13 **Abstract.** Worldwide, the amount of water used for agricultural purposes is rising and the quantification of irrigation is
14 becoming a crucial topic. Because of ~~the~~ the limited availability of in situ observations, an increasing number of studies is
15 focusing on the synergistic use of models and satellite data to detect and quantify irrigation. The parameterization of irrigation
16 in large scale Land Surface Models (LSM) is improving, but it is still hampered by the lack of information about dynamic crop
17 rotations or the extent of irrigated areas, and the mostly unknown timing and amount of irrigation. On the other hand, remote
18 sensing observations offer an opportunity to fill this gap as they are directly affected by, and hence potentially able to detect,
19 irrigation. Therefore, combining LSMs and satellite information through data assimilation can offer the optimal way to quantify
20 the water used for irrigation.

21 ~~The~~ This work represents the first and necessary step towards building a reliable LSM data assimilation system which, in
22 future analysis, will investigate the potential of high-resolution radar backscatter observations from Sentinel-1 to improve
23 irrigation quantification. Specifically, the aim of this study is to ~~optimize a land modelling system, consisting of couple the~~
24 ~~Noah-MP LSM, coupled running within the NASA Land Information System (LIS), with a backscatter observation operator,~~
25 ~~over irrigated land in order to simulate for simulating unbiased backscatter predictions. This is a first step towards building a~~
26 ~~reliable data assimilation system to ingest level 1 Sentinel 1 observations, over irrigated lands. In this context, we first tested~~
27 ~~how well modelled soil moisture~~ Surface Soil Moisture (SSM) and vegetation estimates ~~from the Noah MP LSM running~~
28 ~~within the NASA Land Information System (LIS), with, with or without irrigation simulation, are able to capture the signal~~
29 ~~of high resolution~~ aggregated 1-km Sentinel-1 backscatter observations over the Po river Valley, an important agricultural area
30 in Northern Italy. Next, ~~aggregated 1 km Sentinel-1 backscatter observations, together with simulated SSM and LAI, were~~
31 ~~used to calibrate~~ optimize a Water Cloud Model (WCM) as ~~which will represent the observation operator using simulated soil~~

32 ~~moisture and Leaf Area Index estimates in future data assimilation experiments.~~ The WCM was calibrated with and without
33 ~~activating~~ an irrigation scheme in Noah-MP₂ and considering two different cost functions. Results demonstrate that
34 ~~activating~~ using an irrigation scheme provides ~~the optimal~~ a better calibration of the WCM, even if the simulated irrigation
35 estimates are inaccurate. The Bayesian optimization is shown to result in the best unbiased calibrated system, with minimal
36 chance of having error cross-correlations between the model and observations. Our time series analysis further confirms that
37 Sentinel-1 is able to track the impact of human activities on the water cycle, highlighting its potential to improve irrigation,
38 soil moisture, and vegetation estimates via future data assimilation.

39 1 INTRODUCTION

40 Over the last century, the global water withdrawal grew 1.7 times faster than the population (FAO, 2006). This aggravates the
41 concern over the sustainability of water use as demand for agricultural uses continues to increase (Foley et al., 2011; FAO
42 AQUASTAT http://www.fao.org/nr/water/aquastat/water_use/index.stm, last access 20 May 2021). The strong impact of
43 irrigation on the global water budget is highlighted by many studies and it has been estimated that about 87% of the global fresh
44 water withdrawals have been used for agriculture (Douglas et al., 2009). Accordingly, the quantification of irrigation on a
45 regional to global scale has become a hot research topic.

46 Correctly quantifying irrigation in Earth system models can serve two purposes. On the one hand, it can help improve water
47 management (Le Page et al., 2020, Bretreger et al., 2020), on the other hand, it allows to quantitatively assess its effects on the
48 terrestrial water, carbon and energy cycles (Haddeland et al., 2007; Breña-Naranjo et al., 2014; Hu et al., 2016; Qian et al. 2020).
49 Indeed, results of large-scale irrigation studies using land surface models (LSMs) have demonstrated that irrigation increases
50 soil moisture and evapotranspiration (ET), and consequently latent heat flux with a decrease in sensible heat flux (i.e., Badger
51 & Dirmeyer, 2015; Lawston et al., 2015; Ozdogan et al., 2010b).

52 Despite the significant impact of irrigation on the water and energy cycles, its simulation within LSMs is not yet common
53 practice (Giroto et al., 2017). ~~Attempts~~In earlier studies, ~~attempts~~ to simulate irrigation in LSMs ~~have in the past~~ relied on
54 ~~different parameterizations of well-known irrigation systems (like sprinkler, flood, and drip systems; Ozdogan et al., 2010b;~~
55 ~~Evans and Zaitchik, 2008)~~ either without specifying the source of water withdrawals and by relying on additional fictitious
56 ~~rainfall (-), making simplifying assumptions. For instance, in Ozdogan et al. (2010b) or taking irrigation water is not withdrawn~~
57 ~~from groundwater (a source (such as a river) but instead added as fictitious rainfall. In contrast, Nie et al., (2018)-) accounted~~
58 ~~for source water partitioning, albeit only partially, by considering groundwater irrigation.~~ Irrigation is normally applied when
59 soil moisture drops below a user-defined threshold (Ozdogan et al. 2010b), typically dependent on the soil properties obtained
60 via soil texture maps.

61 Moreover, LSMs equipped with irrigation schemes need to be provided with auxiliary information about crop types and whether
62 or not the crops are irrigated. This is because different crop types are characterized by different rooting depths, which means

63 they require more or less water to restore root zone field capacity. This information is normally gathered from static maps derived
64 from statistical analysis and/or remote sensing (Ozdogan et al., 2010b; Monfreda et al., 2008; Salmon et al., 2015) collected
65 during specific historical periods which are normally different ~~from~~ to the desired period of analysis. It is thus clear that the
66 modelling of irrigation is subject to many simplifying assumptions, which span from neglecting the year-to-year crop variability
67 and the irrigation system used to the definition of irrigation application times based on water availability and crop conditions
68 rather than actual farmer decisions.

69 Remote sensing (RS) technologies offer the opportunity to observe directly the Earth surface and its changes, and hence are
70 potentially able to monitor irrigated lands worldwide (Ambika et al., 2016; Gao et al., 2018; Bousbih et al., 2018; Bazzi et al.,
71 2019; Le Page et al., 2020; Dari et al., 2020). In the last decade, some authors used visible and near infrared RS observations
72 jointly with in situ data collected from inventories to map areas equipped for irrigation (Ambika et al., 2016; Ozdogan & Gutman,
73 2008). Kumar et al. (2015a) were the first to propose the use of coarse resolution satellite microwave (MW) sensors to detect
74 irrigation. The authors compared different coarse-scale active and passive MW surface soil moisture (SSM) retrievals with SSM
75 simulations from the Noah LSM (version 3.3; Ek et al., 2003) without activating an irrigation scheme over a continental US
76 domain. Areas where the distributions of model and RS data sets deviated (based on a Kolmogorov-Smirnov test) were assumed
77 to be irrigated. Even though some of the products showed a potential ability to detect irrigation, the authors concluded that the
78 spatial mismatch between the satellite footprint and the irrigated fields, radio-frequency interference (RFI), vegetation, and
79 topography could all deteriorate the accuracy of the results. Similar conclusions were found over the same area by Zaussinger
80 et al. (2019) who compared coarse-scale satellite SSM products with soil moisture predictions from the Modern-Era
81 Retrospective analysis for Research and Applications 2 (MERRA-2) in the absence of precipitation, and Escorihuela and
82 Quintana-Seguí (2016) who additionally compared a downscaled version of the Soil Moisture and Salinity mission (SMOS)
83 SSM to SURFEX LSM simulations. Brocca et al. (2018), Jalilvand et al. (2019) and Dari et al. (2020) used a conceptually
84 different approach with the same coarse scale MW SSM products and estimated irrigation by directly inverting a simple water
85 balance equation (Brocca et al. 2014).

86 The Copernicus Sentinel-1 satellites (Sentinel-1A and Sentinel-1B) offer a new perspective for agricultural applications, thanks
87 to the finer spatial resolution (up to 10-20 m) of the Synthetic Aperture Radar (SAR) backscatter (σ^0) data. For instance, Gao et
88 al. (2018) proposed an approach to map irrigated lands over the Urgell region in Catalonia (Spain), and Le Page et al. (2020)
89 proposed a methodology to detect irrigation timing in south-west France comparing the SSM signal at the plot scale, derived
90 using Sentinel-1 σ^0 and NDVI from Sentinel-2 (El Hajj et al., 2017), with a water budget model forced by Sentinel-2 optical
91 data for the detection of irrigation timing.

