Abstract. Spatiotemporally comprehensive stream temperature datasets are rare because interest in these data is relatively recent and there is little money to support instrumentation at regional or national scales. This lack of data has been recognized as a major limitation for understanding thermal regimes of riverine ecosystems. To overcome these barriers, we first aggregated one of the largest stream temperature databases on record with data from 1700 individual stations over nine years from 2009–2017 (n=45,000,000 hourly measurements) across France (area = 552,000 km²). For each station, we calculated a simple, ecologically relevant metric—the thermal peak—that captures the magnitude of summer thermal extremes. We then used three statistical models to extrapolate the thermal peak to nearly every stream reach in France and Corsica (n=105,800) and compared relative model performances among each other and with an air temperature proxy. In general, the hottest thermal peaks were found along major rivers, whereas the coldest thermal peaks were found along small rivers with forested riparian zones, strong groundwater inputs, and which were located in mountainous regions. Several key predictors of the thermal peak emerged, including drainage area, mean summer air temperature, minimum monthly specific discharge, and vegetation cover in the riparian zone. Despite differing predictor importance across model structures, we observed strong concordance among models in their spatial distributions of the thermal peak, suggesting its robustness as a useful metric at the regional scale. However, air temperature was a poor proxy for the stream temperature thermal peak across nearly all stations and reaches, highlighting the growing need to measure and account for stream temperature in regional ecological studies.

1 Introduction

Stream temperature is a master variable affecting ecosystem processes in lotic systems. It controls the solubility of gases and related biogeochemical reactions, regulates metabolism (Wolter, 2007), nutrient cycling (Malard et al., 2002), and decomposition rates, and dictates animal ingestion and digestion rates (Elliott, 1976), reproduction cycles (Daufresne et al., 2004), and mobility (Ojanguren and Braña, 2000). Stream temperature can also be a source of stress and mortality for aquatic organisms, especially when coupled to additional stressors like low water levels (Miller et al., 2007). Consequently, the dynamics of populations and communities, their relative composition (Kishi et al., 2005) and their size structure (Daufresne et al., 2009) are intimately related to stream thermal regimes. Climate change threatens freshwater ecosystems through multiple pathways, but rising stream temperatures and reduced flows and levels may be most common and deleterious for aquatic organisms. In particular, many ectotherm species are unlikely to tolerate warmer environmental conditions (Tisseuil et al., 2012). In response, cold-water fish species will likely shift towards higher latitudes and altitudes, while warm-water species will likely expand their geographical distribution (Heino et al., 2009). However, the magnitude and direction of these

40 expected changes will depend strongly on patterns of stream temperature change, which is currently poorly constrained. Hence, it is critical to describe and analyze the spatiotemporal variability of river thermal regimes. The five main components of stream thermal regimes comprise temperature magnitude, frequency, duration, rate of change, and timing, with different metrics to quantify the biological or ecological importance of each component (Steel et al., 2017; Olden and Naiman, 2010; Tsang et al., 2016). However, these metrics can be accurately determined only if continuous time series of stream temperature are available (Jones and Schmidt, 2018).

45 Although recent advancements in in-situ sensor technology have greatly expanded stream temperature data availability (Isaak et al., 2017) there is still a lack of long-term data for the vast majority of stream reaches, limiting understanding of thermal regimes at river network and regional scales (Arismendi et al., 2014). In addition, stream temperature data collection is often spatiotemporally uncoordinated across regions and river networks, resulting in snapshot datasets that are regularly supported or replaced with air temperature proxies in aquatic ecology studies (Conti et al., 2015; Logez et al., 2012; Tisseuil et al., 2012). While air temperature can be used to fill data gaps (Buisson and Grenouillet, 2009; Durance and Ormerod, 2009), air temperature is a poor surrogate for stream temperature in several cases. In particular, air temperature correlates poorly with stream temperature in headwater reaches (Caissie, 2006), in reaches with strong local controls (e.g., riparian vegetation, groundwater inflows, bed form, impoundments), and in reaches with large environmental heterogeneity (Moatar and Gailhard, 2006; Hill and Hawkins, 2014; Loicq et al., 2018; Chandesris et al., 2019; Seyedhashemi et al., 2021). Hence, using air temperature metrics to study climate change impacts on the aquatic species distributions may result in misguided inference and consequent management decisions.

55 In addition to air temperature proxies, many studies have turned to regionalized deterministic and statistical models to fill stream temperature data gaps (e.g. Mohseni et al., 1998; Segura et al., 2015; Chang and Psaris, 2013; Beaufort et al., 2016; Westhoff et al., 2007; Yearsley, 2012). Deterministic models rely on a physically based formulation of stream energy conservation to compute water temperature (Yearsley, 2012; van Vliet et al., 2012; Beaufort et al., 2016). However, such models suffer from large data requirements leading to a preference for statistical approaches, especially in ungauged catchments. Some of these approaches empirically relate stream temperature to climatic and environmental variables, such as air temperature, discharge, altitude or channel width (Benyahya et al., 2007; Moore et al., 2013). Other statistical methods include lumped regression-based models (Daigle et al., 2010; Ducharne, 2008; Hrachowitz et al., 2010; Bustillo et al., 2014), distributed stream-network models (Detenbeck et al., 2016; Isaak et al., 2017), and machine learning methods (Chenard and Caissie, 2008; DeWeber and Wagner, 2014). Still, these approaches often have dense spatial data requirements and their estimates are usually temporally limited (Isaak et al., 2010; Pratt and Chang, 2012; Hill et al., 2013). Indeed, few studies estimate stream temperature over a full year, likely because of non-linear relationships and seasonal hysteresis between air and stream temperature, missing data, and autocorrelation (Jackson et al., 2018; Letcher et al., 2016; Sohrabi et al., 2017). However, for management purposes in the context of climate change, annual stream temperature patterns may be unnecessary. Indeed, stream temperature metrics that focus on extreme periods (e.g., summer) are likely adequate to understand trends of increasing pressures on aquatic ecosystems.

