowlands of East African region, there is a need to study the sensitivity of forested water towers to changes in climate and land use.

Various approaches have been used for studying the effects of climate change and land-use changes on streamflow. Jiang et al. (2015) categorized such methods into two:—(a) deterministic rainfall-runoff models and (b) statistical methods. (Ma et al., (2014) combined the two categories by running rainfall statistics and recorded land-use change patterns in reverse order in calibrated process-based models. Dey and Mishra (2017) reviewed the existing approaches and categorized these approaches into four categories; (i) experimental approach e.g. paired catchment

method (Bosch and Hewlett, 1982)es, (ii) hydrological modeling e.g. SWAT (Tech, 2019), (iii) conceptual approaches e.g. Budyko approach (Budyko, 1974), and (iv) analytical approaches e.g. climate elasticity method (Schaake, 1990).

Generally, the different approaches can be grouped into modeling (or distributed models) and conceptual approaches (Marhaento et al., 2017; Mianabadi et al., 2020). The advantage of modeling approaches is that the results are more reliable (Booij et al., 2019). However, the challenges of modeling approaches e.g. SWAT is that the underlying processes must be explicit, require complex and multiple data inputs, and a time-consuming calibration and validation (Zhang et al., 2012). The application of modeling approaches is therefore limited to small watersheds where detailed streamflow observations are available or in watersheds that are well monitored with extensive, long-term available data on vegetation, soil, topography, land use, hydrology, and climate (Wei and Zhang, 2011). Conceptual approaches such as Budyko frameworks require fewer data, hence flexible in their application from small to large study areas and generally give logical primary results (Marhaento et al., 2017; Booij et al., 2019). These primary results can be very crucial for data-limited regions such as East Africa and can form the basis for detail hydrological studies (Teng et al., 2012). In this study, we selected the Budyko framework assuming a steady-state to analyze the impact of land use and climate changes on water yield for the selected forested water towers of East Africa.

The Budyko model-framework(Budyko, 1974) is a conceptual approach that considers both water and energy constraints in hydrological processes over a long-term period. The framework has been applied to quantify or separate the impacts of climate change and human activities on runoff (Jiang et al., 2015; Xu et al., 2013; Roderick and Farquhar, 2011).

A steady-state is reached when the total input (i.e., precipitation) equals the total output (i.e., evapotranspiration and water yield) (Han et al., 2020) and changes in soil water storage are zero (Donohue et al., 2007). Hence a simple water balance equation assuming steady-state conditions can be written as:

$$P = ET + Q \quad (1)$$

where  $P$  is precipitation,  $ET$  is actual evapotranspiration and  $Q$  is water yield.

The steady-state assumption of the Budyko curve has been challenged in several studies (Van der Velde et al., 2014; Donohue et al., 2007; Mianabadi et al., 2020; Du et al., 2016). Most of these studies have however challenged the steady-state assumption for studies focused on catchments in the lower slopes at finer temporal or spatial scales and the unreliability of the Budyko framework to predict future water cycles. In the lower slopes, the hydrological processes are under - influence of anthropogenic changes e.g. urbanization, water abstraction, agricultural intensification, deforestation, etc. To our knowledge, the steady-state assumption has not been challenged on studies focussing on the upper slopes of the elevated forested mountains – where we assume steady-state assumptions would probably hold due to pristine conditions. Actually, (Du et al., (2016) demonstrated that the basins in the upper slopes met steady-state conditions, while this was not the case for downstream basins due to human interference and water inflows from the upstream basins. In their study, Van der Velde et al. (2014) demonstrated that the climate and land-use changes do not outpace the ability of the forests to adapt their water-use and energy-use strategies to the prevailing conditions. (Han et al., (2020) studied 1,057 global unimpaired catchments and showed that over 70% of the catchments attain a steady-state within 10 years with co-evolution between climate and vegetation coverage playing a key role in maintaining the steady-state conditions.

Generally, the Budyko framework, either in the original format (i.e. steady-state) or in the modified format (i.e. non-steady-state conditions) is a quick first-order tool for estimating precipitation partitioning into evaporation and water yield (Mianabadi et al., 2020; Teng et al., 2012; Zeng et al., 2020). The framework is particularly useful in evaluating the sensitivity of water yield to changes in climate and catchment characteristics (Mianabadi et al., 2020; Liu et al., 2013; Sankarasubramanian et al., 2001; Sun et al., 2014; Yang et al., 2014; Zhang et al., 2004; Roderick and Farquhar, 2011; Creed et al., 2014; Jiang et al., 2015; Xu et al., 2013; Mwangi et al., 2016). (Creed

et al., 2014; Jiang et al., 2015; Mwangi et al., 2016; Roderick and Farquhar, 2011; Xu et al., 2013; Zhang et al., 2004) The Budyko framework has been applied successfully in numerous studies focusing on the partitioning of precipitation into streamflow and evapotranspiration (Creed et al., 2014; Jiang et al., 2015; Mwangi et al., 2016; Roderick and Farquhar, 2011; Xu et al., 2013; Zhang et al., 2004). In spite of the criticism on the validity of the Budyko model outlined before, it is being applied widely and successfully at scales ranging from coarse global grid resolution to smaller basins of less than 10 km<sup>2</sup> (Zhang et al., 2004; Redhead et al., 2016; Teuling et al., 2019).

Field Code Changed

In this paper, we aims to use the Budyko framework to analyze the effects of climate and land-use hydroclimatic changes over the past decades focussing on the and their impacts on the amount and distribution of water resources from selected forested water towers of East Africa.

The selection of water towers was based on aridity index (AI), high elevation, and continuous forest block. The selected water towers have AI>0.65 (i.e humid), located in high elevated areas under a continuous forest block from the footslope contour to the peak. The montane forests are the three major forest ecosystems in East Africa – as defined and delineated by (UNEP, 2010; EAC et al., 2016), and they include the Albertine Rift, the Kenyan Highlands, and the Ethiopian Highlands. They were defined and delineated based on major rivers in the region. All the selected water towers in this study fall in the three forest ecosystems. The water yield simulations were evaluated against observation-based runoff. The Budyko framework was used to answer the following research question: What are the effects of climate and land-use changes on water yield for the selected forested water towers?

We hypothesize that, in areas considered as pristine or protected zones (i.e. high elevated forested areas), with AI>0.65, changes in water yield would majorly be attributed to climate changes and negligibly due to land use/cover changes. The high elevated forested areas would then be expected to fall on the theoretical Budyko curve over the study period. The water yield simulations were evaluated against observation-based runoff.

## 2. Data and Methodology

We used the Budyko conceptual framework was adopted to evaluate the impacts of land-use changes and climate changes on water yield from the selected forested water towers. The study area is the East-African region. The montane forest ecosystems are the major forest types in Eastern Africa. They range from Ethiopian highlands to Albertine rift mountains stretching along the Congo DRC and bordering Uganda, Rwanda, Burundi, and Tanzania. This study focused on montane forest ecosystems and their moorlands. The selected water towers are shown in Fig 1, and summarized in Table 1 and Table A2.

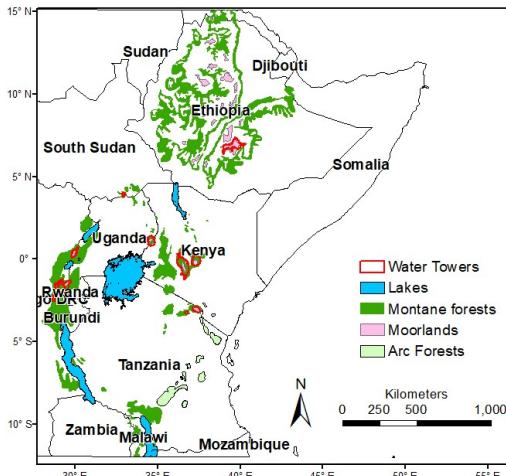

Figure 1. The East African Forest Ecosystems and the location of the selected water towers (adapted from The Nature Conservancy, 2012)

Table 1. The selected water towers of East Africa

Mountain Ecosystems	Location	Peak (m)	Elevation – asl	Foot slope contour - asl (m)
Mt Kilimanjaro	Tanzania	5,895	2000	
Mt Kenya	Kenya	5,199	2000	
Mt Elgon	Kenya/Uganda	4,321	2000	
Aberdare Ranges	Kenya	3,999	2100	
Rwenzori Mountains	Uganda/Congo	5,109	2000	
Mt Meru	Tanzania	4,565	2000	
Virunga Mountains	Congo/Rwanda/Uganda	4,507	2000	
Bale Mountains	Ethiopia	4,337	2600	
Imatong Mountains	South Sudan/Uganda	3,187	2000	

Formatted Table

Note: The selected water towers have an aridity index above 0.65 (i.e humid), located in high elevated areas. The footslope was selected such that there is a continuous forest block from the footslope contour to the peak. The footslope contour were adjusted upwards for two water towers (i.e Aberdare ranges and Bale mountains) to 2,100 m a.s.l and 2,600 m a.s.l respectively to ensure we capture majorly the elevated forested areas presumably under pristine conditions.

## 2.1. Data and analysis

Precipitation (P) data was were gathered from the Climate Hazards Group Infrared Precipitation with Stations (CHIRPS-v2) with a temporal coverage beginning 1981 and a spatial resolution of 0.05°. CHIRPS uses the Tropical Rainfall Measuring Mission Multi-satellite Precipitation Analysis version 7 (TMPA 3B42 v7) to calibrate global Cold Cloud Duration (CCD) rainfall estimates (Funk et al., 2015). Potential Evapotranspiration (PET) data was were sourced from the Climate Research Unit (CRU) database with temporal coverage beginning 1981 and a spatial resolution of 0.5°. The CRU-PET is calculated using the Penman-Monteith formula (Harris et al., 2020; Ekström et al., 2007). Normalized Difference Vegetation Index (NDVI) data to estimate land surface characteristics was were sourced from the Global Inventory Monitoring and Modeling System (GIMMS) Third Generation (3 g) Advanced Very High-Resolution Radiometer (AVHRR) sensor onboard the National Oceanic and Atmospheric Administration (NOAA) satellites at a spatial resolution of 0.07° (Pinzon and Tucker, 2014; Tucker et al., 2005; Kalisa et al., 2019). The NDVI is derived using the Bayesian methods with high-quality well-calibrated SeaWiFS NDVI data. The resulting NDVI values give an error of  $\pm 0.005$  NDVI (Pinzon and Tucker, 2014).