92 Despite the high potential demonstrated by RS in detecting, mapping and quantifying irrigation, the uncertainties of the satellite
93 retrievals, the relatively low revisit time of high resolution active MW products and the too coarse spatial resolution of passive
94 MW products with respect to the mean size of irrigated fields represent main limitations for irrigation information retrieval
95 (Romaguera et al., 2010, La Page et al., 2020). Data assimilation (DA) could reduce some uncertainties by optimally integrating

96 LSM estimates and RS observations. Indeed, the LSM estimates resolve processes at desired spatio-temporal scales, while the
97 RS observations can track in a more realistic way human processes like irrigation and their interactions with the water and energy
98 cycles. Contrasting LSM simulations with RS observations offers an opportunity to correct for unmodeled processes or missed
99 events, such as irrigation (Kumar et al., 2015a; Giroto et al., 2017). More generally, DA of satellite-based observations has
100 shown the potential to update soil moisture (De Lannoy & Reichle, 2016; Kolassa et al., 2017) and vegetation (Albergel et al.,
101 2018; Kumar et al., 2020) and important impacts have been reported over agricultural areas (Kumar et al., 2020).

102 **The assimilation of MW RS observations in LSMs often involves retrieval assimilation. However, assimilating retrievals (i.e.,**
103 **SSM or vegetation optical depth rather than MW brightness temperature (T_b)-or σ^0 measurements) can be problematic as the**
104 **retrievals may ~~have been~~ produced with ~~inconsistent~~ ancillary data that are inconsistent with those used in the LSM (De**
105 **Lannoy et al. 2016). This is particularly true for passive MW retrievals while active MW retrievals generally rely on change**
106 **detection methods that lack land-specific ancillary information altogether. An alternative ~~solution~~ approach, which we follow in**
107 **this study, is to directly assimilate MW observations and equip the LSM with an observation operator that links land surface**
108 **variables of interest (e.g., soil moisture and vegetation) with RS data. This allows us to obtain consistent parameters and to**
109 **reduce the chance of cross-correlated errors between model states and corresponding geophysical satellite retrievals.** The direct
110 assimilation of MW observations has already been demonstrated successfully for the update of soil moisture by using T_b derived
111 from the SMOS and SMAP missions (De Lannoy et al. 2016, Carrera et al., 2019, Reichle et al. 2019), as well as using radar σ^0
112 from ASCAT (Lievens et al., 2017b), and σ^0 from Sentinel-1 in synergy with SMAP T_b (Lievens et al., 2017a). However, to our
113 knowledge, none of these studies considered the joint updating of soil moisture and vegetation, and none specifically
114 ~~fo~~**ocused** on the performance over irrigated areas. The σ^0 from Sentinel-1 contains information on both soil moisture
115 (Zribi et al., 2011; Liu and Shi, 2016; Li and Wang, 2018; Bauer-Marschallinger et al., 2018) and vegetation (Vreugdenhil et
116 al., 2018; Vreugdenhil et al., 2020) and assimilating this data could allow us to update both soil moisture and vegetation in a
117 land data assimilation system and, in doing so, correct for missed irrigation events.

118 To that end, the LSM needs to be coupled to a backscatter forward model as an observation operator. Different SAR σ^0 models
119 have been proposed to simulate the backscattering contributions of soil and vegetation (Attema & Ulaby, 1978; Oh, 2004; Zribi
120 et al., 2005; Bai et al., 2015; Baghdadi et al., 2017). Most commonly used, the Water Cloud Model (WCM hereafter) developed
121 by Attema and Ulaby (1978) is a σ^0 model that represents the vegetation canopy as a homogeneous cloud containing randomly
122 distributed water droplets. In order to use the WCM as the forward operator in a σ^0 data assimilation system, it first needs to be
123 calibrated to account for biases between the LSM simulations and the satellite observations. However, calibrating a WCM to
124 simulate σ^0 over irrigated areas, is not a straightforward process and it represents a key research problem if the same σ^0 signal is
125 used for the calibration of WCM parameters and later for assimilation and state updating. In fact, if the objective is to assimilate
126 radar σ^0 to realistically inform the model about irrigation applications, the WCM parameters have to maintain a certain degree
127 of independence from the irrigation signal contained in the observed σ^0 as otherwise the assumption of uncorrelated errors
128 between model and observations typical of classical Bayesian-based filters is violated. More specifically, if the LSM provides

129 unrealistic simulations as input (i.e., absence of irrigation), then the WCM calibration with observed σ^0 would compensate for
130 this bias. This would in turn lead to a biased backscatter model with undesirable calibrated parameters for the subsequent data
131 assimilation experiments. Therefore, different strategies can be adopted, for instance calibrating the model during non-irrigated
132 periods or over non-irrigated areas, or equipping the LSM with an irrigation module that makes the WCM less constrained by
133 inconsistencies between simulated and observed σ^0 during irrigation periods. The efficacy of these strategies has so far never
134 been explored.

135 The main objective of this study is to simulate radar σ^0 using a LSM coupled with a WCM and to provide solutions and
136 recommendations for the optimization of the WCM as an observation operator. This is a major stepping-stone towards the
137 development of a reliable system for the assimilation of high-resolution Sentinel-1 σ^0 observations over irrigated areas.
138 Additionally, we aim at:

- 139 1) testing the ability of a sprinkler irrigation system coupled with a LSM to simulate irrigation so as to highlight the
140 potential and limitations of such a tool to optimize a backscatter forward operator over heavily irrigated areas;
- 141 2) demonstrating that Sentinel-1 σ^0 observations contain valuable information to improve both SM and vegetation
142 predictions over irrigated land (i.e., soil moisture and vegetation consistent with human alterations in the water
143 cycle due to intensive irrigation).

144 The analysis is carried out over the Po river valley, one of the most important agricultural areas in Italy and also one of the more
145 intensively irrigated areas in Europe (water withdrawal in the Po basin is estimated to be 20.5 billion m³/year, of which 16.5
146 billion of m³/year is withdrawn for irrigation; Po River Watershed Authority, 2006). We use the Noah-MP v.3.6 LSM (Noah-
147 MP hereafter) as part of the NASA Land Information System (LIS) framework together with the WCM from Attema and Ulaby
148 (1978) for the simulation of both σ^0 vertical send and receive (VV) and vertical send and horizontal receive (VH) polarization.
149 Level-1 Sentinel-1 σ^0 observations are used to calibrate the WCM at 1-km resolution, using simulated SSM and Leaf Area Index
150 (LAI) estimates from Noah-MP. The WCM is calibrated for a total of four calibration experiments for each polarization: 1) with
151 or without activating an irrigation scheme within Noah-MP; and, 2) considering two different cost functions. Specifically, we
152 want to demonstrate that activating an -even poor- irrigation scheme is needed to obtain long-term unbiased σ^0 simulations and
153 uncorrelated errors between the WCM and Sentinel-1 and that the calibration process can be sensitive to different cost functions.
154 The manuscript is organized as follows. Section 2 provides information on the study area, the selected datasets, and methods
155 used for our analysis. Specifically, Sections 2.3 and 2.4 provide a detailed description of the Noah-MP LSM and the WCM.
156 Section 2.5 describes the cost functions used for the WCM calibration while Section 2.6 is a description of the experimental set-
157 up designed for the calibration. Finally, Section 2.7 provides insights on the Noah-MP and WCM evaluations. Section 3 presents
158 the results, with an assessment of the Noah-MP evaluation, both regional (Section 3.1) and over the test sites (Section 3.2). The
159 WCM calibration and evaluation results are described in Sections 3.3 and 3.4, respectively. We provide discussion in Section 4
160 while conclusions are reported in Section 5.