75 To that end, our objective here is to develop empirical statistical models to predict a simple, ecologically relevant stream thermal metric that captures the magnitude of the stream temperature extremes at the regional scale. To do so, we first define an interannual thermal metric, which we term the “thermal peak”, using heterogeneous and non-concomitant time series of stream temperature and estimate it at 1,700 stations for 2009–2017. We then test three

statistical models and one multi-model approach to predict this metric at the regional scale and compare their predictive capacity with that of air temperature.

2. Methods

80 2.1 Study area and monitoring network

The study area is continental France and Corsica (550,000 km²). France is located in a temperate zone characterized by a variety of climates due to the influences of the Atlantic Ocean, the Mediterranean Sea, and mountain areas.

We assembled the most exhaustive stream temperature dataset in France to date by combining data from both
85 public (national, regional) and private managers (fishermen associations). Due to the diversity of station ownership, the assembled times series do not have a consistent spatial and temporal structure. Some regions are densely monitored while others have few instrumented streams and much of the data do not exhibit temporal overlap, challenging our ability to define comparable metrics among streams. Hence, our main challenge was to pool the maximum of observation stations to optimize the number of monitored streams while dealing with the
90 non-continuous observation periods of the stations. The large spatial and temporal heterogeneity of the monitoring data precluded application of spatial autocorrelation methods, and we have therefore chosen to consider only non-spatial statistical models.

The stream temperature data used here comprise approximately 45,000,000 hourly measurements from 1,700 unique measurement stations ($n=2,107,623$ site-days) collected between 2009 and 2017, primarily during summer.
95 All the stations under strong human influence (i.e., dam releases and nuclear power thermal effluent) and stations without seasonal dynamics were previously excluded from this data set. All data were recorded by automatic data loggers managed by professional biologists or hydrologists. Outliers from each station's time series were removed with automatic outlier detection filters and the resulting data were screened visually before being averaged into mean daily stream temperature data (hereafter referred to as T_w). The automatic outlier detection consists of three
100 steps with eight unique filters that remove, in order, 1) hourly T_w anomalies, 2) monthly anomalies between T_w and T_{air} , and 3) daily anomalies between T_w and T_{air} (Moatar et al., 2001; Beaufort et al., 2020b).

To address ecologically meaningful temperature metrics under climate change, we focused on the two hottest stream temperature months, July and August (hereafter referred to as summer), a time period essential for the growth and survival of many aquatic species. This focus also has the benefit of maximizing the number of
105 observation stations for analysis. Still, out of the 1700 stations, 490 stations have just one year of data, 88 stations have observations covering summer over all nine years, and only 30 have year-round observations for all nine years (Figure 1a,b). To obtain hydraulic and hydrologic characteristics for each station, stations were projected onto the Theoretical Hydrographic Network for France (RHT; Pella et al., 2012), an oriented hydrographic network with defined flow directions that comprises 114,600 reaches of median length 1,961 m ($2,475 \pm 1,512$ m, mean \pm sd).
110 A majority of stations were located on RHT river reaches with drainage areas 20–500 km², whereas most reaches are small streams with a drainage area of less than 20 km² (Figure 1c).