The research borrows from the concept of quantifying the long-term impact of climate and land-use changes on mean annual evapotranspiration and water yield at catchment scales based on data and parameters that are easily measurable at a regional scale (Zhang et al., 2001). Forested catchments generally have higher evapotranspiration than other land covers such as grassed catchments. Therefore changes in land use and forest management have an impact on catchment water balance and hence water yield (Zhang et al., 2001; Teuling and Hoek van Dijke, 2020).

One way of estimating water yield (Q) and actual evaporation ( $ET_{ET}$ ) is to assume that evapotranspiration from land surfaces is controlled by water availability and atmospheric demand (Zhang et al., 2001). The water availability can be approximated by precipitation; the atmospheric demand represents the maximum possible evapotranspiration and is often considered as the potential evapotranspiration (PET). Under very dry conditions, PET exceeds precipitation (P) and actual evapotranspiration ( $ET_{ET}$ ) equals precipitation. About 60% of the world's land surface is considered an arid area (i.e. P/PET ratio also known as aridity index (AI) of below 0.65 (Biodiversity of Dry and Sub-Humid Land Ecosystems, 2021). Under very wet conditions water availability exceeds PET, and  $ET_{ET}$  will asymptotically approach the potential evapotranspiration (Zhang et al., 2001), (see Fig A1 for key assumptions on energy and water limits). The Budyko Curve provides a “business as usual” reference condition for the water balance. Assuming that it can depict the expected partitioning of P into  $ET_{ET}$  and Q, then it is possible to account for the reasons why some points depart from the baseline (Creed and Sparre, 2012b). The vertical deviations reflect a change in the partitioning of P into  $ET_{ET}$  and Q, hence, the higher the evaporative index (EI), the less the streamflow (Q). The horizontal deviations reflect the change in climatic

conditions (i.e. temperature and precipitation); thus, the higher the dryness index (DI), the warmer/drier the conditions.—One important feature of the Budyko curve is the assumption that, under stationary conditions (i.e. naturally occurring fluctuations due to P and PET), hydrologic partitioning of study areas will follow fall on the Budyko Curve. However, under non-stationary conditions (i.e. anthropogenic influence manifested in ET changes), each catchment will deviate from the Budyko curve depending on land cover and physical catchment characteristics (Creed and Spargo, 2012b; Mwangi et al., 2016)(Creed and Spargo, 2012b), and thisThis feature might can be used to separate land cover change effects from climate change.

In this study, we used the Budyko framework and two recently introduced Budyko metrics (deviation and elasticity) (Creed et al., 2014) to study the changes in the water yields. Similar methodologies were adopted by Helman et al. (2017) to determine the resilience of forested catchments and Sinha et al. (2018) to understand the involvement of anthropogenic stress and climatic variance on the partitioning of precipitation. Based on these studies, catchments can be assumed to shift predictably along the Budyko curve. This forms the basis for interpreting the vertical and horizontal deviations as a result of changes in climate and anthropogenic effects. The elasticity is defined as a measure of a catchment's ability to maintain hydroclimatic conditions as the climate varies. In contrast to other studies using the Budyko framework to look at different drivers of change, we used Budyko-derived data rather than observations. Therefore, the deviations are thereby constructed and presented as a way to visualize and interpret the results. Beyond the maps and graphs presented following the Budyko equation we further illustrate the movement of water towers within the Budyko space.

### 2.1.1. The Budyko equations

Several analytical equations have been proposed for the Budyko curve. In this study, FuU's equation was used (Equation 42) in a 10-years time step for 1981-2010 and 9 years for 2011-2019. The equation has been applied in different studies (Teuling et al., 2019; Li et al., 2013; Zhang et al., 2004)(Teuling et al., 2019; Li et al., 2013).

$$\frac{ET}{P} = 1 + \frac{PET}{P} - \left[ 1 + \left( \frac{PET}{P} \right)^\omega \right]^{1/\omega} \quad (24)$$

where  $P$ ,  $PET$ , and  $ET/ET$  are the precipitation, potential evaporation, and actual evapotranspiration.  $PET/P$  and  $ET/ET/P$  are termed “dryness index” and “evaporation ratio”, respectively. Parameter ( $\omega$ ) is an empirical parameter that controls how much of the available water will be evaporated given the available energy.

The  $\omega$  parameter is the most difficult parameter to estimate in Budyko framework applications (Bai et al., 2019). It reflects the impact of other factors such as land surface characteristics and climate seasonality on water and energy balances (Li et al., 2013). Previous studies have adopted various ways to estimate the  $\omega$  parameter. Some studies used fitted values based on land-use/cover of the areas under investigation. For instance, (Zhang et al., 2012) used values of 2, 0.5, and 1 to represent  $\omega$  for the forest, grassland and shrubland respectively. (Creed et al., 2014) used  $\omega = 2$  in forested catchments,  $\omega = 0.5$  in grassland or cropland catchments, and  $\omega = 1$  in mixed cover catchments. Other studies calibrated it based on historical data (Gunkel and Lange, 2017; Redhead et al., 2016; Yang et al., 2014). However, for data-limited regions, calibration-based estimations are impossible and simpler methods to estimate the  $\omega$  parameter based on readily available data are desirable. Land surface hydrology varies due to variations in different factors such as vegetation, soil types, and topography, and climate seasonality, etc (Li et al., 2013; Yan et al., 2020)(Li et al., 2013). Soil texture and topography influence the amount of water available for vegetation – hence the vegetation signatures can reflect the underlying conditions of soil water conditions, topography, seasonality etc. Donohue et al. (2007) argued based on the theory of ecohydrological equilibrium that in water-limited environments, vegetation is the integrated response to all processes affecting the availability of water. Therefore, vegetation information can serve as a good integrated indicator of these ecohydrological impacts on water and energy balances as it reflects the integrated landscape and climatic features. Using data from 26 major global river basins under a wide range of climate regimes, Li et al. (2013) developed a simple parameterization for Budyko  $\omega$  parameter based solely on vegetation information as shown in equation 3 below: Vegetation information can serve as a good integrated indicator of these ecohydrological impacts on water and energy balances as it reflects the integrated landscape and climatic features (Donohue et al., 2007). The fact that vegetation coverage integrates the effects of the eco-hydrological processes on water and energy balances

Field Code Changed  
Field Code Changed  
Field Code Changed

warrants a simple parameterization for ( $\omega$ ) using only vegetation information in the large-scale basins (Li et al., 2013). According to Li et al. (2013), ( $\omega$ ) parameters can be calculated using the following equation:

$$\omega = 2.36M + 1.16 \quad (23)$$

Where  $M$  represents the vegetation coverage – which is calculated based on NDVI indices (Yang et al., 2009):

$$M = \frac{NDVI - NDVI_{min}}{NDVI_{max} - NDVI_{min}} \quad (34)$$

In this study, the  $M$  values were calculated for 1985, 1995, 2005, and 2015, and assumed to represent the ( $\omega$ ) parameters for the respective periods of 1981-1990, 1991-2000, 2001-2010, and 2010-2019.

Over a long period (i.e. 5-10 years) it is reasonable to assume that changes in soil water storage are zero (Creed et al., 2014; Teuling et al., 2019; Zhang et al., 2001). Therefore, the water yield is estimated using the following equation:

$$Q = P - ET + \Delta S \quad (45)$$

Where  $Q$  represents the water yield (parameter to be estimated),  $P$  is precipitation (input from datasets), and  $ET$  is the simulated actual evapotranspiration (input from Budyko equation), and  $\Delta S$  is the water storage term. Over a long period (i.e. 5-10 years) it is reasonable to assume that changes in soil water storage are zero under steady-state stationary climate conditions (Teuling et al., 2019; Creed et al., 2014; Zhang et al., 2001). Therefore,  $\Delta S$  was assumed to be zero in our study.

### 2.1.2. Developing the Budyko curves

To develop the Budyko curves that are representative of the selected forested water towers, 100 random points were generated in each of the water towers in ArcGIS. The random points were used to extract values from raster  $P$ ,  $PET$ , and  $ET$  grids into excel format for external analysis developing the Budyko curves. For maximum representation, the minimum allowed distance between the random points was set to 100 meters. The random points generated were assigned the respective values of  $PET$ ,  $ET$ , and  $P$  using the Extract Multi Values to Points tool in ArcGIS. The Evaporative index (EI) values – calculated as a ratio of  $ET$  and  $P$ , and Dryness index (DI) values – a ratio of  $PET$  and  $P$  were used to draw the Budyko curves. In this study, the Budyko curve for the 1981-1990 period was used as the reference condition for the water balance, to effectively assess the trends in the succeeding periods of 1991-1990, 1991-2000, 2001-2010, and 2011-2019.

### 2.1.3. Evaluating the effects of land use and climate changes

To evaluate the impacts of climate and land-use changes, the sensitivity of climate and land-use changes was conducted. The climate and land-use values for the years 1981-1990 were used as the reference conditions in the Budyko framework. The climatic conditions (i.e.  $P$  and  $PET$ ) for the years 1981-1990 were held constant in the Budyko framework to evaluate the impacts under changing land-use conditions in the succeeding periods of 1991-2000, 2001-2010, and 2011-2019. Similarly, the land-use conditions – (i.e. ( $\omega$ ) parameters) for the years 1981-1990 were held constant in the Budyko framework to evaluate the impacts under changing climatic conditions in the succeeding periods of 1991-2000, 2001-2010, and 2011-2019.