161 2 DATA AND METHODS

162 2.1 Study area and in situ data

163 The analysis was carried out over an area of 24,000 km² located within the Po river valley, one of the most important agricultural
164 areas in Europe (Figure 1, left-bottom corner: 44°N, 10.5°W; top-right corner: 45.5°N, 12.2°W). The Po river valley is part of
165 the Po river basin district (~74,000 km²), a mountain-fed catchment which extends from the Alps in the West, to the Adriatic
166 Sea in the East. The Po district is one of the eight districts mentioned in the Water Framework Directive (WFD, 2000) initiated
167 by the European Commission and has been hit by seasonal drought events which impacted all water use sectors, in particular
168 agriculture (Strosser et al., 2012). The water assessment and impact evaluation of human activities over the Po river valley is
169 thus a topic of major interest, considering the significant requirements from the agricultural management sector.

170 According to the Köppen-Geiger climate classes (Peel et al., 2007) the study area is classified as "Cfa" (temperate climate,
171 without dry season and with hot summers). From a geographical point of view, the Po river flows from the west to the east,
172 splitting the area of interest in northern and southern areas, respectively. North of the Po river, the agricultural plain area can be
173 additionally subdivided into the Veneto region to the east and the Lombardy region to the west (Figure 1). Lombardy lands have
174 a high water availability, thanks to the presence of several Alpine lakes and reservoirs (Musolino et al., 2017), as does the Veneto
175 region. Wine cultivation plays an important role, especially in the Garda Lake surroundings (located to the north-west side of
176 the study area). In the south, the Emilia Romagna region is an agricultural as well as urbanized-industrialized area. Compared
177 to Lombardy and Veneto, Emilia Romagna is much poorer both in water availability and storage capacity, but its irrigation
178 system is considered the most technologically advanced and efficient in the Po river basin (Musolino et al., 2017). Specifically,
179 it hosts the Canale Emiliano ~~Romagnolo~~ **Romagnolo** (CER, <https://consorzioцер.it/>, last access 20 May 2021), one of the most
180 important Italian hydraulic systems for agricultural water supply. The main crops in the study region include general summer
181 and winter crops, orchards (i.e., peach, pear, kiwi), olive groves, and vineyards ([https://sites.google.com/drive.arpae.it/servizio-](https://sites.google.com/drive.arpae.it/servizio-climatico-icolt/home)
182 [climatico-icolt/home](https://sites.google.com/drive.arpae.it/servizio-climatico-icolt/home), last access 20 May 2021). The plain area is surrounded by a forested hilly and mountainous area of the
183 Tuscan-Emilian Appennine to the south/south-west.

184 In situ data were collected over two test sites, located in the Emilia Romagna region:

- 185 • ~~The~~ **For an analysis at plot scale we selected the Budrio test site (Figure 1a) is**, an experimental farm managed by
186 **the CER authority and which includes two plots of 0.39-0.49 ha.** The main crops are maize for field 1 (in yellow) and
187 tomatoes in field 2 (red colour). Daily irrigation data, in mm, were collected for the summer 2015-2016 over field 1,
188 whereas daily irrigation water amounts were collected for the summer 2017 over field 2. Additionally, for field 2,
189 hourly in situ soil moisture data, aggregated here at daily scale, were made available from the Department of Physics
190 and Earth Science of the University of Ferrara. The soil moisture data were derived from an innovative Proximal
191 Gamma-Ray (PGR SM hereafter; Filippucci et al., 2020, Strati et al., 2018) station, equipped with a 1L NaI(Tl)
192 detector placed at 2.25 m above the ground and a commercial agro-meteorological station (MeteoSense 2.0, Netsen;
193 Strati et al., 2018). The PGR is a nuclear non-invasive and non-contact technique, which allows to overcome the issue

194 connected to in situ point measurements, probing soil moisture with a field scale footprint ($\sim 10^4 \text{ m}^2$) up to a depth of
195 30 ~ cm. The quantification of PGR soil moisture is derived from measurements of gamma signals emitted by the
196 decay of ^{40}K , which is extremely sensitive to different soil water contents in agricultural soils (for more information
197 on the PGR soil moisture deriving procedure the reader can refer to Baldoncini et al., 2019). Finally, daily rainfall
198 data were collected from the national rainfall network managed by the Department of Civil and Environmental
199 Protection (DPC) of Italy, for the irrigated periods.

- 200 • **The second test site (Figure 1b) is located around the city of Faenza (hereafter Faenza test site) and has a total extent**
201 **of 1051 ha, consisting of two ~~different fields-~~fields which allow an analysis at the small-district spatial scale.** The first
202 one is called San Silvestro (290 ha) and it is located north of the city. The second one is called Formellino (760 ha),
203 located east to the San Silvestro field and north-east to the city of Faenza. Fruit trees are prevalent on the fields; in
204 particular, pear trees and kiwi dominate the area. The water used for irrigation was provided by CER, at hourly time
205 scale and in mm, for the 2-years time period 2016-2017. Daily rainfall data were collected from the national rainfall
206 network managed from the DPC.

207 2.2 Sentinel-1 σ^0 and reference remote sensing products

208 The Copernicus-ESA Sentinel-1 ~~observations~~ σ^0 observations were used in this study for the calibration of the WCM. The
209 Sentinel-1 constellation consists of two satellites, Sentinel-1A and Sentinel-1B, launched in 2014 and 2016, respectively. Each
210 satellite carries a Synthetic Aperture Radar (SAR) operating at C-band (5.4 GHz) in the microwave portion of the
211 electromagnetic spectrum. The processing of the ground-range detected (GRD) Interferometric Wide Swath (IW) observations
212 in VV- and VH-polarization was done using Google Earth Engine's Python interface and included standard techniques: precise
213 orbit file application, border noise removal, thermal noise removal, radiometric calibration, and range-Doppler terrain correction.
214 Furthermore, the σ^0 observations acquired at $5 \times 20 \text{ m}^2$ resolution were aggregated and projected on the 1 km Equal Area Scalable
215 Earth version 2 (EASE-2) grid (Brodzik et al., 2012). After applying an orbit bias-correction (Lievens et al., 2019), the
216 observations from different orbits, either from Sentinel-1A or -1B and ascending or descending tracks, were combined at the
217 daily time-scale.

218 Additionally, RS observations were used for the evaluation of the SSM and LAI simulated in Noah-MP LSM for the period 31
219 March 2015- December 2019:

- 220 • The NASA Soil Moisture Active Passive (SMAP; Entekhabi et al., 2010) is an orbiting observatory launched in
221 January 2015 carrying two instruments: a SAR which suffered a failure in early July 2015, and a radiometer measuring
222 Tb at L-band, with a native spatial resolution of 40 km, a revisit time of 2–3 days, and ascending and descending
223 overpasses at 6:00 PM and 6:00 AM (local time), respectively. For this study, the 9-km SMAP Enhanced Level-2
224 SSM version 4 (0-5 cm; SMAP L2 hereafter) product was used (O'Neill et al., 2020; Chan et al., 2018). The product

225 is derived from SMAP Level-1B (L1B) interpolated antenna temperatures using the Backus-Gilbert optimal
226 interpolation technique. Both ascending and descending tracks were collected.

- 227 • The Metop ASCAT SSM Climate Data Records (CDR) H115 and its extension H116 are provided by the European
228 Organization for the Exploitation of Meteorological Satellites (EUMETSAT) Support to Operational Hydrology and
229 Water Management (H SAF; <http://hsaf.meteoam.it/>, last access 20 May 2021). The SSM is retrieved from σ^0 using
230 a change detection algorithm (Wagner et al., 2013), and is characterized by a spatial sampling of 12.5 km and a
231 temporal resolution of one to two observations per day, depending on the latitude.
- 232 • The PROBA-V LAI is derived from the PROBA-V satellite mission (Francois et al., 2014; Dierckx et al., 2014) and
233 provided by the Copernicus Global Land Service programme (CGLS, <https://land.copernicus.eu/global/>). The CGLS
234 product at 1 km spatial resolution and 10-day (dekadal) temporal resolution is developed based on the work by Verger
235 et al. (2014).

236 In order to compare Noah-MP simulations and reference data at the same spatial resolution, Sentinel-1 observations (σ^0 -VV and
237 -VH), as well as ASCAT SSM, SMAP L2 SSM and PROBA-V LAI were extracted over the study domain (left-bottom corner:
238 44°N, 10.5°W; top-right corner: 45.5°N, 12.2°W) and re-gridded over the LIS grid domain (0.01°) using the nearest-neighbour
239 approach.