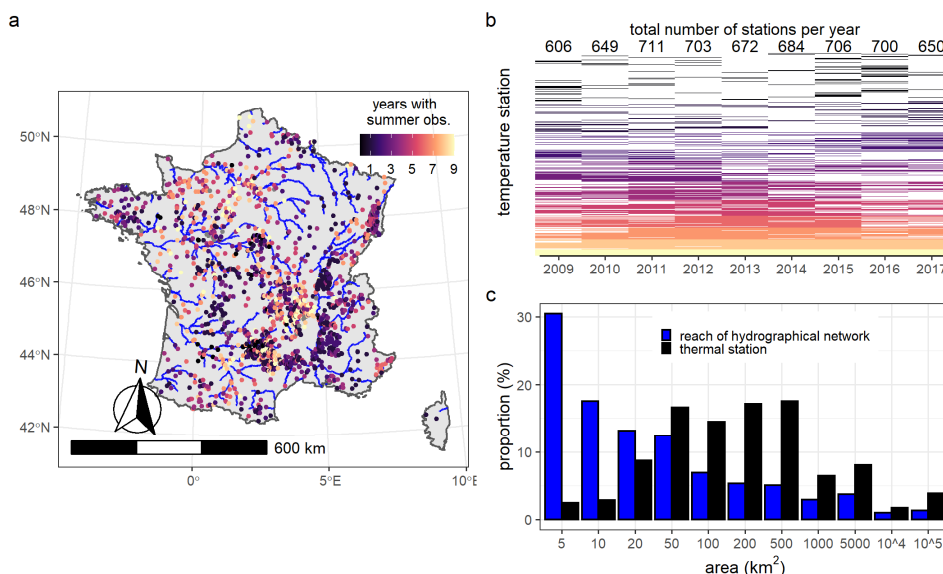

Figure 1. Data availability for each temperature station used in this study. a) Map of stream temperature stations in France with RHT network shown for all reaches of Strahler order >4, and b) Heatmap of data availability by year (x-axis) and station (y-axis) with the total stations per year listed at the top of each column. Sites are colored by the number of years with observations. c) Distributions of drainage area for RHT reaches (blue) and of thermal stations (black).

2.2 Defining the thermal peak stream temperature metric

Due to the limited concordance among stream temperature time series (Figure 1b) and to focus our analysis towards ecologically relevant ends, we summarized our stream temperature data with a simple metric. This kind of metric has precedent in regional species distribution models that instead used air temperature (hereafter referred to as T_{air}) as a proxy (Buisson and Grenouillet, 2009).

We refer to this metric as the thermal peak (T_p), and define it as the interannual average of the mean temperature of the 30 hottest consecutive days of each year ($\overline{T_{w,30}}_i$):

$$T_p = \frac{\sum_{i=1}^N (\overline{T_{w,30}}_i)}{N} \quad (1)$$

Where i = year index; and N = the number of years of observation available from 2009–2017 ($N = 1-9$). Across sites, the hottest day of the year always occurred within the approximate 30 day period between July 28 and August 30 (mean±sd: August 12±16 days), lending support to this focused approach.

2.3 Climate correction of the thermal peak

The thermal peak can be biased depending on the climatic variability of the years of observation for each station. Indeed, only 30 of our stations have T_p calculated using all nine years of data, and therefore have the highest level of confidence in their estimate. We refer to the T_p from these 30 stations as $T_{p,\text{ref}}$, indicating that these are reference,

or true estimates of T_p (Table 1). To account for the bias associated with missing data at the remaining 1670 stations, we gap-filled missing data at these stations using site-specific stream-air temperature regressions. This method accounts for interannual variation in climatic forcing on stream temperature, and we therefore refer to it as a climate correction.

The climate correction is achieved by first calculating station-specific regressions between daily T_w and a right-aligned moving average of daily T_{air} at lags ranging from 2–10 days. The moving average lag whose regression produced the highest coefficient of determination was then used to fill gaps in the time series of T_w for each station. Next, we reconstructed summer stream temperature using this regression and subsequently recalculated T_p based on this reconstructed data. We refer to T_p from these climate-corrected data as $T_{p,clim}$ to indicate that missing data were gap-filled with the climate correction procedure (Table 1).

To validate this approach, we conducted a permutation test on the 30 stations with full annual monitoring from 2009–2017 (i.e., sites where a $T_{p,ref}$ is known). At each site, we introduced randomly placed, artificial annual gaps into observed data ranging from 1–9 years to simulate missing data. We then backfilled these introduced gaps according to the climate correction method. Following gap-filling, we calculated two metrics: 1) T_p using gap-induced data without gap-filling ($T_{p,gap}$), and 2) the thermal peak using the gap-filled data ($T_{p,fill}$; Table 1). We then compare these two metrics to the reference thermal peak ($T_{p,ref}$) using absolute biases at each tested permutation (i.e., the number of introduced gap years). This approach allowed us to assess whether the climate-corrected reconstruction of the gaps in time series is 1) a useful approach, and 2) lower in bias and uncertainty compared to using observed data alone.

Table 1. List of thermal peak terminology with the count of days (n) used in their calculation

Notation	Definition	n
$T_{p,obs}$	thermal peak, or the interannual average of the mean temperature of the 30 hottest consecutive days of each year for station with observations	1700
$T_{p,ref}$	thermal peak for reference stations with all nine years of data	30
$T_{p,clim}$	thermal peak for stations with less than nine years of data to which climate correction was applied	1670
$T_{p,gap}$	thermal peak for reference stations with introduced data gaps	30
$T_{p,fill}$	thermal peak for reference stations whose introduced data gaps were filled with climate correction	30
$T_{p,m}$	modeled thermal peak using statistical extrapolation to the RHT network using statistical method m	114,600
$T_{p,air}$	thermal peak estimated using the air temperature proxy	114,600

2.4 Extrapolating the thermal peak to national scale with statistical modeling

We estimated T_p throughout the entire RHT network using four distinct statistical models. For modeling ($T_{p,m}$) it is not clear how to choose *a priori* a particular model structure due to the complexity of the processes involved in determining local stream temperature. Therefore, we tested four different structures: 1) a multiple linear regression model (REG), 2) an artificial neural network model (ANN) that is potentially non-linear, but encompasses a linear model as a special case, 3) a random forest model (RF) that can also be non-linear, but with a different strategy than ANN, and 4) a multi-model combination (MM), which combines the three prior structures ANN, RF, and REG. All these models are based on a function to estimate T_p at all stations (i):

$$T_{p,m,i} = f(g_{1,i}, \dots, g_{n,i}) \quad (5)$$

Where $g_{n,i}$ = the n th explanatory variable defined for each i th station.