Additionally, the deviations from the Budyko curves were also investigated to give a further illustration on the movement of water towers in the Budyko space understanding of the type of changes observed in the different water towers. The x-axis (horizontal deviations) in the Budyko space illustrates the aridity indices and the y-axis (vertical deviations) characterizes the evaporative indices (Heidari et al., 2021). Vertical deviations from the Budyko curve indicate anthropogenic effects which result in increases or decreases in water yield (Creed and Spargo, 2012b, a). The horizontal deviations reflect a shift to warmer or humid conditions mainly due to resultant variations in temperature and precipitation (Creed and Spargo, 2012b, a). The deviation (d) and elasticity (e) are the two indices used to describe the potential departure from the theoretical Budyko curve of a catchment's DI and EI points with time (Creed et al., 2014). The deviation (d) was defined as vertical deviation from the Budyko curve calculated using the following formula;

$$d = EI_{Sim} - EI_{Bud} \quad (56)$$

5 ~~W~~here  $EI_{Sim}$  represents EI simulated for periods in 1991-2000, 2001-2010 and 2011-2019 and  $EI_{Bud}$  represents the predicted theoretical Budyko value for the reference period of 1981-1990. ~~The  $EI_{Bud}$  therefore represents the 'theoretical value' (i.e. point on the Budyko curve where the water tower was expected to fall at a particular period. The  $EI_{Sim}$  represents the point where the water tower plotted in that period. The difference between the expected/reference point ( $EI_{Bud}$ ) and the actual point ( $EI_{Sim}$ ) was then calculated to give the deviation ( $d$ ) from the Budyko curve.~~ A negative ( $d$ ) represents a downward shift from the Budyko curve and hence an increase in Q (Creed and Spargo, 2012a). A positive ( $d$ ) represents an upward shift from the Budyko curve and hence a decrease in Q. ~~Elasticity ( $e$ ) was defined as the ratio of interdecadal variation in dryness index (DI) to interdecadal variation in the evaporative index (EI). The elasticity ( $e$ ) was calculated as a ratio of DI ranges to EI ranges~~ as shown in the following formula ~~below~~:

$$e = \frac{\Delta DI}{\Delta EI} \quad (67)$$

10 Where  $\Delta DI$  represents a range in DI values and  $\Delta EI$  represents a range in EI values observed in the periods of 1991-2000, 2001-2010, and 2011-2019 using the period of 1981-1990 as the reference period. ~~In our study, the evaporative indices (EI) for the four periods (i.e. 1981-1990, 1991-2000, 2001-2010, and 2011-2019) were calculated (based on averages of ET and P for each period). The range in EI (i.e.  $\Delta EI$ ) is the difference between the reference/baseline EI (of 1981-1990) and succeeding periods of 1991-2000, 2001-2010, and 2011-2019. The water towers with lower elasticity values indicate greater ranges in their EI values. The and the water towers with higher elasticity values demonstrate lesser ranges in their EI values (i.e. larger denominator reduces elasticity).~~

#### 2.1.4. Comparison of simulated streamflow with observation-based runoff

20 The simulated streamflow of the water towers was compared with composite runoff data downloaded from the Global Runoff Data Centre (GRDC). The composite runoff fields, developed through combining observed river discharge information with a climate-driven water balance model, provide the "best estimate" of terrestrial runoff over large domains (Fekete et al., 2002). A total of 312 points above 2000 meters above sea level, which is the focus of this study (i.e. elevated water towers), were randomly generated in ArcGIS. For maximum representation, the minimum allowed distance between the random points was set to 100 meters. The selected random points and their respective values of simulated streamflow and composite runoff were compared.

### 3. Results

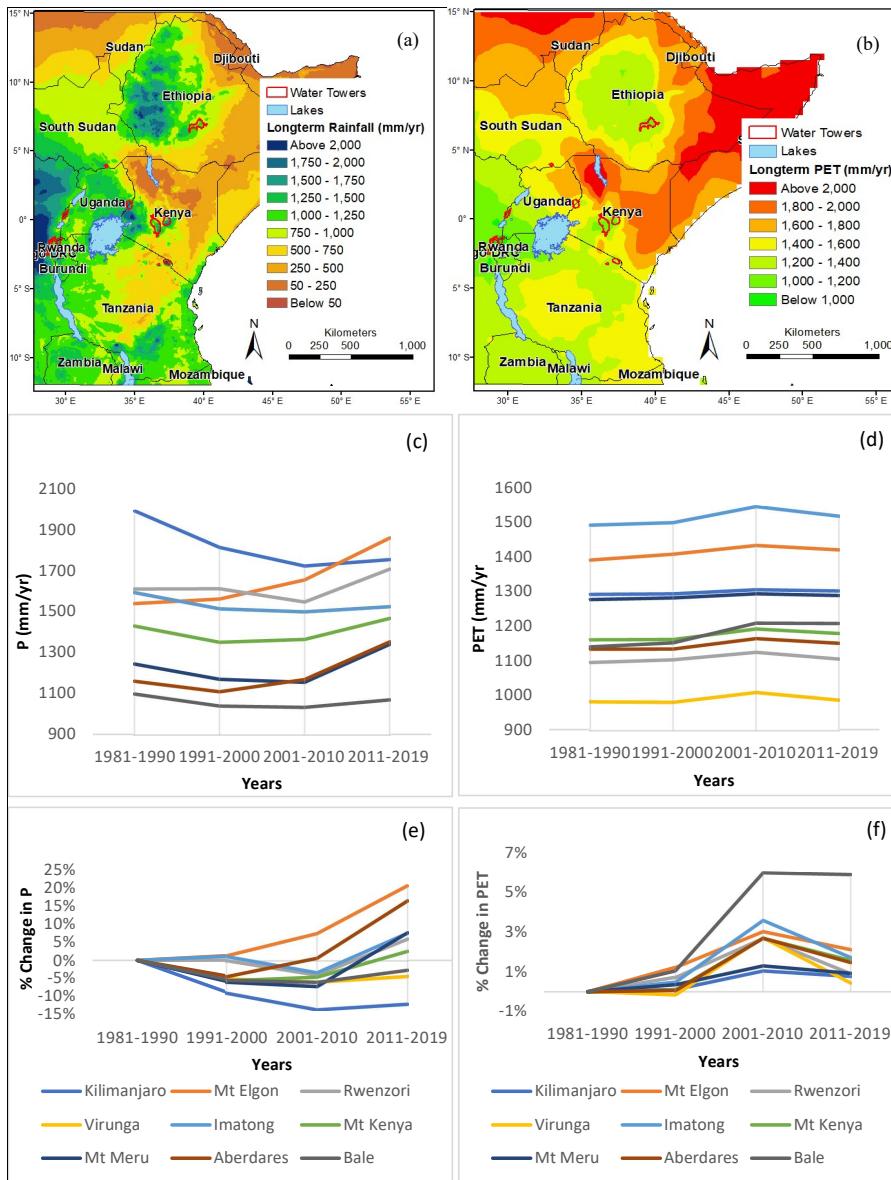

#### 3.1. Climate characteristics over the period 1981 – 2019 (Precipitation and Potential evapotranspiration)

25 Higher long-term mean annual rainfall of above 1000 mm  $yr^{-1}$  was ~~generally~~ observed ~~majorly~~ in the mountainous forest ecosystems located in the western region and the Ethiopian highlands in the north of East Africa (Fig 2a). The mountainous forest ecosystems are important rainfall regions in drier environments as represented by Mt Kilimanjaro (average 1800 mm  $yr^{-1}$ ), Mt Meru (average 1200 mm  $yr^{-1}$ ), Mt Kenya (average 1400 mm  $yr^{-1}$ ), and Aberdare ranges (average 1200 mm  $yr^{-1}$ ) as shown in Fig 2a and Fig 2cb. The 10-year moving averages analysis revealed patterns of ~~high-increasing~~ and ~~decreasing low~~ trends in precipitation in the different water towers (Fig A2).

30 35 ~~Using the 1981-1990 period as the reference period, e~~Changes in ~~Precipitation~~ precipitation relative to 1981-1990 period, showed a ~~Longitudinal-longitudinal~~ gradient. Negative changes in rainfall were observed in the water towers located towards the eastern side except for the Virunga mountains. Positive trends were observed in the water towers located towards the western side with exception of ~~the~~ Aberdare ranges. Mt Kilimanjaro experienced a strong mean annual rainfall reduction with an average annual reduction of 13.5 % and 12 % observed in ~~the~~ periods of 2001-2010 and 2011-2019 respectively (Fig 2ee). ~~Conversely~~ ~~Contrasting~~ly, a steady increase in mean annual rainfall was observed in Mt Elgon with an average increase of over 20 % recorded in the years of 2011-2019 (Fig 2ee).

Long-term assessment of atmospheric demand (PET) showed areas with relatively higher mean annual PET to coincide with areas of low rainfall and vice-versa (Fig 2d2b). Generally, atmospheric demand continued to increase over time in all the water towers with a peak observed in [the-years-of](#) 2001-2010 (Fig 2e-2d and Fig A3). [The](#) 5 [Imatong Mountains water tower had the highest atmospheric demand with an average long-term mean of appx approximately 1500 mm yr<sup>-1</sup>, followed closely by Mt Elgon with an average long-term mean of approximately appx 1400 mm yr<sup>-1</sup>. The water towers located towards the western side exhibited lower atmospheric demand \(examples are Virunga mountains – long-term mean of 990 mm yr<sup>-1</sup> and Rwenzori mountains – long-term mean of 1100 mm yr<sup>-1</sup>\).](#)

10 [Using the 1981-1990 period as the reference period, aAll](#) water towers experienced increases in the annual atmospheric demand [relative to 1981-1990 period](#) (Fig 2f.) Bale mountains saw a sharp increase in atmospheric demand [by of](#) approximately 6 % in [the-periods-of](#) 2001-2010 and 2011-2019. A minimal increase in atmospheric demand was observed [in-at](#) Mt Kilimanjaro with an average annual increase of 0.1 %, 1.0 %, and 0.8 % in [the periods-of](#) 1991-2000, 2001-2010, and 2011-2019 respectively as shown in Fig 2f.

**Figure 2. Long-term mean annual rainfall (a, b, e) and Potential Evapotranspiration. The left panels show the precipitation and the observed changes (d, e, f) for the period 1981-2019 (a, c, e). The right panels show potential evapotranspiration and the observed changes for the period 1981-2019 (b, d, f)**

### 3.2. Land cover characteristics over the period 1981 – 2019

Higher values for the Budyko parameter ( $\omega$ ) were observed derived in the western part of Congo/Uganda, the Ethiopian Highlands and along the coastline of Tanzania, Kenya, and Somalia (Fig 3a). The land surface characteristics ( $\omega$ ) ranged between 2.4 and 3.1 in the different water towers, with exception of the Bale mountains where a drop to 2.3 was observed in 2015 (Fig 3b). Using the year 1985 as the reference period for the land cover characteristics, different patterns of negative changes and positive changes were observed. A major drop was observed in Mt Meru and Mt Kilimanjaro while Mt Elgon and Imatong mountains maintained a positive change (Fig 3c).