240 **2.3 Land surface and irrigation modelling**

241 **2.3.1 Noah-MP v.3.6**

242 The analysis was carried out using the Noah-MP (Niu et al., 2011) LSM, running within NASA's LIS 7.2 version (Kumar et al.,
243 2008). LIS is a software framework for terrestrial hydrology modelling and DA, which supports different LSMs that can be
244 conditioned on multiple remote sensing products from active and/or passive microwave sensors. The Noah-MP LSM, which
245 was chosen for this study, is an evolution of the baseline Noah LSM (Mahrt and Ek, 1984; Chen et al., 1996; Chen and Dudhia,
246 2001) wherein main improvements and augmentations are: 1) the presence of four soil layers; 2) up to three snow layers; 3) one
247 canopy layer which allows to dynamically simulate the vegetation and to compute separately the ground surface temperature; 4)
248 a two-stream radiation transfer scheme based on the canopy layer sub-grid scheme; 5) a Ball-Berry type stomatal resistance
249 scheme; 6) and finally, a simple groundwater model with a TOPMODEL-based runoff scheme (Niu et al., 2005, 2007). The
250 model was set up selecting four soil layers at depths 0–10, 10–40, 40–100 and 100–200 cm, a dynamic vegetation model with a
251 Ball-Berry type canopy stomatal resistance model (Ball et al., 1987), and TOPMODEL-based runoff.

252 The parameterization followed the recommended options provided in the LIS documentation
253 (<https://modelingguru.nasa.gov/docs/DOC-2634>). A model time step of 15 minutes and a 6 hours output interval were selected
254 together with a spatial resolution of 0.01°. The meteorological forcings used for running Noah-MP LSM were obtained from
255 MERRA-2 (Gelaro et al. 2017). The MERRA-2 original spatial resolution of 0.5°x0.625° was re-mapped to 0.01° through

256 bilinear interpolation. Land model data and parameters were pre-processed and adapted to the LIS longitude/latitude projection
257 using the Land Surface Data Toolkit (LDT; Arsenault et al., 2018) in order to run Noah-MP at the chosen spatial resolution.
258 For this study, the default LIS Land Cover (LC) map from the University of Maryland (UMD) global land cover product (Hansen
259 et al., 2000) based on the Advanced Very High Resolution Radiometer (AVHRR) data was replaced with the 2015 global LC
260 map, available from the CGLS at 100 m spatial resolution (Buchhorn et al., 2020; available at
261 <https://land.copernicus.eu/global/products/lc> , last access 20 May 2021). The CGLS provides Dynamic Land Cover Layers at
262 100 m spatial resolution (CGLS-LC100), obtained by combining information derived from the vegetation instrument on board
263 the PROBA-V satellite, a database of high-quality LC reference sites, and several ancillary datasets. For a more detailed
264 explanation of the LC maps generation process we refer to the Algorithm Theoretical Basis Document (ATBD; Buchorn et al.,
265 2020). The 23 classes of the PROBA-V LC map were reclassified to the 14 classes used in the UMD-AVHRR classification
266 supported by LIS. Additionally, the LC map was regridded at 0.01° (Figure 2a) by identifying the most representative class over
267 each LIS grid cell. For additional information on the reclassification process, we refer the reader to Table S1 in the
268 Supplementary Material section. Similarly, the default FAO Soil Map (FAO Soil Map of the World, 1971) was replaced by the
269 Harmonized Soil World Database (HWSD v1.21, 1 km; Figure 2b) and mapped to 5 soil classes over the study region. Other
270 model pre-processed parameters inputs were: i) the Shuttle Radar Topography Mission elevation data (SRTM30, 30 m spatial
271 resolution); 2) climatological global Greenness Vegetation Fraction (GVF) data (0.144° ; Gutman and Ignatov, 1998) derived
272 from 5 years (1985-1989) of normalized difference vegetation index (NDVI) data from the AVHRR (Miller et al., 2006); 3) a
273 snow-free albedo and a Noah-specific maximum snow albedo product from NCEP (original resolution 1° and regridded); and
274 finally, 4) soil, vegetation, and other general parameter tables for Noah-MP from the LIS official Data Portal
275 (https://portal.nccs.nasa.gov/lisdata_pub/data/, last access 20 May 2021).

276 **2.3.2 Irrigation modelling**

277 The ability of Noah-MP to dynamically simulate the vegetation and the option to activate irrigation are particularly important
278 considering an extensively irrigated area such as the Po river valley. Indeed, in a recent study by Nie et al. (2018), Noah-MP
279 was coupled with a sprinkler irrigation scheme (Ozdogan et al., 2010b) (where irrigation is applied as supplementary rainfall),
280 which requires three pieces of information:

- 281 • the irrigation location, only occurring over potentially irrigated croplands (expanding over grassland if the intensity
282 exceeds the gridcell's total crop fraction). This information is extracted from a LC map associated with an additional
283 dataset providing information on the percent of irrigated area per grid cell. In this study, the reclassified PROBA-V LC
284 map was coupled with the information contained in the 500 m Global Rain-fed, Irrigated and Paddy Croplands data set
285 (GRIPC; Salmon et al., 2015);
- 286 • the timing of irrigation, which is determined by checking the start and end of the growing season based on a GVF
287 threshold, separately at each grid cell. Following Ozdogan et al.(2010b), we set this threshold to 40% of the GVF;

the amount of water used for irrigation. This quantity is derived from the root zone soil moisture (RZSM) availability (MA) as $MA = (RZSM - SM_{WP}) / (SM_{FC} - SM_{WP})$ where RZSM is the current RZSM, SM_{WP} is the wilting point, and SM_{FC} is the field capacity. When the MA falls below a user-defined threshold, irrigation is triggered and the quantity is defined by calculating the amount of irrigation needed to raise the RZSM to the SM_{FC} . For this study, the MA threshold was defined as the 50% of SM_{FC} as in Ozdogan et al. (2010b). MA is calculated at each time step but the irrigation is only applied between 06:00 and 10:00 LT. Following Ozdogan et al. (2010b), this time frame is typically chosen by farmers to reduce evaporative losses. In this context, the maximum rooting depth becomes a crucial information to compute the amount of irrigation water. This information is related to an assigned crop type, cultivated over the study area, through a maximum rooting depth table. Considering the high crop variability over the Po river valley as well as the lack of high resolution dynamic crop maps for the entire study area, a generic crop type with 1 m root depth was selected for the irrigation simulations. The reference rooting depth was verified to be feasible over the study area based on the European Soil Data Centre (ESDAC, available at <https://esdac.jrc.ec.europa.eu/content/european-soil-database-derived-data>, last access 20 May 2021) rooting depths map (Figure S1 in the Supplementary Material).

2.4 Water Cloud Model

The WCM allows to simulate the top-of-vegetation σ^0 as a function of SSM and vegetation, using empirical fitting parameters. σ^0 is modeled as the sum of the backscatter from the vegetation (σ_{veg}^0 , in dB) and from the bare soil (σ_{soil}^0 , in dB), attenuated by the t^2 coefficient that describes the two-way attenuation from the vegetation layer. Scattering interactions between the ground and the vegetation are not accounted for. As reported in Baghdadi et al. (2018), for a given polarization pq (i.e., VV and VH), the WCM can be written as follows:

$$\sigma_{pq}^0 = \sigma_{veg,pq}^0 \sigma_{pq}^0 = \sigma_{veg,pq}^0 + t_{pq}^2 \sigma_{soil,pq}^0 t_{pq}^2 \sigma_{soil,pq}^0 \quad (1)$$

where:

$$\sigma_{veg,pq}^0 \sigma_{pq}^0 = A_{pq} V_1 \cos \theta A_{pq} V_1 \cos \theta (1 - t_{pq}^2 t_{pq}^2) \quad (2)$$

$$t_{pq}^2 t_{pq}^2 = \exp \left(\frac{-2B_{pq} V_z}{\cos \theta} - \frac{2B_{pq} V_2}{\cos \theta} \right) \quad (3)$$

$$\sigma_{soil,pq}^0 = C_{pq} + D_{pq} \cdot SSM \sigma_{soil,pq}^0 = C_{pq} + D_{pq} \cdot SSM \quad (4)$$