To measure how stream thermal regime estimations might be different if using a T_{air} proxy, we also calculated $T_{\text{p,air}}$ using T_{air} from SAFRAN data. The $T_{\text{p,air}}$ is calculated identically to T_{p} , but using daily T_{air} instead of daily T_{w} , as would be done in ecological studies using T_{air} as a proxy for T_{w} . Finally, to determine the effect of climate corrections on the full RHT extrapolation, we compared the distribution of $T_{\text{p,m}}$ values when models were fit using either $T_{\text{p,obs}}$ or $T_{\text{p,clim}}$.

2.4.1 Explanatory variables

We selected sixteen variables (Table 2) to explain the spatial distribution of $T_{\text{p,m}}$ based both on results from a prior analysis (Beaufort et al., 2019), and on a principal component analysis to minimize variable dependencies. We further considered the ability to calculate or estimate each variable at the scale of the entire RHT network. The variables fall into three categories: climate, hydrology, and catchment characteristics.

The four climatic variables were determined from SAFRAN reanalysis data for the years 2009–2017: 1) mean annual precipitation, 2) mean summer precipitation, 3) mean annual snowfall, and 4) mean summer air temperature. The SAFRAN reanalysis data (grid 8 km) were available at hourly time step (Quintana-Segui et al., 2008; Vidal et al., 2010) and climatic variables were extracted from the SAFRAN meshes overlapping the station location.

The four hydrological variables were determined by extrapolation based on prior datasets. The first two variables, monthly minimum discharge (Sauquet et al. 2008) and the annual minimum monthly discharge with a return period of five years (Catalogne, 2012), describe the low-flow regime of each site. The remaining two variables, the hydrologic regime (HR; Sauquet et al., 2008) and the concavity index (CI; Sauquet and Catalogne, 2011), are dimensionless and characterize the general hydrology of each site. More specifically, the HR groups sites into one of 12 classes ranging from rainfall-dominated, to transitional, to glacial and snow melt dominated. The CI describes the concavity of the flow duration curve, where values close to 1 indicate low flow variability (e.g., large high storage capacity in aquifer or snow) and values close to 0 indicate high flow variability (e.g., low storage capacity exemplary of Mediterranean systems).

The eight variables relating to catchment characteristics were extracted from either the SYRAH-CE database (Valette et al., 2012) or the RHT database (Pella et al., 2012). The three variables from RHT comprise: 1) mean altitude, 2) catchment drainage area, and 3) mean slope. The five variables from SYRAH-CE comprise: 1) riparian vegetation cover in a 10 m buffer, 2) linear upstream weir density along the stream, 3) areal upstream weir density for the catchment, 4) upstream pond cover as a fraction of stream area, and 5) incision class describing the rate of incision of the valley.

Table 2. List of explanatory variables used in models.

Category	Variable	Notation	Source
Climate	Mean annual precipitation (2009–2017) [mm]	P_{annual}	SAFRAN
	Mean summer precipitation, July–August (2009–2017) [mm]	P_{summer}	SAFRAN
	Mean annual snow accumulation (2009–2017) [mm]	S_{annual}	SAFRAN
	Mean summer air temperature, July–August (2009–2017) [°C]	T_{summer}	SAFRAN
Hydrology	Mean monthly annual minimum discharges with a return period of 5 years* [$\text{L s}^{-1} \text{km}^2$]	Q_{min}	RHT
	Mean monthly minimum specific discharge* [$\text{L s}^{-1} \text{km}^2$]	q_{min}	RHT
	Concavity index† [-]	CI	RHT
	Hydrological regime‡ [-]	HR	RHT

	Mean catchment elevation [m]	elev	RHT
	Drainage area [km ²]	area	RHT
	Mean streams slope over the catchment [m km ⁻¹]	slope	RHT
Catchment characteristics	Riparian vegetation cover ratio in 10 meters buffer (%)**	veg	SYRAH
	Linear weir density upstream of stations (# km ⁻¹)**	weirs	SYRAH
	Areal weir density upstream of stations (# km ⁻²)**	weir area	SYRAH
	Pond cover ratio upstream of stations (%)**	ponds	SYRAH
	Stream incision class **	SI	SYRAH

*determined by geostatistical interpolation on the RHT network (Sauquet et al., 2000)

†ratio of flow duration quantiles $Q_{10}-Q_{90}/Q_1-Q_{90}$, as defined by Sauquet and Catalogne (2011)

‡classes from 1–12 with pluvial regimes from 1–6, transition regimes from 7–8; and glacial and snow melting regimes from 9–12 (Sauquet et al., 2008)

**Detailed description of these variables in Valette et al. (2012).

195

2.4.2 Multiple regression

We first fit a multiple linear regression model between T_p and explanatory variables using all possible variables. Prior to fitting, we scaled the explanatory variables so that their fitted coefficients could be compared in terms of relative influence.