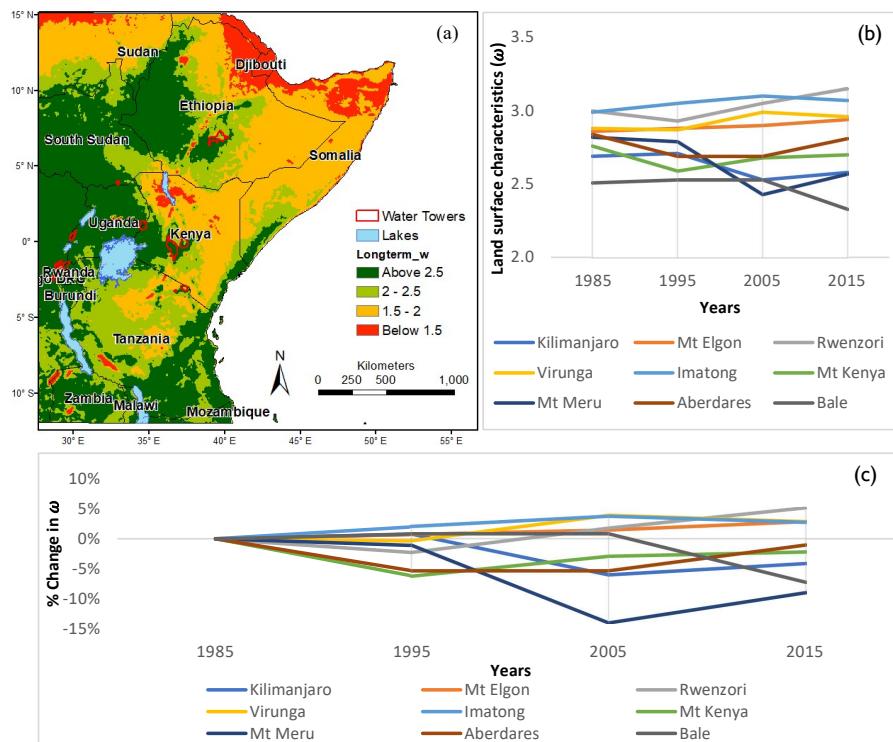

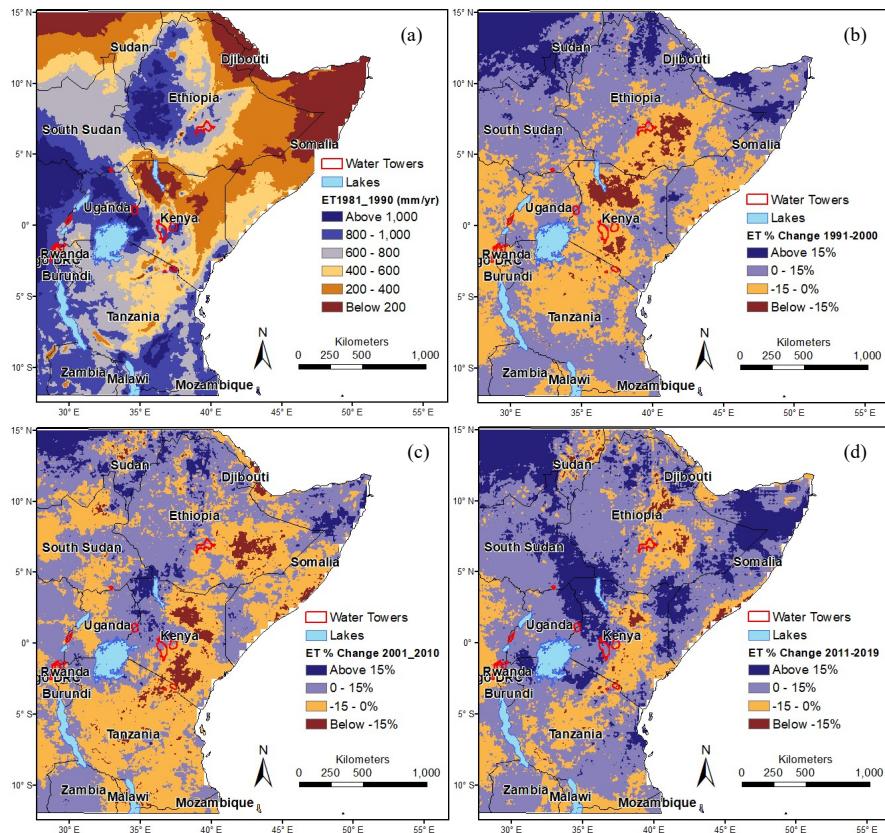

Figure 3. The Land surface characteristics. Spatial distribution of Budyko parameter ( $\omega$ ) for 1985 to 2015 (a), the changes observed between 1985 and 2015 (b) & and (c)

### 3.3. Simulation of actual evapotranspiration

The long-term actual evapotranspiration (ET<sub>ta</sub>) assessment revealed longitudinal differences in the spatial distribution. The water towers towards the west were observed to be located in regions with higher ET<sub>aET</sub> (examples are Mt Elgon, Imatong mountains, Rwenzori mountains, and Virunga mountains). The water towers towards the east are located in regions with relatively lower ET<sub>aET</sub> (examples are Mt Meru, Mt Kilimanjaro, Aberdare Ranges, and Mt Kenya). (Fig 4a and Fig 5a, 5b, 5c, 5d). The changes in ET<sub>aET</sub> in the region were analyzed using the 1981-1990 period as the baseline (Fig 4a). The decreases in ET<sub>aET</sub> were observed in the South-south-Eastern-eastern parts of Ethiopia, along a North-south gradient in Kenya, central Tanzania, and the western side of Congo/Burundi region as shown in Fig 4b, 4c, and 4d. The increases in ET<sub>aET</sub> were observed in

northern parts of Eastern Africa (i.e. Sudan, South Sudan, Djibouti, Northern Somalia, the Kenyan-Somali border, and parts of north-western Kenya bordering Uganda and South Sudan (Fig 4b, 4c, and 4d).

**Figure 4. Distribution of simulated actual evapotranspiration in East Africa. Simulation of Actual Evapotranspiration (Eta) in the East African region:** (a) ETaET for 1981-1990, (b) ETaET changes in 1991-2000, (c) ETaET changes in 2001-2010, and (d) ETaET changes in 2011-2019

5

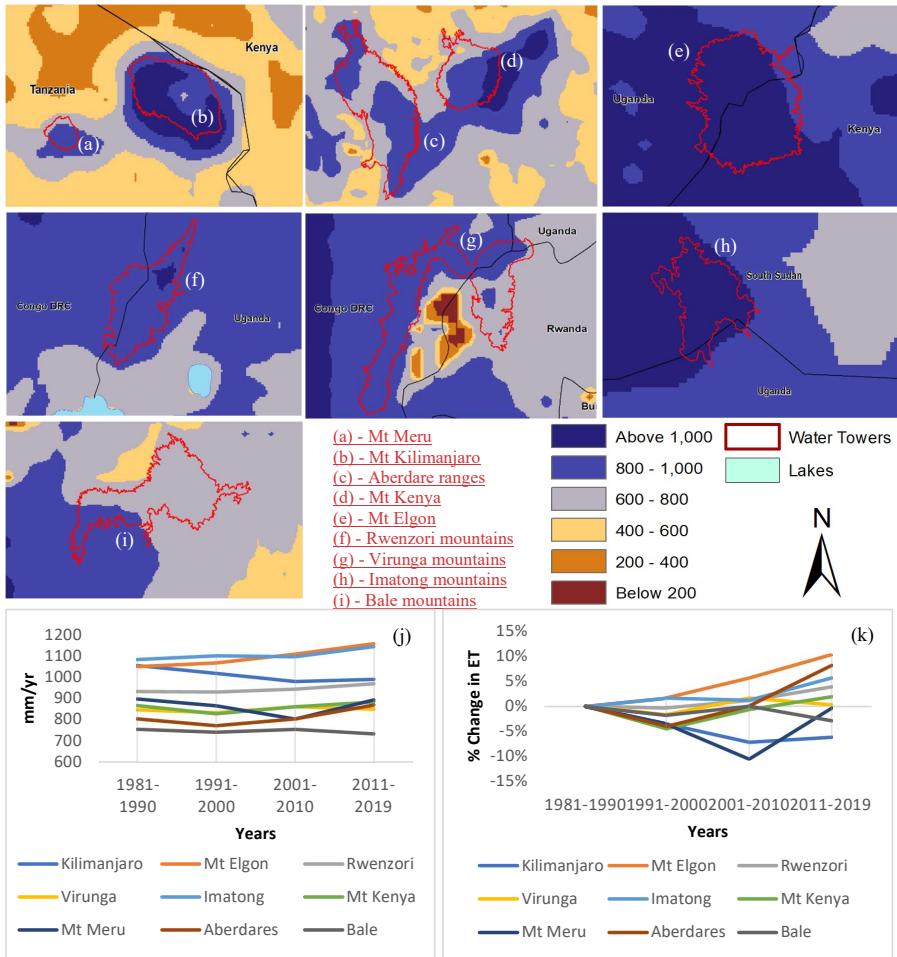

Despite the longitudinal differences [in the region](#), the individual water towers recorded varied ETaET values. Higher ETaET values were simulated around the Imatong Mountains – with a long-term mean of 1107 mm yr<sup>-1</sup>,

10 Mt Elgon – with long-term a mean of 1097 mm yr<sup>-1</sup>, and Mt Kilimanjaro – with long-term a mean of 1012 mm yr<sup>-1</sup>.

15 The lowest ETaET values were observed in the Bale mountains – with a long-term mean of 747 mm yr<sup>-1</sup> (Fig 5j). Using the 1981-1990 period as the reference period, Mt Elgon recorded a steady increase in annual mean ETaET with an average increase of the order of 10 % [observed](#) between 2011 and 2019. Pronounced decreases in ETaET were observed in [the](#) Mt Kilimanjaro and Mt Meru water towers (Fig 5k), consistent with the decreasing trend in precipitation.