317 Equations 2 and 3 describe the vegetation-related terms. V_1 and V_2 represent two bulk vegetation descriptors, the first one
 318 accounting for the direct vegetation σ^0 , and the second one representing the attenuation. $A_{pq}[-]$ and $B_{pq}[-]$ are the two related
 319 fitting parameters. Common vegetation descriptors used in previous studies are the Vegetation Water Content (VWC, Paloscia
 320 et al., 2013), the NDVI (El Hajj et al., 2016; Li and Wang, 2018) and LAI (Kumar et al., 2015b; Bai and He, 2015), while θ
 321 represents the incidence angle, which is assumed to be 37° for Sentinel-1. ~~Many following previous studies assumed $V_1=V_2$~~
 322 ~~represented by the unique vegetation descriptor (see Lievens et al, 2017b; Baghdadi et al. 2017; Li and Wang, 2018); we~~
 323 ~~assumed $V_1=V_2$ represented by the dynamically simulated LAI vegetation descriptor.~~

324 Equation 4 describes the soil-related term. Following the work by Lievens et al. (2017b), the σ_{soil}^0 can be described, in a
 325 simple linear approach, as a function of the SSM. There are several semi-empirical models (e.g., the Oh model; Oh et al., 1992)
 326 or theoretical models (e.g., the Integral Equation Model (IEM), Fung, 1994) which describe the scattering processes related to
 327 the bare soil, but their application as a forward operator coupled to an LSM has two main limitations: the first one lies in the
 328 difficulty in retrieving soil roughness values over extended reference areas required to parameterize these models; the second
 329 one is their saturation of σ^0 in moist conditions which causes low variability in simulated σ^0 if the LSM soil moisture
 330 simulations are biased wet (for more information -see Lievens et al., 2017b). Those limitations justify the use of a linear fitted
 331 approach. In Equation 4, the C and D parameters (here fitted in dB and dB/m³/m³, respectively, but σ_{soil}^0 is transformed
 332 back to the linear scale in Equation 1) describe the linear relation between $\sigma_{soil,pq}^0$ and SSM. Those parameters, as
 333 well as A and B (-), need to be calibrated separately for each polarization.

334 2.5 Calibration algorithms

335 We considered two different objective functions to optimize the A, B, C and D parameters:

- 336 • a Bayesian solution, which minimizes the Sum of Squared Errors (SSE) between σ^0 observations from Sentinel-1 and
 337 WCM simulations. The SSE Bayesian calibration solution aims at identifying the optimal parameter vector α which
 338 maximizes the probability of the resulting σ^0 simulations $p(\hat{y}^-) = p(\hat{y}^-|\alpha)p(\alpha)$, where $p(\alpha)$ is the prior parameter
 339 distribution and $p(\hat{y}^-|\alpha)$ is the likelihood. Starting from the assumption of an independent and identically distributed
 340 normal error model, the posterior probability can be maximized by maximizing:

$$341 \quad p(\hat{y}^-|\alpha)p(\alpha) = \prod_i^{N_i} \left\{ \frac{1}{s_i\sqrt{2\pi}} \exp\left(-\frac{(\hat{y}^- - \hat{y}_i^-)^2}{2s_i^2}\right) \right\} \cdot \prod_j^{N_\alpha} \left\{ \frac{1}{s_j\sqrt{2\pi}} \exp\left(-\frac{(\alpha_0 - \alpha_j)^2}{2s_j^2}\right) \right\} \quad (5)$$

342 i.e., the combination of the likelihood and a prior parameter constraint. The latter helps in reducing problems of
 343 equifinality. In Equation (5), \hat{y} represents the observed σ^0 , \hat{y}^- is the simulated σ^0 , i is the timestep and s_i is the standard
 344 deviation of the residual differences between the observed and simulated σ^0 values for N_i time steps. N_α is the number
 345 of parameters to be calibrated, α_0 is the prior parameter constraint and the parameter deviation is limited by s_j^2 , the

variance of a uniform distribution $s_j^2 = (\alpha_{max,j} - \alpha_{min,j})^2 / 12$ with determined boundaries of the parameters $[\alpha_{min}, \alpha_{max}]$. The maximum likelihood solution is found by minimizing the following cost function J :

$$J = \sum_i^{N_i} \left\{ \ln(s_i) + \frac{(\hat{y} - \hat{y}^-)_i^2}{2s_i^2} \right\} + \sum_j^{N_\alpha} \left\{ \frac{(\alpha_0 - \alpha)_j^2}{2s_j^2} \right\} = J_0 + J_\alpha \quad (6)$$

where s_i is assumed to be constant in time and represented by a target accuracy of 1 dB, leaving the SSE in the first term of J_0 to minimize. The second term (J_α) constrains the optimal solution by avoiding strong deviations from initial parameter guesses.

- a solution that maximizes the Kling-Gupta Efficiency (KGE; Gupta et al., 2009). Even though this objective function does not ensure Bayesian optimality, it is a widely used metric which could help to better tune the dynamic σ^0 behaviour:

$$KGE = 1 - \sqrt{(r - 1)^2 + \left(\frac{\langle \hat{y}^- \rangle}{\langle \hat{y} \rangle} - 1 \right)^2 + \left(\frac{s[\hat{y}^-] / \langle \hat{y}^- \rangle}{s[\hat{y}] / \langle \hat{y} \rangle} - 1 \right)^2} \quad (407)$$

The *KGE* formulation embeds three terms: 1) the first term accounting for the Pearson Correlation (Pearson-R) between the observed (\hat{y}) and simulated (\hat{y}^-) σ^0 time series; 2) a second term accounting for the bias, where the long-term mean is represented as $\langle . \rangle$; and finally, 3) a term accounting for the variability of the simulated and observed signal through the use of the standard deviation $s[.]$. *KGE* = 1 indicates a perfect agreement between simulations and observations. Note that *KGE* redistributes the weight of the bias, variance and correlation components, compared to J in Equation 6, which can help in reducing differences between simulated and observed σ^0 also in terms of temporal dynamics during the calibration. On the other hand, in the *KGE* cost function parameters are not constrained by prior values α_0 . This could possibly result in overfitting and a larger prediction uncertainty.

The Particle Swarm Optimization (PSO; Kennedy and Eberhart, 1995) was used to minimize J and maximize *KGE*. For our case study the PSO parameters were set as in De Lannoy et al. (2013).

2.6 Experimental setup

~~Building an optimal DA system able to correct for the poor parameterization of irrigation within LSMs via the ingestion of radar σ^0 requires the minimization of the impact of the irrigation signal already contained in σ^0 observations on the WCM parameters, while simultaneously guaranteeing long term unbiased σ^0 simulations compared to observations. Here we tested the hypothesis that this can be only achieved by activating irrigation in the LSM. An optimal DA system requires long-term unbiased σ^0 simulations (with respect to the assimilated observations). The risk, over an intensively irrigated area, is that an unmodelled irrigation signal would manifest itself as a predominant bias in the σ^0 simulations. The calibration would then~~

inadvertently correct for this supposed bias (i.e., the irrigation signal), thus preventing the DA system from propagating the missing irrigation signal from the observations into the model. Even though existing irrigation schemes are evidently unrealistic and inaccurate, we conjecture that using such a scheme when calibrating the WCM will more likely yield optimal WCM parameters than when neglecting irrigation.

To that end, we considered two different experiment lines (referred to as *Natural* and *Irrigation*, respectively) that produced a total of eight different σ^0 simulation runs (see Figure 3). The *Natural* experiment line differs from the *Irrigation* line by the activation of an irrigation module in Noah-MP, and both are subjected to the calibration algorithms described in Section 2.5. The *Natural* line was used as a diagnostic experiment against which to compare *Irrigation*, which, according to our initial hypothesis, should minimize the impact of the irrigation signal contained in the σ^0 observations on WCM parameters. As a first step, a model spin up was performed, starting in January 1982 and ending in December 2014. Then, a study period from January 2015 to December 2019 was selected for the different model runs based on the availability of the processed Sentinel-1 σ^0 and reference irrigation data (see Sections 2.1 and 2.2). Daily surface model and irrigation outputs were produced. Considering that the main source of irrigation in the Po river valley is related to surface water abstraction, the sprinkler irrigation scheme did not account for groundwater withdrawals (see Nie et al., 2018).