200

2.4.3 Artificial neural network

We then used an ANN—specifically a feed-forward neural network with one hidden layer (R package *nnet*; Venables and Ripley 2002)—to estimate T_p as a potentially non-linear function of covariates. We included a direct connection between covariate inputs and outputs so that the case with zero hidden units corresponded to a linear relationship. We used weight decay regularization, also known as ridge regression, to control overfitting by decreasing less relevant coefficients. Both the number of hidden units and the amount of weight decay were selected with a first cross-validation procedure (Bishop, 2006). To quantify the relevance of the different covariates, we used a connection weight approach (Olden and Jackson, 2002; Olden et al., 2004):

205

$$W_V = \sum_{h=1}^{nhu} A_{V,h} B_h \quad (6)$$

Where W_V (-) = the relevance of covariate V , $A_{V,h}$ (-) = the ANN coefficients connecting hidden unit h to covariate V , B_h (-) = the ANN coefficients connecting hidden unit h to the output, and nhu = the number of hidden units.

210

2.4.4 Random forest

We used a random forest for the third statistical model structure, using Breiman's algorithm (Breiman, 2001) with the R package *randomForest* (Liaw and Wiener, 2002) allowing 500 trees. The relevance of each predictor variable was provided as standard output by the *randomForest* package, which determines how much the mean square errors in prediction increases when that covariate is randomly permuted within the tree.

215

2.4.5 Multi-model combination

Finally, we used a multi-model combination approach to obtain a consensus estimation map of $T_{p,m}$. The estimates from each previously described model were linearly combined to reduce the associated uncertainties through multiple linear regression.

220

$$T_{p,mm} = aT_{p,ANN} + bT_{p,RF} + cT_{p,REG} + d \quad (7)$$

With $T_{p,mm}$ = T_p based on observed and reconstructed T_w ; $T_{p,ANN}$ = T_p estimated by ANN; $T_{p,RF}$ = T_p estimated by RF; $T_{p,REG}$ = T_p estimated by multiple regression; and a, b, c, d = fitted regression coefficients.

2.4.4 Model cross-validation

225 To assess model performance prior to spatial extrapolation to the entire RHT network, we conducted a cross-
validation on observed data from our 1700 stations. For each model, including $T_{p,air}$, we used 80% of stations ($n =$
1360) as training data to estimate model parameters. Using those model parameters, we estimated validation data
 T_p at the remaining 20% of stations ($n=340$) and cross-validated those estimates with $T_{p,obs}$. We conducted this
230 cross-validation this 100 times allowing for random selection of stations used in the training and validation data
sets. We evaluated the results of the cross-validation with the Nash-Sutcliffe efficiency criterion (NSE, Nash and
Sutcliffe, 1970), the RMSE (Root Mean Square Error) and biases between observed $T_{p,obs}$ and $T_{p,m}$.

3. Results

3.1 Validation of the climate correction approach

Gap-filling T_w with our climate correction approach resulted in consistently lower absolute biases for T_p (i.e., $T_{p,fill}$)
235 compared to only using available data (i.e., $T_{p,gap}$), regardless of the length of introduced annual gaps (Figure 2).
This bias was less than 0.5°C for more than 75% of stations with only one year of observation. In contrast, when
there is only one year available, the biases for data with artificial gaps, $T_{p,gap}$, are higher than 0.5°C for 75% of
the stations. There was no systematic bias regardless of the years taken into account in the regressions.

240 **Figure 2.** Improvement in absolute bias of thermal peaks across all reference sites ($T_{p,ref}$, $n=30$) when introduced
annual gaps were filled with the climate correction procedure ($T_{p,fill}-T_{p,ref}$, red boxplots) compared to when gaps
were unfilled ($T_{p,gap}-T_{p,ref}$, blue boxplots) regardless of the number of introduced gaps.

3.2 Model cross-validation

245 In cross validation, all four statistical models performed substantially better than air temperature at accurately
predicting T_p (Figure 3). Indeed, $T_{p,air}$ overestimates the observed $T_{p,ref}$ by 2.5°C on average (Figure 3a), and the

negative NSE for $T_{p,air}$ indicates that using a simple mean of T_w observations is a better predictor of T_p than using T_{air} (Figure 3b). Overall, models tend to slightly underestimate T_p (Figure 3a), but mean biases are close to 0°C . The REG and ANN models had similar performance (median RMSE $> 1.5^\circ\text{C}$; median NSE = 0.6), whereas the RF and MM models obtained the best performances (median RMSE $< 1.5^\circ\text{C}$; median NSE = 0.7) with the MM slightly superior for NSE (Figure 3b,c). We did not observe any spatial patterning in performance metrics (not shown).