15

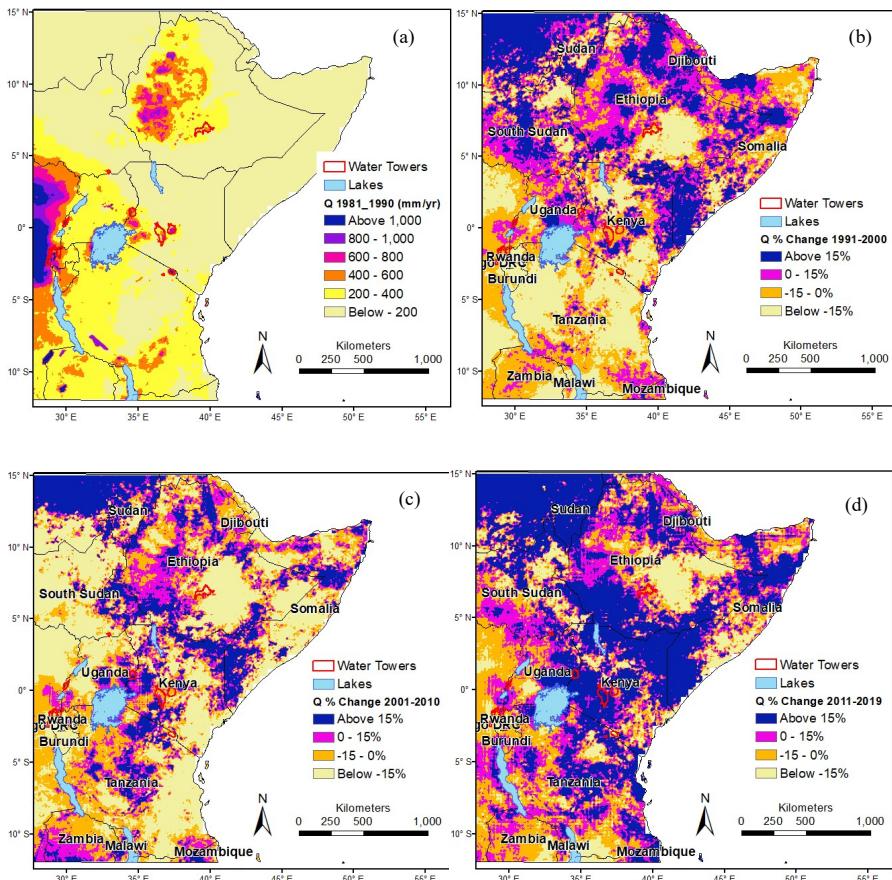

12

### 5 3.4. Simulation of water yield

Similarly to what was observed in-for ETaET spatial distribution, the long-term water yield (Q) assessment also showed that the water towers located towards the east are surrounded by regions with low water yield potential below 200 mm yr<sup>-1</sup> (examples are Mt Meru, Mt Kilimanjaro, the Aberdare Ranges, and Mt Kenya (Fig 6a and Fig 7a, 7b, 7c, 7d). Using the period 1981-1991 as the baseline, major increases in Q were observed in areas of Sudan, and the Kenya-Somali border as shown in Fig 6b, 6c, and 6d.

**Figure 6. Spatial distribution of simulated water yield. Simulation of Water Yield (Q) in the East African region: (a) Q for 1981-1990, (b) Q changes in 1991-2000, (c) Q changes in 2001-2010, and (d) Q changes in 2011-2019**

Despite longitudinal differences, the higher mean annual water yield was observed in the Mt Kilimanjaro water tower located on the eastern side – with the long-term annual mean of 794 mm yr<sup>-1</sup>, followed by two water towers located on the western side (i.e. Virunga mountains – with a long-term annual mean of 676 mm yr<sup>-1</sup> and Rwenzori mountains – with a long-term annual mean of 650 mm yr<sup>-1</sup>). The lowest annual mean water yield was observed in the Bale mountains – with a long-term annual mean of 315 mm yr<sup>-1</sup> (Fig 7j). Conversion of water yield units from mm/yr to m<sup>3</sup>/s per unit area revealed that Mt Kilimanjaro and Mt Kenya are important sources of water in the drier parts of the East African region (Table A1).

Using the period 1981-1990 as the reference point, positive and negative changes in water yield were observed in the different water towers. There was a consistent increase in annual mean water yield in the Mt Elgon water tower with an order of increases of 11.4 % and 42.9 % recorded in the periods of 2001-2010 and 2011-2019 respectively (Fig 7k). There was a decrease in water yield in the Aberdare and Mt Meru water towers during the 1991-2000 period, after which an increase in annual mean water yield was recorded in the later years. A consistent decline was observed in Mt Kilimanjaro and the Virunga mountains during the study period.

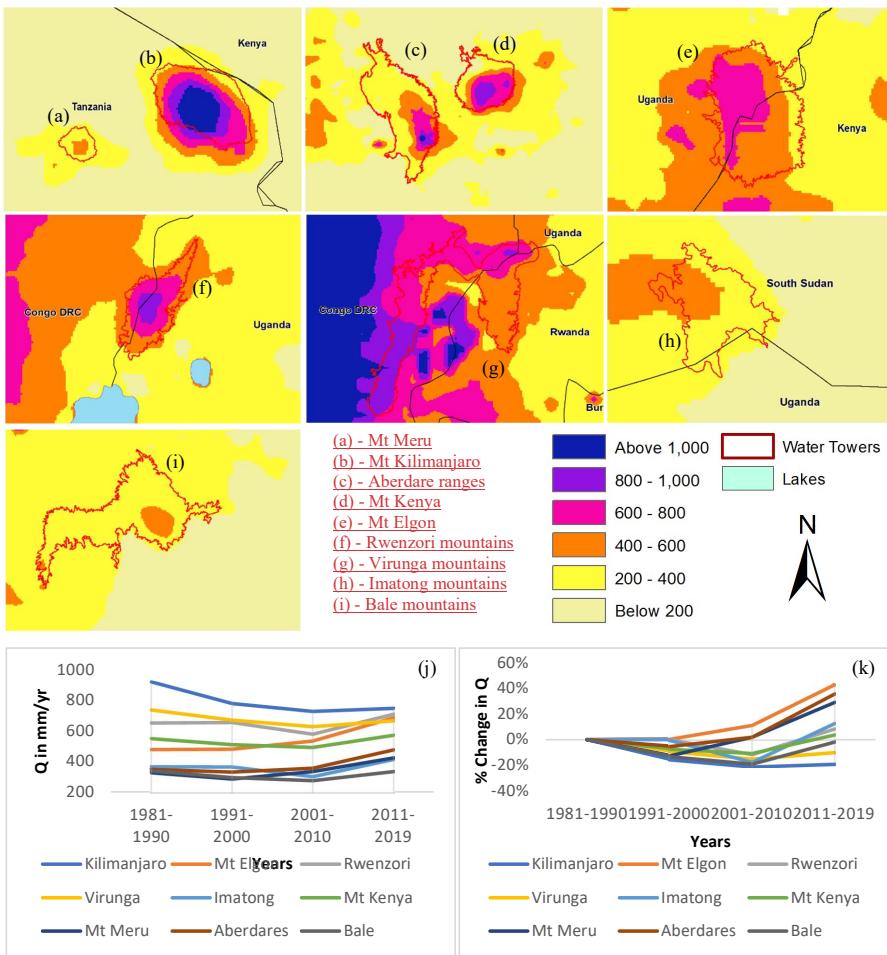

Figure 7. Distribution of long-term water yield (Q). Spatial distribution in and around the water towers (a-i) and changes in simulated annual mean water yield in the different water towers (j&k)

The elevation plays a key important role in influencing hydroclimatic conditions in the East African region. The average atmospheric demand increases with a reducing elevation gradient. A steady increase in P, ET, and Q was observed as elevation increases. For regions above 2000 m a.s.l, the precipitation exceeds potential evapotranspiration as shown in Fig A4. This demonstrates the importance of the elevated humid zones in generating and sustaining water yield to the adjacent lowland areas in the region.

5

### 3.5. Comparison of simulated streamflow with existing runoff data

The simulated streamflow was compared with composite runoff data downloaded from the Global Runoff Data Centre (GRDC) (Fekete et al., 2002). The spatial pattern of the simulated streamflow closely resembles the pattern produced by GRDC composite runoff as shown in Fig 8a and 8b. A total of 312 points above 2000 meters, the focus of this study (i.e. elevated water towers), were randomly selected and their respective values

10

of simulated streamflow and composite runoff were compared. The Kling-Gupta efficiency test revealed positive values (KGE=0.33) as shown in (Fig 8c).

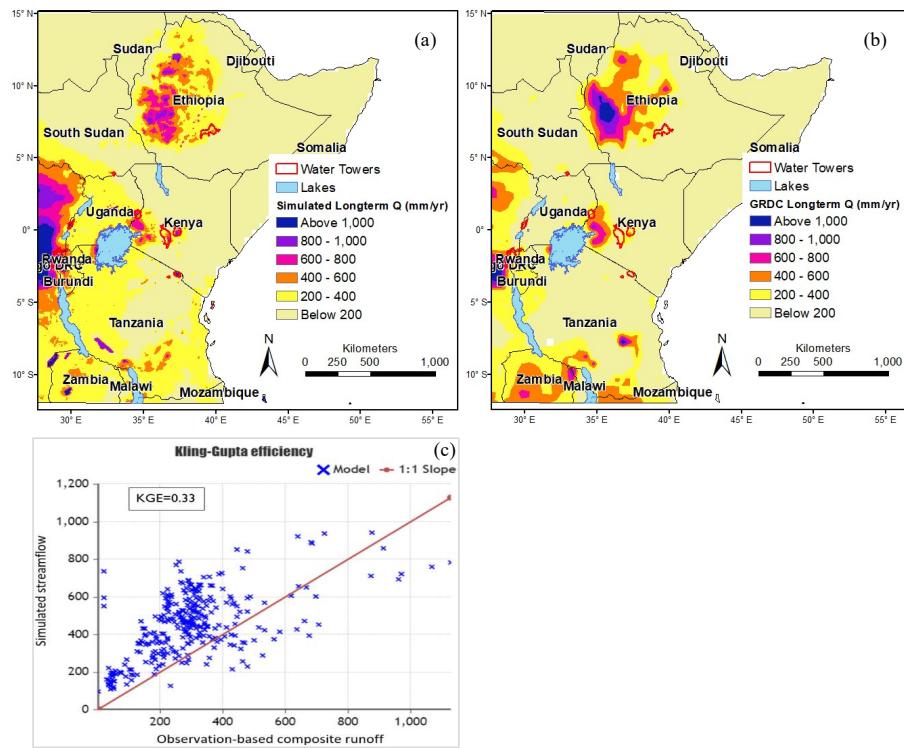

Figure 8. Comparison of simulated streamflow and observation-based runoff. Spatial distribution of streamflow in the East African region. (a) Simulated streamflow, (b) Observation-based composite runoff, and (c) Kling-Gupta efficiency calculation

5

### 3.6. The effects of land use and climate changes on water yield

The water yield was observed to be relatively more sensitive to climate changes (i.e. P and PET) than land-use changes within the selected East African water towers. However, a closer look at the regions surrounding the selected water towers revealed that the effects of land-use changes have greater impacts on water yield outside the water towers boundaries (Fig 9). An example is on the Eastern side of Mt Elgon where there was a major reduction in water yield especially in the periods of 2001-2010 and 2011-2019, (Fig 9, Row-row no 3, column B). Climate changes showed a reduction of water yield in seven water towers in the periods of 1991-2000 and 2001-2010. However, in the years of 2011-2019, climate changes triggered increased water yield in seven water towers (Fig 10). The climate changes in Mt Elgon resulted in a consistent increase in water yield, while a consistent decrease was inferred for Mt Kilimanjaro.