The A, B, C, and D parameters of the WCM (see section 2.4) were fitted for each grid cell based on separately to Sentinel-1 σ^0 VV and VH observations separately, during the period January 2017 - December 2019. Following previous literature (Lievens et al., 2017b; De Lannoy et al., 2014; De Lannoy et al., 2013), we performed a grid cell-based calibration to account for the spatial variability in the simulated and observed σ^0 signals that stems from specific features within the observed footprints as well as from the soil and vegetation parameterization of Noah-MP. Both the calibration using the SSE with prior constraint (Bayesian J) and the KGE were applied to the *Natural* and *Irrigation* runs providing eight different experiments named J -VV *Natural*, J -VH *Natural*, J -VV *Irrigation*, J -VH *Irrigation*, KGE -VV *Natural*, KGE -VH *Natural*, KGE -VV *Irrigation* and KGE -VH *Irrigation*.

Lower and upper boundaries as well as prior guess values of the WCM parameters were defined based on the work of Lievens et al. (2017b) and on a sensitivity analysis (not shown here). The selected values are displayed in Table 1. Finally, it should be noted that all the calibration experiments were realized by considering daily values of σ^0 simulations and observations.

Table 1: Lower boundaries (LB), upper boundaries (UB), and prior guess values of the WCM parameters for both VV and VH polarization

	A-VV[-]	A-VH[-]	B-VV[-]	B-VH[-]	C-VV[dB]	C-VH[dB]	D-VV[dB/m ³ /m ³]	D-VH[dB/m ³ /m ³]

400

401 2.7 Noah-MP LSM and WCM evaluations

402 The validation aims at i) evaluating the performance of Noah-MP in simulating irrigation, soil moisture, and vegetation and
403 the ability of the WCM to simulate radar σ^0 , and ii) unveiling the information about irrigation contained in Sentinel-1 radar σ^0
404 in order to assess its potential to improve both soil moisture and vegetation representation within Noah-MP.

405 ~~The evaluation was carried out on both on the regional scale (i.e., over the entire study area) and on the two selected sites,~~
406 ~~Faenza (small-district scale) and Budrio and Faenza, (plot scale), where irrigation data were available. Considering the lack of~~
407 ~~benchmark data for irrigation evaluation (Foster et al., 2020) we decided to use in situ data for the small Budrio fields spatial~~
408 ~~scale (i.e., 0.45-0.49 Ha) even though model simulations are made at a much coarser resolution (i.e., ~1 km). We are aware that~~
409 ~~differences in spatial scale can increase the uncertainty of our evaluation, but 0.01° LSM spatial resolution is still a good~~
410 ~~compromise for an analysis at regional, small-district and plot scale. Additionally, limitations are partly reduced by the low~~
411 ~~chance of including non-irrigated fields within the 1 km LIS grid cells within the Po River Valley, as the latter is almost entirely~~
412 ~~irrigated (Salmon et al., 2015).~~ We compared Noah-MP (with and without using the irrigation module) SSM and LAI
413 simulations with satellite SSM from ASCAT and SMAP, and LAI from PROBA-V, respectively, during the period 2015-2019.
414 Furthermore, these land surface simulations were compared to Sentinel-1 σ^0 to understand how much of the SSM and LAI
415 signal was captured by Sentinel-1.

416 As the irrigation timing is often driven by the stakeholders' turns to withdraw water and by water availability rather than by
417 the conditions of the soil and crops themselves, the comparisons between simulated SSM and satellite SSM were carried out
418 by aggregating the two variables over a bi-weekly time window. On the other hand, the LAI from Noah-MP was aggregated
419 to ten-daily values in order to match the dekadal PROBA-V LAI values. We used the Pearson-R for SSM and LAI evaluation.
420 ~~For LAI, we also considered~~For SSM, we also computed the Root Mean Square Error (RMSE), calculated considering the
421 ~~original temporal resolution of the satellite products, while for LAI, we also tested the ratio bias, i.e., the ratio between the~~
422 ~~long-term mean of the simulations and the long-term mean of observations. This~~In particular, this additional score ~~for LAI~~
423 was used to provide a further evaluation of the ability of the Noah-MP to simulate crop phenology during the irrigated vs non-
424 irrigated periods so as to not rely solely on the evaluation of temporal dynamics, which, due to the uncertainty in the Noah-
425 MP crop type parameterization, could be affected by time shifts in the LAI climatology. This parameterization uncertainty
426 comes from the lack of knowledge of the spatial crop type information and is difficult to be reduced without additional
427 information. Our assumption is that radar σ^0 assimilation can also correct for this with future data assimilation.
428 Following Vreugdenhil et al. (2018) and Vreugdenhil et al. (2020), Noah-MP LAI and PROBA-V LAI were also compared
429 with the Sentinel-1 σ^0 VH/ σ^0 VV cross ratio (CR), which was demonstrated to have a high agreement with the vegetation
430 signal. Though the σ^0 VH was demonstrated to increase with the vegetation signal (Macelloni et al., 2001), the CR will be

431 more sensitive to vegetation changes as the ratio is less sensitive to changes in soil moisture and soil-vegetation interaction
432 (Veloso et al., 2017; Vreugdenhil et al., 2020).

433 To evaluate WCM simulations, we used bi-weekly values of σ^0 simulations and observations considering a two-years period
434 independent from the calibration period: 2015-2016. Statistical metrics such as grid-based temporal Pearson-R, KGE, and bias
435 were calculated between Sentinel-1 σ^0 and calibrated WCM simulations. The analysis of the parameters was restricted to the
436 cropland area as no difference between our experiment lines exists over other land cover types (i.e., the irrigation module is
437 active only over grid points classified as crop).

438 **3 RESULTS**

439 **3.1 Noah MP regional evaluation**

440 Figure 4 shows maps of the Pearson-R between bi-weekly Noah-MP SSM *Natural* and *Irrigation* simulations and bi-weekly
441 ASCAT and SMAP L2 SSM retrievals, respectively, for April 2015 to December 2019. The Noah-MP SSM *Irrigation* run
442 provides a higher agreement with both satellite SSM data sets compared to the *Natural* run. Indeed, the median Pearson-R
443 between SMAP L2 SSM and Noah-MP SSM increases from 0.68 to 0.73, for the *Natural* run (Figure 4a) and the *Irrigation*
444 run (Figure 4b), respectively. A similar improvement can be observed considering the ASCAT reference SSM, with an
445 improvement in the median Pearson-R of 0.08 when irrigation is activated in the model (from 0.7 to 0.78; Figure 4e). Areas
446 characterized by higher correlation when irrigation is simulated are represented in blue in the Pearson correlation difference
447 map of Figure 4f (obtained by subtracting the map in Figure 4d from the map in Figure 4e). Almost all cropland areas are
448 characterized by a higher agreement between observations and simulations for the *Irrigation run*. Note that for the evaluation
449 of Noah-MP against SMAP, we relaxed retrieval quality flags, which would otherwise mask out almost the entire study area.
450 The Supplementary material (Figure S2) shows the coverage when using the recommended quality flags. Results in Figure 4
451 were confirmed by analyzing the RMSE between satellite SSM products and Noah-MP simulations for both the *Natural* and
452 *Irrigation* runs, after rescaling them based on their mean and standard deviation, because SSM retrievals and SSM simulations
453 do not have the same units. Results are displayed in Figure S3 of the Supplementary material and show, for both the satellite
454 products, a general reduction in RMSE when compared with the *Irrigation* run. An improvement in performances can be
455 observed over the entire cropland area, in particular over the central triangle feature where sandy-loam soil texture is present
456 and where, consequently, more irrigation is simulated in the model due to the higher permeability of the soil.

457 The evaluation of the LAI simulation was limited to the regional scale analysis due to a lack of in situ vegetation data over the
458 selected test sites. The comparison between dekadal values of Noah-MP LAI, from both model runs, and the PROBA-V LAI
459 product was carried out over the reference period January 2015 to October 2019 using the temporal Pearson-R and the ratio
460 bias, shown in Figure 5.

461 Figure 5a and 5b show that the Pearson-R for vegetation has a lower median value of 0.67 when irrigation is simulated in
462 Noah-MP, whereas this value equals 0.72 for the *Natural* run. The difference between the two Pearson-R maps is shown in
463 Figure 5c, providing evidence of the areas facing a deterioration of the performance in terms of Pearson-R related to the
464 *Irrigation* run. This deterioration is particularly strong over cropland areas south to the Po river (red colour) while the northern
465 area also shows grid cells where the performance improves (blue colour).