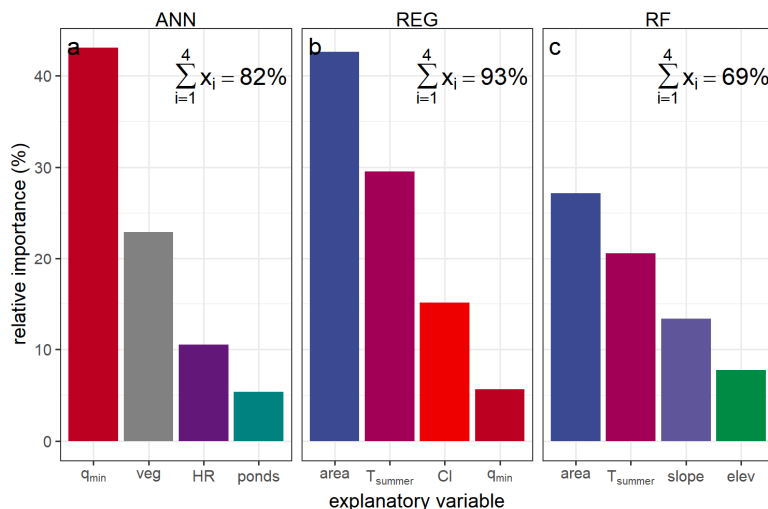

Figure 3. Cross validation performance metrics for modeled thermal peaks ($T_{p,m}$), where 80% of stations ($n = 1360$) were training data and 20% of stations ($n=340$) were validation data. Violin plots show distributions of 100 replicates of training-validation data for each model's performance metrics: a) bias relative to $T_{p,ref}$; b) NSE; c) RMSE of $T_{p,m}$ relative to observed T_p . Horizontal lines indicate sample medians and red points indicate sample means.

3.3 Relevance of explanatory variables in models

Explanatory power varied among modeling approaches, and the maximum variance explained for any one variable was between 25–30%. (Figure 4) The two most relevant variables were catchment area (area) and mean summer air temperature (T_{summer}) for the RF and multiple regression models (Figure 4b,c), but were minimum monthly specific discharge (q_{min}) and riparian vegetation cover (veg) for the ANN model (Figure 4a; q_{min} is not correlated with area, $R^2 = 0$). Surprisingly, area and T_{summer} obtained relative importances of less than 5% in ANN whereas they were the most influential variables in the RF and the REG models. It should be noted that the cumulative importance of the four most relevant variables of the REG and ANN models is respectively 92% and 81%, which

means that the other variables have very little weight in the estimates. This sum is only 69% for RF, which indicates that the relative importance of the explanatory variables are more distributed and the other explanatory variables have a significant weight in the estimates which could explain the best performances in cross validation of RF.

270 **Figure 4.** Relative importance of top four explanatory variables calculated in cross validation for the estimation of T_p with the models: a) ANN; b) REG and c) RF. To compare the relative importance of each variable for each model, all variables were centered and scaled. Text in the upper right of each panel refers to the sum of the relative importances of the first four explanatory variables in each model; colors indicate the explanatory variable.

3.4 Spatial extrapolation of thermal peaks

275 The statistical models could extrapolate T_p to 92% (105,800 reaches) of the RHT network, and the resulting spatial structure of the extrapolations was consistent across models (Figure 5). On average, T_p was 18.2°C and ranged between 6.3°C and 27.0°C. The highest $T_{p,m}$ (i.e., $T_p > 22^\circ\text{C}$) were generally found on the largest rivers located in the southeast and in the sedimentary plains. The lowest $T_{p,m}$ are found in the mountain streams of the Alps, Pyrenees and Massif Central, and in the northwest. Although the distribution $T_{p,m}$ is consistent among models (Figure 5), there are some clear disparities, particularly at the extremes. The ANN model simulates $T_{p,m}$ below 14°C on more streams (> 15%) compared to other models (< 10%; Figure 6a). In stark contrast, estimating T_p with air temperature (i.e., $T_{p,air}$) led to consistently higher values than were obtained with statistical models, with $T_{p,air}$ greater than 20°C for more than 70% of the reaches (Figure 5a, Figure 6a).

280 Application of the climate correction prior to model fitting and subsequent extrapolation showed that differences at the RHT are less than 0.5°C at 89% of the reaches (Figure 6b). Still, 10% of the reaches exhibited $T_{p,m}$ differences greater than 0.5°C, and the vast majority of these differences are negative (9.4% vs. 1.6%), suggesting that climate correction more often than not reduces overestimates in T_p .