### 3.7. Analyzing the water towers in the Budyko space

The analysis of vertical deviations revealed downward shifts and upward shifts from the Budyko curve in the different water towers. The vertical deviations ( $d$ ) ranged from negative ( $-0.05$ ) to positive ( $+0.02$ ) (Fig 11a). There were no vertical deviations observed in Mt Elgon and Imatong mountains indicating that the values observed (between 1991 and 2019) were approximately close to those predicted by the reference Budyko curve. The elasticity ( $e$ ) values ranged from 0.49 to 17.6 with most of the water towers recording lower elasticity values as shown in Fig 11b. The higher elasticity ( $e$ ) values were observed in the Mt Kenya water tower in the years of 1991-2000, the Bale mountains in the period of 2011-2019, and the Aberdare ranges in the periods of 1991-2000 and 2001-2010.

**Figure 11. The illustration of the water towers in the Budyko space. (a) Deviation from the Budyko curve (a) and (b) elasticity (b) in the Water Towers**

The horizontal shifts either to the left or to the right relative to the dryness index (DI) were observed in the water towers. Figure A5 It was observed demonstrates that seven out of the nine water towers plotted in the left (i.e. DI values less than 1, towards humid conditions) (see Fig A4 a-i in the appendix). However, two of the water towers (i.e. Mt Meru and Bale mountains) plotted more towards the right (i.e. DI values greater than 1). Mt Meru seems to have shifted from warmer to humid conditions in the period of 2011-2019 as shown in Fig A5.

#### 4. Discussion

We found that within the water towers, water yield was more sensitive to climate changes than to land-use changes. In contrast, outside the water towers, the water yield was observed to be more sensitive to land-use changes than to climate changes. This suggests that anthropogenic influences are relatively higher outside the water towers.

5 Contrary to our expectation, our analysis showed that most of the water towers (i.e. seven of nine) did not plot on the reference Budyko curve over the study period. This is a relevant finding since all water towers were considered pristine and protected. Only two water towers, Mt Elgon and Imatong mountains showed no deviations from the reference Budyko curve. Generally, our investigation highlights the importance of elevated water towers in a semi-arid region in the generation and supply of water to adjacent lowland areas. The forested water towers located in 10 drier environments (such as Mt Kilimanjaro, Mt Meru, Mt Kenya, and Aberdare ranges) are important rainfall regions as they receive relatively higher rainfall than the adjacent areas. This ensures water availability in the adjacent lowlands in the arid and semi-arid (ASAL) regions.

15 Our results indicate that changes in precipitation and potential evapotranspiration are currently the major determinants of water availability from high elevated forested water towers in the East African region. Related observations have been made in the region: where climate changes in Africa have been reported to have a higher impact on water yield compared to other drivers such as land-use changes (Alcamo et al., 2007; Niang et al., 2014). However, the lack of evidence of sensitivity to land-use changes within the water towers themselves may be linked to existing institutional arrangements. We presume that the results would be different if such rules would be relaxed. That said, the movement of water towers in the Budyko space revealed that anthropogenic influence within 20 the water towers cannot be ruled out. Our analysis revealed vertical deviations (d) from the Budyko curve for seven of nine forested water towers. According to Creed et al. (2014), these vertical deviations may indicate the presence of anthropogenic effects within the water towers. The two water towers where no deviations were observed (i.e. Mt Elgon and Imatong mountains) indicate that the hydroclimatic conditions in the study period did not vary much from the reference conditions of 1981-1990 and any changes in water yield in the two water towers 25 can largely be associated with climatic changes in P and PET.

30 Moreover, the lack of deviations in the two water towers may indicate the resilience of forested regions (i.e. adaptable nature of forests) as described in (Van der Velde et al., 2014; Creed et al., 2014; Helman et al., 2017). Such resilience (measured as elasticity) could be a key factor in forested water towers indicating their ability to resist change or bouncing back to their initial natural conditions, hence plotting along the reference Budyko curve. Long-term adaptations of forests have been achieved by trees even in the most water-limited forests (Helman et 35 al., 2017). However, our investigations on elasticity (that refers to the degree of initial change using 1981-1990 as the reference period) did not support the above science as lower elasticity values were observed in most of the water towers. Given that low elasticity indicates broad ranges in the evaporative index (EI) compared to the dryness index (DI), this may further indicate the presence of anthropogenic influence within the water towers. According to Creed et al. (2014), elastic catchments are expected to plot along the Budyko curve (i.e. high elasticity = resilient to climate changes) while inelastic catchments (i.e. low elasticity = non-resilience to climate changes) would deviate from the Budyko curve.

40 Further illustrations can be shown in the Budyko space based on the horizontal shifts relative to the dryness index (DI). The horizontal shifts are important indicators of the behavior of the water towers towards warmer or humid conditions. These horizontal deviations reflect a change in the climatic conditions specifically, temperature and precipitation (Creed and Spargo, 2012a). This study observed that the majority of the water towers (seven of nine) plotted within humid conditions (i.e. DI < 1). On the other hand, two of the water towers (i.e. Mt Meru and Bale mountains) demonstrated warmer conditions (i.e. DI > 1). One major observation is that water towers in Eastern 45 Africa seem to shift towards the left in the Budyko space, an indication of the increased humid conditions especially in the period of 2011-2019. At the same time, a gradual increase in PET was observed in all the water towers. A climate shift to wetter conditions and simultaneous increases in regional temperatures have also been reported in the East African region and projected to increase by the end of 21<sup>st</sup> century (Niang et al., 2014; Giannini et al., 2018; Omambia et al., 2012).

50 The effects of increasing temperatures have already been identified to have decreased the surface area of glaciers by 80 % in East African water towers (EAC et al., 2016), affecting runoff and water resources downstream.

According to Niang et al. (2014), the temperatures in Africa is projected to rise faster than other parts of the world, which could exceed 2°C by the mid-21<sup>st</sup> century and 4°C by the end of the 21<sup>st</sup> century. Therefore, the water towers are under pressure from climate changes and PET is proving to be an important climate driver influencing water availability in the region. There are chances that the shifts to wetter conditions in the water towers may also be as a result of the extended impact of increasing PET on the El Nino-Southern Oscillation (ENSO), a phenomenon that influences precipitation in the East African region. (Li et al., 2016) investigated annual flood frequencies, from 1990 to 2014, and observed upward trends that were linked to the ENSO phenomenon in Africa. Furthermore, the shifts to wetter conditions also coincide with the recent reports on the 'rising lake levels phenomenon' in the Eastern Africa region (Rising Waters on Kenya's Great Rift Valley Lakes, 2021; Wambua, 2020; Chebet, 2020; Chepkoech, 2020). We however do not believe we have the results to link the climatic shifts and 'swelling' of lakes to ENSO variations in our study which requires further scientific investigations.

The simulated actual evapotranspiration (ET) and water yield (Q) revealed longitudinal differences with low to high values ranging from East to West. A related pattern on climate varying across East Africa from arid conditions in the east to more humid conditions in the west was also observed by Daron (2014). However, the individual water towers revealed independent variations that do not follow the longitudinal pattern. For instance, a higher mean annual water yield was observed at Mt Kilimanjaro despite being located in a drier environment on the Eastern side. This emphasizes the importance of elevated forested areas in ensuring water availability in semi-arid areas. This study revealed that in high elevated forested zones, the precipitation exceeds potential evapotranspiration, which ensures a surplus of water that eventually flows downstream.

The extreme opposite temporal trends observed in water yields from the different water towers confirm a strong variation in the regional climatic patterns. For instance, while there was a consistent increase in annual mean water yield at Mt Elgon, the opposite was true at Mt Kilimanjaro where a steady decline in water yield was observed. Our results further revealed that precipitation (P) is the dominant driver in the East African region. For instance, a consistent increase in Q at Mt Elgon coincided with a steady increase in land surface characteristics ( $\omega$ ) as shown in Figure 3 C. Ideally, a decrease in Q would have occurred due to the increases in ET (associated with increases in land surface characteristics), but this was diffused by the increases in rainfall as shown in Figure 2 C. At Kilimanjaro water tower, a continuous decrease in Q coincided with a steady reduction in  $\omega$ . Again, an increase in Q would have been expected due to decreases in ET. Therefore, precipitation is the dominant driver in the generation and supply of water from the forested water towers in the East African region.

As a first-order tool, the Budyko framework provides an important reference point for relating variations in water yield to variations in climatic conditions and catchment properties. In this study, the spatial pattern of the simulated streamflow in the Budyko framework closely resembles the pattern observed in the GRDC composite runoff. We however noted overestimation of water yield in the comparison. This type of observation was also reported by (Teng et al., 2012), where the Budyko equation was found to overestimate water yield in drier regions. Moreover, other factors such as interception, soil type, topography, seasonality, water storage, etc were not accounted for in the quantitative framework which can affect the simulations in the selected forested water towers.

Canopy interception, for instance, plays an important role in the water balance of forested ecosystems as noted in several studies (Teuling et al., 2019; Gash et al., 1980; Zimmerman et al., 1999; Astuti and Suryatmojo, 2019). In their study, (Teuling et al., 2019) found many forested points to have average yearly observed evapotranspiration (ET) that exceeds the average potential evapotranspiration (PET). Van Dijk et al. (2015) opined that this is possible due to underestimation of evapotranspiration which was attributed to evaporation of interception water by energy not captured in the formulation of PET. The forest evapotranspiration paradox is further discussed in (Teuling, 2018). The correction of underestimation in (Teuling et al., 2019) indicates the need for long-term lysimeter observations for studies focussing on forested ecosystems. Availability of meteorological data in the upper slopes of the East African mountains is a big gap as the majority of meteorological observations are conducted below 1500 m a.s.l and most of the upper slopes data rely on extrapolation of hydrological analysis in the lowlands (Rohr and Killingveit, 2003).

Local-based runoff measurements would have helped to interpret if there is indeed an overestimation in our study. That said, we observed positive KGE which indicates a "good" model performance (Knoben et al., 2019). Therefore, we considered the Budyko simulations as acceptable. However, it should be noted that this comparison

Field Code Changed

is added for reference only and should not be seen as validation. This is because, the Global composite runoff (Fekete et al., 2002) is not a strictly observational dataset, and it is used here as the “best estimate” available for long-term estimates of streamflow in the East African region. The fact the Budyko framework uses lesser data and parameters that are easily measurable at a regional scale makes it a suitable approach for data-limited regions such as East Africa.