466 By contrast, the ratio bias evaluation score (Figures 5d, 5e, 5f) highlights an improvement in long-term mean vegetation
467 simulations when irrigation is included (Figure 5e). Here the optimal condition is represented by a ratio bias equal to 1 when
468 the mean of the simulated LAI is equal to the mean of the observed LAI. In this context, Figure 5d displays ratio bias values
469 lower than one over a large central triangle-shaped cropland area and median ratio bias value of 0.73, highlighting an
470 underestimation of the LAI simulation related to the *Natural* run. Conversely, Figure 5e shows ratio bias values close to one
471 when irrigation is simulated over an extended cropland area and a median bias value of 0.99. The improvement given by the
472 *Irrigation* run is emphasized in Figure 5f where the histograms of the ratio bias distributions related to both model runs show
473 the higher performance of the *Irrigation* run (red) compared to the *Natural* run (blue) for which the distribution is more skewed
474 to the zero value.

475 **3.2 Noah MP site evaluation**

476 The Noah-MP SSM was evaluated at the Budrio test site field 2 (Figure 1a), using the daily reference PGR SM for the year
477 2017. Comparisons between the SSM simulations of the *Natural* and *Irrigation* runs with in situ PGR SM are shown in Figure
478 6a, while daily observed irrigation and rainfall data are compared with daily irrigation simulations in Figure 6b. Soil moisture
479 data are plotted at their original temporal resolution (i.e., daily) to illustrate an issue related to the irrigation timing: SSM
480 simulations in Figure 6a show the ability of the sprinkler irrigation scheme to simulate irrigation in the summer season, but
481 there is an inevitable problem in reproducing the correct timing and magnitude of irrigation. Indeed, the total amount of
482 simulated irrigation is 604 mm for the 2017 summer season, which overestimates the total amount of observed irrigation, being
483 349.5 mm. Furthermore, the model simulations not only miss irrigation, but also suffer from erroneous precipitation input,
484 such as on the 11th of July 2017, where the observed precipitation event in the growing season is not found in the model SSM
485 simulations. In any case, bi-weekly Pearson-R between simulated SSM and in situ PGR SM are higher for the *Irrigation* run
486 than for the *Natural* run (0.54 vs 0.42) suggesting the benefit in activating irrigation.

487 For the Budrio field 1 test site (Figure 1a), two summer seasons of irrigation data were available. To assess the irrigation
488 information contained in Sentinel-1 σ^0 observations (and the potential added value for a forthcoming DA experiment) we
489 compared bi-weekly values of Sentinel-1 σ^0 VV and VH with SSM estimates from both the *Natural* run and *Irrigation* run
490 (Figure 7a) for this site. Although the σ^0 VV is generally used to retrieve SSM (Wagner et al., 2013; Gruber et al., 2013; Bauer-
491 Marschallinger et al., 2018), data at both polarizations were analyzed in order to understand the soil contribution contained in
492 the two signals. Information related to the irrigation periods are shown in Figure 7c, where irrigation observations and irrigation

493 simulations from Noah-MP are compared. Figure 7a indicates that the SSM simulations are better reflected in the Sentinel-1
494 σ^0 VV than σ^0 VH data, particularly when irrigation is simulated (orange line). The SSM estimates from the *Natural* run (light
495 blue line) agree poorly with the Sentinel-1 data, with Pearson-R values equal to 0.1432 and -0.131 for the σ^0 VV (blue dots)
496 and σ^0 VH (cyan dots), respectively. When irrigation is simulated, the σ^0 VV data better follow the modelled SSM signal
497 (Pearson-R of 0.3653) especially during the summer irrigation season when the backscatter signal remains higher and stable.
498 On the other hand, σ^0 VH seems to provide poor performances also when irrigation is simulated, with a Pearson-R value equal
499 to -0.03-06, confirming findings by Baghdadi et al. (2017) which highlighted how the use of VH alone to retrieve SSM is
500 suboptimal when vegetation cover is well developed.

501 In Figure 7b, the Sentinel-1 σ^0 CR (VH/VV) is compared with Noah-MP LAI from the *Natural* run (light-blue line) and
502 *Irrigation* run (orange line). The performance in terms of Pearson-R decreases from 0.876 to 0.5465, when the irrigation is
503 simulated. This is due to a time shift of the Noah-MP LAI growing season in the *Irrigation* run. PROBA-V LAI (in green) was
504 additionally compared with the Sentinel-1 CR (blue dots) showing a Pearson-R of 0.8884. The higher agreement between the
505 RS products (Sentinel-1 and PROBA-V) highlights the strong relation between the σ^0 CR and the vegetation signal, suggesting
506 a potential benefit of Sentinel-1 assimilation to correct the simulated vegetation phenology.

507 Finally, Figure 7c shows a comparison between 15-days accumulated mm of simulated irrigation (in orange) and observed
508 irrigation (in green). The Pearson-R is equal to 0.77, indicating that the sprinkler irrigation scheme can provide acceptable
509 irrigation estimates at this temporal resolution though absolute irrigation amounts are overestimated.

510 **3.3 WCM calibration**

511 The WCM parameters A and B (vegetation parameters), and C and D (soil parameters) were calibrated for each grid cell
512 separately during the reference period January 2017 to December 2019 (Figure 3), using daily σ^0 simulations and observations.
513 The calibrated parameters related to the entire study area for each of the eight experiments are shown in Figure 8 where the
514 blue left parts of the violin plots identify experiments of the *Natural* run, while the orange right parts of the violin plots are
515 related to the *Irrigation* run.

516 Generally, the *J*-calibration provides parameter distributions closer around their prior guess as compared to the *KGE*-
517 calibration for which the distributions are often multimodal, especially for the C and D parameters (i.e., Figure 8d, 8h). This
518 is due to the prior parameter penalty, which is included in the Bayesian solution but not in the *KGE*. In general, the calibration
519 of the two functions using the *Natural* run provides wider distributions between lower and upper boundaries for the A
520 vegetation parameter with a high number of grid cells characterized by A-values higher than 0.1 (see *KGE-VV Natural* and *J*-
521 *VV Natural* experiments in Figures 8a and 8e respectively). Conversely, the *Irrigation* run provides A distributions more
522 skewed to the lower boundary (being also the guess value in each calibration experiment), with a smaller number of grid cells
523 characterized by high A values compared to the *Natural* run. In a preliminary sensitivity study (not shown), we observed that
524 high values of the vegetation parameters A and B, as obtained for the *Natural* run, have the tendency to generate high peaks

525 in the simulated σ^0 during the growing season. Indeed, in the summer, the SSM *Natural* signal is low and not consistent with
526 the Sentinel-1 σ^0 , which observes irrigation. In order to follow the temporal dynamics of the Sentinel-1 σ^0 , the calibration
527 algorithms attribute a relatively higher weight (higher A values) to the LAI than to SSM to compensate for the underestimated
528 SSM in the *Natural* run. By contrast, the *Irrigation* run provides vegetation parameter distributions more skewed to the lower
529 boundaries (see also Section 3.4.2). ~~Also the~~The C and D parameter distributions show more realistic values using *Irrigation*
530 ~~run input data, and feature a better sensitivity of σ^0 to soil moisture dynamics using the *Irrigation* run input data, which is the~~
531 ~~expected behaviour considering that they describe the σ^0_{soil} .~~ This is true especially when using the *J* cost function (see parameters
532 distributions for the *J-VV Natural* and for the *J-VV Irrigation* experiments in Figures 8g and 8h), which results in more
533 ~~uniform spread in the~~ calibrated C and D distributions for the *Irrigation* simulations (esp. especially in VV polarization),
534 whereas the mode of the C and D parameter distributions for the *Natural* experiments is more shifted to the upper and lower
535 boundaries, respectively.

536 ~~The~~Figure 9 shows the spatial pattern of the parameters over the study area to better understand the differences between the
537 *Natural* and *Irrigation* calibration runs. We found a connection between the WCM parameters distribution and model
538 parameters, in particular with the HWSO soil texture map (shown in Figure 2). For both the *J-VV Natural* and *J-VV Irrigation*
539 experiments, the activation of the irrigation scheme reduces the dependency of the vegetation-related parameters A and B on
540 soil texture (Figures 9a-b for the *J-VV Natural* and Figures 9e-f for the *J-VV Irrigation* experiment). This is also shown in the
541 parameter maps of the *KGE* calibration experiments (Figure S5 in the Supplementary material). Additionally, the activation of
542 the irrigation scheme, more realistically, shifts the soil texture dependency towards the soil parameters C and D (Figures 9g
543 and 9h), highlighting another important reason for simulating irrigation.