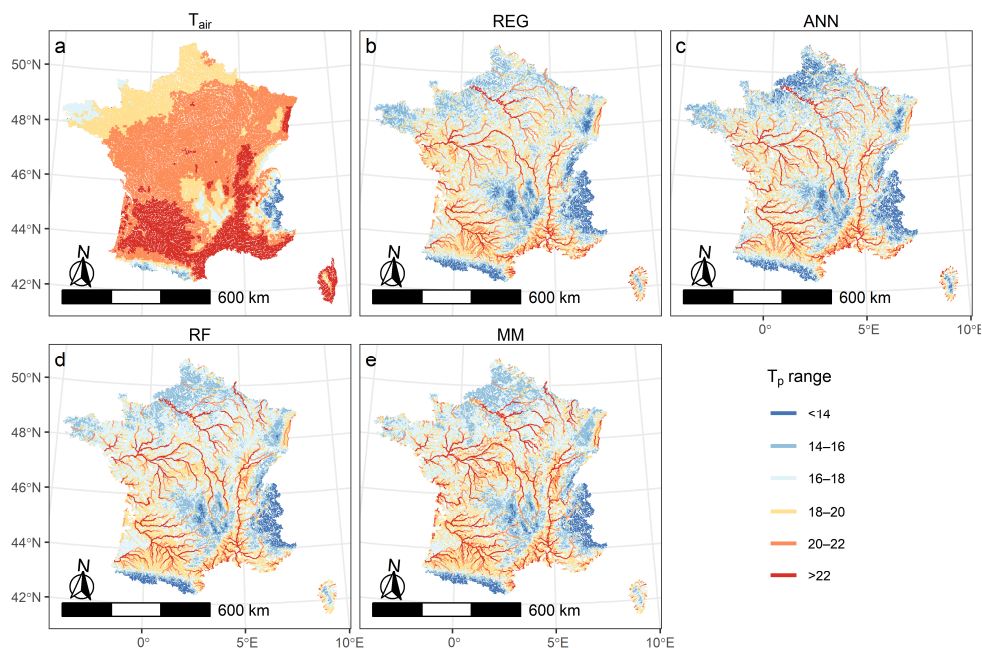

Figure 5. Thermal peaks (T_p) of stream water extrapolated to all reaches of the French hydrographical network
 290 RHT with the different predictive model structures: a) air temperature (T_{air}), b) multiple regression (REG), c)
 artificial neural network (ANN), d) random forest (RF), and e) multi-model combination of all previous models
 (MM). All reaches are colored by their modeled range of T_p .

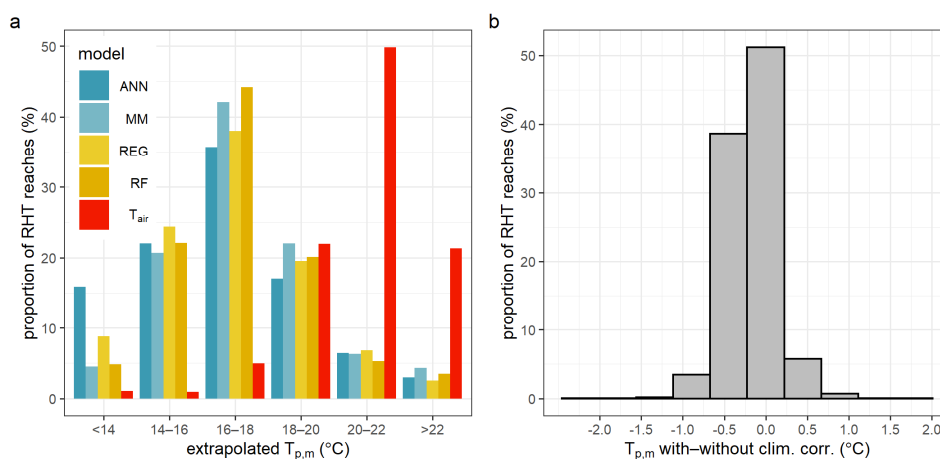

Figure 6. Distributions of $T_{p,m}$ extrapolated to all RHT network reaches. a) Comparison of models according
 295 their extrapolated T_p value, colored by model, and b) differences between $T_{p,m}$ calculated with and without
 climate corrections on the 1,630 stations with gaps in their data.

300 **4. Discussion**

We compiled one of the largest regional stream temperature datasets to address the growing need to understand stream thermal regimes in the context of climate change. We demonstrate that a simple, ecologically meaningful metric, which we term the thermal peak (T_p), can be reliably estimated at the regional scale using a few easily accessible explanatory variables.

305 **4.1 Horizons and limitations in estimating large-scale stream thermal metrics**

Spatiotemporally comprehensive stream temperature datasets are rare because interest in these data is relatively recent and there is little money to support instrumentation at regional or national scales. This lack of data has been recognized as a major limitation for understanding thermal regimes of riverine ecosystems (Arismendi et al., 2012; Ouellet et al., 2020). Existing data typically come from different entities and are not managed according to a predefined regional strategy, precluding broad-scale synthesis and understanding of controls on stream temperature and its subsequent effects on ecosystems and society. To overcome these barriers, we employed a combined empirical approach that allowed us to identify, at the regional scale, a map of summer stream temperature maxima with important implications for aquatic species distributions under climate change. We observed the hottest T_p along major rivers and the coldest T_p along small rivers and in mountainous regions (Figure 5). The downside of the current approach is that it remains based on interannual metrics. Indeed, the non-concomitance of the time series does not allow us to compare extreme years (hot vs. cold).