5 Besides the strengths in using the Budyko approach, uncertainties may exist which could have affected our results. The study used data from different datasets (CHIRPs, CRU, GIMMS/AVHRR) at various scales which could potentially affect results due to various assumptions and approaches in the processing of each dataset. For instance, the CRU dataset is fairly coarse and contains rather few observations in Africa. One substantial weakness of the current CHIRPS algorithm is the lack of uncertainty information provided by the inverse distance weighting algorithm used to blend the CHIRP data and station data (Funk et al., 2015). The overall NDVI3g uncertainty comes from spatial and temporal coherence variability which gives approximately an error of  $\pm 0.002$  NDVI units. However, this NDVI error is considered low uncertainty hence applicable to study seasonal and inter-annual non-stationary phenomena (Pinzon and Tucker, 2014). Uncertainties may also arise in the general assumption that estimation of land surface characteristics ( $\omega$ ) based on NDVI formulation provides values that represent integrated conditions for soil, topography, and climate seasonality. Some studies using various hydrological approaches have reported the significance of these factors in influencing catchment hydrology (Kirkby et al., 2002; Woods, 2002; Western et al., 2004; Troch et al., 2013). There is a need for more research to come up with methodological consistency in estimating  $\omega$  parameters when using the Budyko framework. Although the focus of the study was in the elevated forested areas, empirical adjustment of the Budyko framework may be needed to capture special features such as desert wadis in the application of the Budyko equation in the lowland areas.

10 We also recognize other factors that may influence the results of this study. For instance, increasing atmospheric CO<sub>2</sub> concentrations may affect terrestrial water cycling through changes in climate and changes in transpiration (i.e. stomatal conductance) (Frank et al., 2015; Mamuye, 2018; Huntington, 2008). We also note that if CO<sub>2</sub> leads to higher NDVI, then this effect is accounted for in our modeling approach. Some studies have reported that NDVI linear trends can be linked to increasing CO<sub>2</sub> levels (Krakauer et al., 2017; Yuan et al., 2017). However, detailed investigations are recommended within the East African region. Other factors that may affect our results include the human alteration to water usage. Kiteme et al. (2008) reported unregulated abstraction of water upstream of Mt Kenya water tower leading to hydrological droughts downstream. Intensification of irrigated agriculture and a growing human population was reported at the foot slopes of the water towers (Ulrich et al., 2012; Liniger et al., 2005). The effects of anthropogenic presence at the foot slope of the water towers were not accounted for and further studies are needed to understand how humans living at the foot slope of protected water towers affect the pristine conditions of the water towers at high elevations.

15 Notwithstanding these limitations, our study offers important findings on the sensitivity of water yield to climate and land-use changes and the importance of these water towers in the generation and supply of water to adjacent lowland areas. These results can be used by decision-makers, policymakers, stakeholders, and scientists to emphasize the need to protect and conserve the high elevated forested areas in the region, particularly forest ecosystems above 2000 m a.s.l – where there is a surplus of water. The Budyko framework provides primary results that can inform detail hydrological assessments. For instance, our findings show that elevated forested water towers are important areas for maintaining high ET in the region. This finding can be explored further by studying the role of water towers in the supply of rainfall water in the region (i.e. the role of water towers in regional rainfall/moisture recycling) (Ellison et al., 2017; Keys et al., 2014) - including the effect of mountain rain shadows on water yield (Van den Hende et al., 2021). The major reference period for this study was the 1981-1990 period based on the CHIRPs rainfall dataset with data beginning from 1981 onwards. We believe the results would be different if an older reference period was used e.g. 100 years ago (presumably actual pristine conditions). This would help to strengthen the findings of this study especially after the evidence of climatic shifts towards wetter conditions in all the water towers. The anthropogenic presence both inside and outside the forested water towers indicates the relevance of local context, and ground research for understanding forest-water-people nexus (Noordwijk et al., 2020) is recommended. This will help in understanding in detail the dynamics and co-evolution of coupled human-forest-water systems.

20 **Field Code Changed**

The sensitivity analysis revealed differences brought about by climate changes and land-use changes on water yield within and outside the water towers. Within the water towers, water yield was more sensitive to climate changes compared to land-use changes. Outside the water towers, the water yield was observed to be more sensitive to land-use changes than climate changes. This study, therefore, suggests that the direct anthropogenic influences have a stronger impact outside the water towers. However, the Budyko metrics analysis revealed vertical deviations ( $d$ ) from the Budyko curve. According to Creed et al. (2014), these deviations indicate the presence of anthropogenic effects within the water towers. In some of the water towers such as Mt Elgon and Imatong mountains, no vertical deviations were observed indicating that the changes in the two water towers can majorly be associated with naturally occurring oscillations.

Lower elasticity values were also observed in most of the water towers. Low elasticity indicates broad ranges in the evaporative indexes (EI) compared to Dryness indexes (DI) which further proves the presence of anthropogenic influence within the water towers. According to Creed et al. (2014), elasticity can be used as a measure of resilience. Elastic catchments are expected to plot along the Budyko curve (i.e. resilient to climate changes) while inelastic catchments (non-resilience to climate changes) would deviate from the Budyko curve.

The horizontal shifts of the water towers either to the left or to the right relative to dryness index (DI) is an important indicator of the behavior of the water towers towards warmer conditions or humid conditions. These horizontal deviations reflect a change in the climatic conditions specifically temperature and precipitation (Creed and Spargo, 2012a). This study observed that the majority of the water towers (7 out of 9) plotted within humid conditions (i.e.  $DI < 1$ ). On the other hand, two of the water towers (i.e. Mt Meru and Bale mountains) demonstrated warmer conditions (i.e.  $DI > 1$ ). One major observation is that water towers in Eastern Africa seem to shift towards the left, an indication of the increased humid conditions especially in the period of 2011–2019. This includes Mt Meru which shifted from warmer conditions observed in 1991–2000 and 2001–2010 to humid conditions in the years of 2011–2019.

A gradual increase in PET was observed in all the water towers. This indicates that the atmospheric demand is rising, an important signal of temperature increases in the East African region. The effects of increasing temperature have already been identified to have decreased the surface area of glaciers by 80 % in East African water towers (EAC et al., 2016), affecting runoff and water resources downstream. According to Niang et al. (2015), the temperature in Africa is projected to rise faster than the rest of the world, which could exceed 2°C by the mid-21<sup>st</sup> century and 4°C by the end of the 21<sup>st</sup> century. Therefore, the water towers are under pressure from climate changes and PET is proving to be an important climate driver influencing water availability in the region. The mountainous forest ecosystems located in drier environments (such as Mt Kilimanjaro, Mt Meru, Mt Kenya, and Aberdare ranges) are important rainfall regions as they receive relatively higher rainfall than the adjacent areas. This ensures water availability in the adjacent lowlands in the arid and semi-arid (ASAL) regions.

The simulated evapotranspiration (ET<sub>a</sub>) and water yield (Q) revealed longitudinal differences with low to high values ranging from East to West. A related pattern on climate varying across East Africa from arid conditions in the east to more humid conditions in the west was also observed by (Daron, 2014). However, the individual water towers revealed independent variations that do not follow the longitudinal pattern. For instance, the higher mean annual water yield was observed in Mt Kilimanjaro despite being located in the drier environment on the Eastern side. This emphasizes the importance of elevated forested areas in ensuring water availability in semi-arid areas.

The extreme opposite trends observed in water yields from the different water towers confirm a strong variation in the climatic patterns. For instance, while there was a consistent increase in annual mean water yield in Mt Elgon, the opposite was true in Mt Kilimanjaro where a steady decline in water yield was observed.

The Budyko framework is a suitable approach for analyzing the partitioning of rainfall into precipitation and water yield. The framework gives the possibility for analyzing the combined effects or separating the effects of climate and land-use changes on water yield. In this study, the spatial pattern of the simulated streamflow in the Budyko framework closely resembles the pattern observed in the GRDC composite runoff. The Kling-Gupta efficiency test revealed positive values,  $KGE = 0.33$  which are seen as "good" model performance (Knoben et al., 2019). Therefore, the Budyko simulations in this study were considered acceptable. However, it should be noted that this comparison is added for reference only and should not be seen as validation. This is because, the Global composite runoff (Fekete et al., 2002) is not a strictly observational dataset, and it is used here as the "best estimate" available

for long-term estimates of streamflow in the East African region. The fact the Budyko framework uses data and parameters that are easily measurable at a regional scale makes it a suitable approach for regions such as East Africa where there is a gap in the availability of detailed and quality local climatic data.

5 The major reference period for this study was the 1981-1990 period based on the CHIRPs rainfall with precipitation data beginning 1981 onwards. Further research using a reference period earlier than 1981 would help to strengthen the findings of this study especially after the evidence of shifts towards wetter conditions in all the water towers. Further studies on human-water interactions are also recommended to understand in detail the dynamics and co-evolution of coupled human-water systems.

## 10 5. Conclusions

The forested water towers provide important water sources for the surrounding semi-arid area through both runoff generation and regional rainfall recycling. Climate changes (i.e. changes in precipitation and potential evapotranspiration) have a relatively large effect on water yield within the East African water towers. The effects of land-use changes on water yield are larger in the adjacent regions surrounding the water towers. The majority 15 of East-African water towers are under pressure from human influences both within and outside the water towers. Generally, the patterns in water yield showed a strong longitudinal difference (East to West), though the elevation is a key factor that ensures the generation of water in the water towers located in drier environments. A hydroclimatic phenomenon is occurring in the East-African region as the water towers show a strong shift towards wetter conditions (especially in the period of 2011-2019) while at the same time, the atmospheric demand is 20 gradually increasing. Given that majority-most of the water towers were identified as non-resilient to changes, it means there are greater possibilities of extreme variations in water yield under changing climatic conditions. The Budyko framework is an important first-order tool that uses lesser data inputs and provides important illustrations 25 of hydroclimatic conditions of areas under study. The primary results contribute to the general understanding that can further inform detail hydrological studies. Therefore Budyko is a suitable approach especially for data-deficit regions that lack detailed and quality data such as East Africa.