To enable unbiased comparison among stations from time series with gaps, we used a climate correction of T_w based on regression with T_{air} . The efficacy of regressions between T_w and T_{air} is well-understood (Ducharne, 2008; Segura et al., 2015; Moatar and Gailhard, 2006), and the approach can be easily transferred to other stations and regions. On the other hand, a cautious approach is required for such regressions, because they assume seasonal correlation T_{air} and T_w , and can therefore only apply to rivers having natural seasonal dynamics, without dam release, thermal peaking, or major weirs regulating the flow of streams (Bruno et al., 2013; Chandresis et al., 2019; Seyedhashemi et al., 2021; Casado et al., 2013). However, where possible, climate correction makes it possible to significantly reduce the biases in the estimates of T_p to metrics based only on observations (Figure 3). The biases are particularly reduced when the number of years of observation available is less than four. Beyond this limit, the meteorological variability specific to each year is sufficient to estimate a robust interannual metric T_p , which confirms results obtained by (Jones and Schmidt, 2018). Moreover, climate correction reduces overestimation of T_p , when applied at scale (Figure 6b), reinforcing the importance of taking into account these climatic corrections to temperature metrics even if it only slightly affects the majority of rivers (Isaak et al., 2017)

330 **4.2 Spatial extrapolation of T_p is consistent and best predicted with a random forest model**

All four statistical models achieved similar predictive performance, but the RF model exhibited marginal improvements over the others (Figure 3). The MM approach only slightly improves performance in cross-validation in comparison with RF (vis-à-vis the NSE criterion), so it is unlikely to be a useful approach in future applications due to its complexity. Our model performances (NSE = 0.75, RMSE <2) were of the same order as

335 other large scale stream temperature studies found in the literature (cf. Segura et al., 2015; Daigle et al., 2010; Wehrly et al., 2009), suggesting that our approach is reasonable and broadly applicable.

In spatial extrapolation, the T_p estimates are globally consistent between the models and the same spatial structures are found regardless of the approach used (Figure 5). We observed divergences between the models in particular for T_p less than 14°C where ANN tends to simulate coldest T_p for more reaches compared to other models (Figure 6). Still, because our analysis is limited to 2009–2017, these model differences may diminish as T_w measurements grow in time and space.

4.3 Drivers of thermal peak depend on model structure

We observed clear divergence of variable importance for the estimation of T_p among the ANN, RF, and REG models. The two most relevant variables in RF and REG are catchment area and mean summer air temperature, consistent with other studies (Laanaya et al., 2017; McGarvey et al., 2018). Greater catchment area typically implies larger stream size, and subsequently higher T_p . Large rivers are also more impacted by low flow warming because they are less shaded by riparian vegetation and are less influenced by groundwater inflows. Moreover, longer water travel times in large rivers allow more time for temperature equilibration with the atmosphere compared to small rivers (Beaufort et al., 2019; Mohseni et al., 1998). Importantly, RF had a much more even distribution of variable importances relative to the other models structures, which is likely due to its non-linear structure. In contrast, for ANN, the most important variables were minimum monthly specific discharge (43%) following by riparian vegetation cover (23%). Larger minimum flows imply a consistent groundwater supply, leading to cool surface waters in summer (Hannah et al., 2004; Kelleher et al., 2012; Lalot et al., 2015). Similarly, greater riparian vegetation implies greater shading and reduced temperature increases from solar radiation (Dugdale et al., 2018; Loicq et al., 2018; Moore et al., 2013). These differences in relevance between the variables for each model underlines the importance of using several approaches and shows that an approach combining all the models makes it possible to take into account all these divergences between models. We note that some variables used in models for T_p were not available across the entire hydrographic network for extrapolation. As a result, certain variables could not be used as the base flow index (BFI) whereas they have been successfully used by other studies (Beaufort et al., 2020a; Hill et al., 2013).

4.4 Air temperature is not an appropriate proxy for stream temperature

Estimates of T_p produced by stream temperature were clearly more accurate than those produced by air temperature (Figures 3 and 5). In cross-validation, $T_{p,air}$ overestimated observed T_p by more than 2°C, could not differentiate stream temperature among regions (Figure 5), and could not differentiate large rivers from small rivers. This clearly demonstrates that T_{air} is an inappropriate proxy for T_w , with important implications for ecological studies, especially those that consider temperature tolerance thresholds of aquatic species. Species distribution models may need to use T_{air} instead of T_w because data from T_w are not sufficient in the regions studied (McGarvey et al., 2018). It is therefore important to introduce T_w in input of these models rather than T_{air} in order to limit the biases linked to the poor spatial representativeness of T_{air} . Considering hydrological variables can limit these biases and introduce the effects of the size of the catchment on the variability of T_w metrics. However, there may be local cooling or warming effects, which can only be understood with field observations. We must therefore continue the

efforts already started for the acquisition of time series of T_w and monitoring more streams to obtain better thermal representativeness of hydrosystems.

4. Conclusion

375 Stream thermal regimes are essential controls on aquatic ecosystems, but our understanding of these regimes and
thus our ability to adequately manage them accordingly in the context of climate change is limited by data
availability and simple metrics applicable at large scales. To address these gaps, we developed a simple,
ecologically relevant metric—the thermal peak, T_p — that can be extrapolated at large scales, even when data are
sparse. We developed an innovative climate correction method to reduce biases related to such data sparseness,
380 when applied to summer data. The T_p provides an important perspective on the magnitude of thermal extremes
during summer, but development of additional metrics such as threshold exceedance frequency, duration, and
timing will continue to grow our understanding of stream temperature behavior under climate change. However,
development of these metrics will require longer and more spatially explicit time series. Hence, we argue that to
improve our capacity to manage and benefit from aquatic ecosystems, it is critical to continue and expand our
385 stream temperature measurement networks.