## 6. Appendices

### A. Extended Figures and Tables

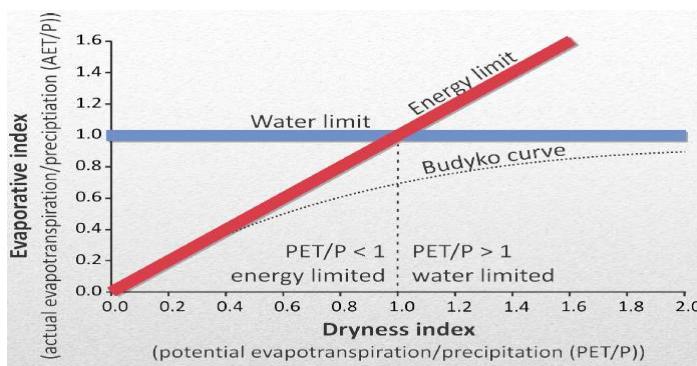

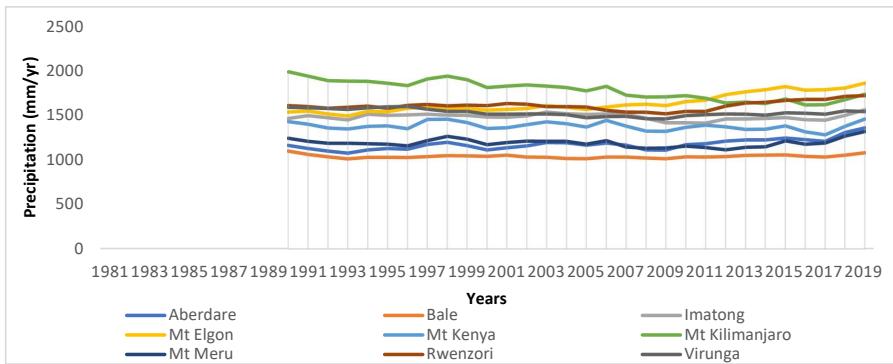

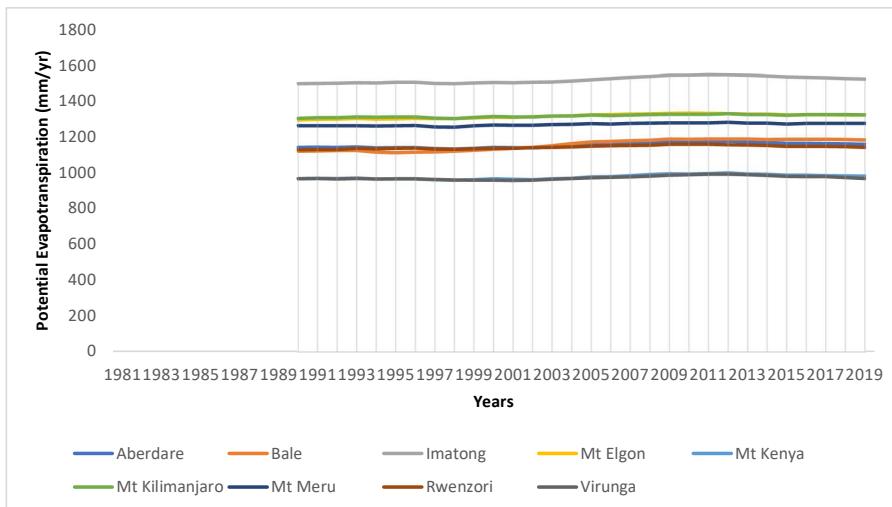

Figure A 1. The Budyko Curve: Water limit ( $ET_a=P$ ); a site cannot plot above the blue line unless there is input of water beyond precipitation. Energy limit ( $ET_a=PET$ ); a site cannot plot above the red line unless precipitation is being lost from system by means other than discharge (adapted from Creed and Spargo, 2012a).

**Figure A 2. The 10-year moving averages of mean annual mean precipitation at the different water towers**

Higher levels of annual precipitation were observed in 1990-1992, 1998-1999, and 2013-2015. Lower levels of annual precipitation were observed in 1987, 1995-1996, 2004-2005, and 2017. Mt Kilimanjaro was observed to have a consistent decline in annual mean rainfall between 1981 and 2017. Mt Elgon water tower recorded a consistent increase in annual mean rainfall during the study period.

**Figure A 3. The 10-year moving averages of Annual mean annual mean-PET in at the different water towers**

Figure A.2. The 10-year Moving averages of Annual mean precipitation in the different water towers

Higher levels of annual precipitation were observed in 1990-1992, 1998-1999, and 2013-2015. Lower levels of annual precipitation were observed in 1987, 1995-1996, 2004-2005, and 2017. Mt Kilimanjaro was observed to have a consistent decline in annual mean rainfall between 1981 and 2017. Mt Elgon water tower recorded a consistent increase in annual mean rainfall during the study period.

Figure A 554. Graphical representation of the baseline Budyko curve (estimated for 1981-1990) and the trends of water towers in the different years

**Table A 2: Description of the selected water towers**

<b>Mt Kilimanjaro</b>	<p>The water tower is of volcanic origin, located in north-eastern Tanzania, near the border with Kenya. High rainfall and extensive forests make the water tower a critical water catchment for both Kenya and Tanzania. Forest fires linked to both human and climate warming are reported in the higher slopes, while forest clearing is reported along the forest boundary. The surrounding area is home to over one million people (Lambrechts et al., 2002; EAC et al., 2016). The water tower attracts more than 35,000 climbers a year, and 5,000-day visitors from around the world (EAC et al., 2016). Hence a major source of foreign exchange earnings for Tanzania.</p>
<b>Mt Kenya</b>	<p>A volcanic water tower located just south of the equator in the central region of Kenya. The vegetation includes savanna grasslands at the base; forests of tall and broad-leaved trees on the lower mountain slopes; podocarpus and cedar trees in the middle slopes; a belt of bamboo from about 2,200 m to 3,100 m, surrounded by thin forests of Hagenia and Hypericum trees above and below the belt; and the alpine zone above 4000 m. Above 5,000 m, the landscape is bare rock and glaciers (UNEP, 2014). The water tower provides fresh water to about 7 million people (EAC et al., 2016). The total population of the communities that live within the districts that border the water tower was estimated at 24.4 million in 2009 (Nyongesa and Vacik, 2019).</p>
<b>Mt Elgon</b>	<p>A volcanic water tower located on the Kenya-Uganda boundary. The moorland zone, containing tree heaths, giant groundsels, and lobelias, extends down to 3,050 m, where it is succeeded by bamboo forest. Below 2,550 m is a temperate deciduous forest. The Ugandan side of Mount Elgon has an average population density of 900 people per square kilometer.</p>
<b>Aberdare Ranges</b>	<p>A volcanic mountain stretching for approximately 100 km from north to south is mainly made up of alkaline rock types (UNEP, 2014). Diverse forests grow above 2,500 m including cedar and riverine forests. From about 2,700 m to 2,900 m there is a belt of bamboo and above 2,900 m cloud forests. Above 3,100 m, the upper limit of the montane forests. The millions of residents of Nairobi (capital city), 50 km away, depend on the water tower for water supplies.</p>
<b>Rwenzori Mountains</b>	<p>A block mountain also known as mountains of the moons, the water tower is located just north of the equator bordering Uganda and Congo. The range is about 120 kilometers long and 65 kilometers wide. Up to about 2,300 m in the Park, the vegetation is mixed broad-leaf forest. Between 2,300 m and 3,200 m the vegetation is characterized by afromontane forest trees. Between 3,200 m and 3,800 m there is a bamboo forest zone. Above this is a grassland zone and cloud woodland. Afro-alpine moorland extends to the snow line at 4,400 m. The population density of the area surrounding the mountain is between 150 and 430 persons per square kilometer (Rwenzori Mountains National Park, 2021).</p>
<b>Mt Meru</b>	<p>A volcanic mountain located 70 km west of Mt Kilimanjaro. The forest covers about 9000 hectares of land and is bordered by 32 villages (Ndomba et al., 2015). The population of the area surrounding Mt Meru is concentrated in the southern flanks with an estimated population of over 1.6 million (Volcanic hazards in Tanzania. Meru case study, 2021).</p>
<b>Virunga Mountains</b>	<p>Located within the Albertine Rift, Virunga is a crescent-shaped collection of mountains covering parts of Uganda, Congo, Rwanda, Burundi, and Tanzania. The vegetation belts in the Virunga mountains are categorized into alpine, subalpine (ericaceous), and montane forest. The region surrounding Virunga has one of the highest human population densities in Africa, with as many as 1,000 people per square kilometer living in the southern sections (USAID, 2013).</p>
<b>Bale Mountains</b>	<p>The Bale Mountains are located in the southern highlands of Ethiopia (06°41'N, 39°03'E and 07°18'N, 40°00'E), and 400 km southeast of Addis Ababa. The water tower represent the largest area in Africa of Afroalpine vegetation over 3,000 m a.s.l (Tallents and Macdonald, 2011). The</p>

	<p>grassland area is situated between an altitude of 2,600-3,000 m a.s.l. There are 25 villages surrounding the water tower. Bale watershed flow to more than 12 million people in southern Ethiopia and western Somalia (Integrating Population, Health, and Environment in Ethiopia's Bale Mountains, 2021).</p>
<b><u>Imatong Mountains</u></b>	<p><u>The Imatong Mountains are located in southeastern South Sudan, and extend into the Northern region of Uganda border between 3°57'N 32°54'E and 3°57'N 32°54'E. Vegetation in the lower areas includes woodlands and mixed lowland semi-evergreen forest up to 1,000 m. Above 1,000 m there is montane forest up to 2,900 m. At the highest levels, the forest is replaced by woodland, heather thicket and areas of bamboo.</u></p>

## 7. Data availability

All climatic data used in this study (i.e. (P, PET, and NDVI) are publicly available. Precipitation data (P) was downloaded from Climate Hazards Group Infrared Precipitation with Stations (CHIRPS-v2) <https://www.chc.ucsb.edu/data/chirps> (last accessed 31 July 2020). Potential Evapotranspiration (PET) data was downloaded from the CRU database <https://crudata.uea.ac.uk/cru/data/hrg/> (last accessed 22 July 2020). Normalized Difference Vegetation Index (NDVI) was sourced from Global Inventory Monitoring and Modeling System (GIMMS) Third Generation (3g) Advanced Very High-Resolution Radiometer (AVHRR) sensor onboard the National Oceanic and Atmospheric Administration (NOAA) satellites <https://ecocast.arc.nasa.gov/data/pub/gimms/3g.v1/> (last accessed 12 July 2020). The water towers analyzed data sets are summarized in Table A1 for each water tower and the full analysis is available in the [SESAM project SharePoint](#). The data can be provided upon request from the 1<sup>st</sup> author (charles.wamucii@wur.nl).

## 8. Author contributions

CNW and AJT designed the study. CNW performed the analysis and wrote the manuscript. All authors helped with the interpretation of the results and commented on the manuscript.

## 9. Competing interests

The authors declare that they have no conflict of interest.

## 10. Acknowledgments

This research was made possible by Wageningen University through the Scenario Evaluation for Sustainable Agro-forestry Management (SESAM) project that was funded by its Interdisciplinary Research and Education Fund (INREF).