544 ~~Finally, the~~ different polarization experiments generally provided similar distributions for the vegetation A and B parameters
545 and the D soil parameter. The largest differences between the VV and VH polarizations are identified for the C parameter
546 distributions. This is due to the lower σ^0 signal associated with the VH polarization. Indeed, Figure 8c and 8g are characterized
547 by higher values of the C in VV polarization, as compared to the distributions for VH polarization in Figures 8k and 8o. In the
548 latter, the C-VH distributions are generally more skewed to the lower boundary of the parameters, with median values closer
549 to the defined guess parameter value.

550 3.4 WCM evaluation

551 3.4.1 Regional evaluation

552 The regional evaluation of the calibration experiments was carried out during the period January 2015 to December 2016 for
553 agricultural areas within the study domain (almost 15,000 km²), by comparing bi-weekly σ^0 simulations with Sentinel-1 σ^0 in
554 terms of Pearson-R, KGE, and bias. The distribution of the evaluation metrics for the eight experiments is shown in Figure
555 9.10. A comparison of the metrics for the *Irrigation* and *Natural* runs confirms better results when irrigation is activated, with
556 violin plots skewed towards more positive values for both KGE and Pearson-R. When stratified by the cost function, the

Pearson-R distribution in Figure 9a10a-d indicates slightly higher performance for the *KGE* (Figures 9a10a and 9e10c) than for *J* (Figure 9b10b and 9d10d). In terms of the *KGE* score, simulations are naturally closer to the observations when the *KGE* cost function is used. On the other hand, in terms of bias, generally better performances are found when the Bayesian solution is used (Figures 9i10i-l). The latter is particularly evident for the VH polarization when comparing the *KGE-VH* and *J-VH* experiments (Figure 9k10k and 9l10l).

The VH simulations exhibit a better performance in the *Irrigation* run than VV simulations (Figure 9e10c-d and Figure 9a10a-b). Indeed, considering all the statistical scores, the VV polarization is characterized by more similar distributions between the *Natural* and *Irrigation* run for both cost functions. This suggests a higher sensitivity of the VH polarization to the change of vegetation introduced by irrigation, confirming the Sentinel-1 σ^0 VH to be strongly influenced by irrigation as witnessed by the larger score improvement obtained for the calibration experiments *KGE-VH Irrigation* (Figure 9g10g) and *J-VH Irrigation* (Figure 9h10h), compared to the *Natural* runs experiments.

In summary, i) VH polarization is more sensitive to the change in the cost function and input data (*Irrigation* or *Natural* run) than VV polarization likely due to its higher sensitivity to vegetation change (Vreugdenhil et al., 2018; Macelloni et al. 2001) which, in the area, is related to the crop development after irrigation, ii) the combination of *J* with activation of the irrigation scheme is able to provide the best unbiased estimates of simulated σ^0 for both VV and VH (*J-VV Irrigation* and *J-VH irrigation* experiments) at the price of generally lower correlations (compared to the *KGE* cost function). This is, however, beneficial for DA as it minimizes the chance of potential error cross correlation between model estimates and observations. Indeed, the match of the temporal dynamic of the signals induced by the correlation term is stronger in the *KGE* than in *J*, which additionally includes a parameter constraint. The higher weight of the correlation in the *KGE* cost function can negatively impact the parameter calibration even when irrigation is turned on in Noah-MP because the simulated irrigation applications are in general not temporally consistent with those seen by Sentinel-1 (see Figure 6).

3.4.2 In situ evaluation

The WCM simulations are further analysed in detail at the Faenza test site (specifically for the San Silvestro field), because it has a larger extent than the Budrio site (see Figure 1), although the same overall conclusions were found for Budrio. Figure 1011 shows simulated and observed σ^0 time series for the different experiments highlighted in Figure 3, and Table 32 summarizes the statistics (i.e., Pearson-R, *KGE* and bias) of each experiment.

The agreement between simulated and observed σ^0 measured by the Pearson-R and *KGE* in Table 32 generally gives better performances after calibration with the *KGE* cost function than with the *J* cost function, ~~except. An example is in the higher correlations found for the *KGE-VH Irrigation* experiment in terms of Pearson-R (Figure 10b). For the latter, we can observe a Pearson-R of 0.33 against 0.37 for~~as compared to the *J-VH Irrigation* (Figure 10d Figures 11b and 11d respectively). On the other hand, in terms of bias the cost function *J* significantly outperforms the calibration with *KGE* in all experiments with surprisingly comparable values between *Natural* and *Irrigation* runs (Table 2).

589 One undesirable feature of *Natural* runs is the presence of high σ^0 peaks during the summer, clearly detectable over the Faenza
590 test site, especially in both VV and the VH polarization, which are less evident in the *Irrigation* run (see Figure ~~10b~~11b and
591 ~~10d~~11d). A similar behaviour was found for Budrio (not shown). These peaks are likely attributed to the poor estimation of
592 model vegetation parameter values, previously discussed in section 3.3, when the WCM attempts to compensate for bias in
593 SSM and vegetation input, i.e., input that is not consistent with observations over irrigated areas. This is particularly true for
594 the *KGE* calibration, which does not use a prior parameter constraint. In contrast, the *J* calibration still provides reasonable σ^0
595 simulations that are closer to the ones of the *Irrigation* run due to the Bayesian technique itself.

596 **Table 2: Results of the site WCM evaluation considering the test site Faenza San Silvestro for each WCM experiment**

597

598 4 DISCUSSION

599 4.1 Noah-MP irrigation modelling

600 The Noah-MP LSM, used as input for the WCM calibration, was evaluated in two configurations, either with a sprinkler
601 irrigation scheme activated or without irrigation (i.e., *Irrigation* run and *Natural* run). Although not all of the Po river valley
602 is irrigated by sprinkler systems, it most likely still leads to more realistic LSM simulations than not considering irrigation at
603 all.

604 The main limitation found in the irrigation simulations was related to the irrigation timing and magnitude that was inconsistent
605 with observations. Although this finding is based on only a single study site, it is very likely that it is a widespread issue within
606 the study area for several reasons. In LSMs, the irrigation application is driven by the RZSM availability and consequently by
607 the soil type and the rooting depth parametrizations. Moreover, it is also influenced by the accuracy of the meteorological
608 forcings (especially precipitation, Reichle et al. 2017) which can determine errors in the soil moisture representation. The main
609 reason, however, is likely that irrigation is often the result of subjective farmer decisions rather than objective rules based on
610 the soil state and crop conditions. In theory, the irrigation timing issue could be partly solved by using temporally consistent
611 high-resolution crop maps which should provide a more realistic information of crop phenology and rooting depth. However,
612 in practice, this is unfeasible over many areas of the world given the absence of this information on a large scale. Also, given

613 that irrigation applications are mainly linked to unmodelled processes like rotation schedules for farmers to withdraw water,
614 the correct simulation of the timing can be unsolvable when using models only.

615 Despite the potential problems related to the unrealistic assumptions in the simulation of irrigation, our results demonstrated
616 that even the use of simple irrigation schemes within Noah-MP can be beneficial. In the regional evaluation, SSM simulations
617 of the *Natural* and *Irrigation* runs were compared with RS SSM from SMAP and ASCAT (Figure 4) on a bi-weekly temporal
618 scale. For both products, we found large improvements in temporal Pearson-R when irrigation was simulated, confirmed by a
619 decrease in the RMSE values over croplands, suggesting that the activation of irrigation modelling provides more realistic
620 SSM estimates. Our findings further confirm the potential of coarse resolution datasets for providing irrigation-related
621 information over intensively irrigated and relatively large agricultural areas, as was shown by Kumar et al. (2015a).

622 While the impact of irrigation was clear in terms of SSM, the regional evaluation of the simulated LAI against the PROBA-
623 V-based LAI provided contradicting results. In this case, the Pearson-R analysis suggested a deterioration of the Noah-MP
624 simulated LAI when irrigation was activated over the cropland area. We interpreted this correlation deterioration by the
625 absence of specific information about the crop phenology in the model parameterization. In practice, information about the
626 specific crop type is not available and the rooting depth is the sole parameter controlling water uptake from the soil layers.
627 Additionally, information on sowing and harvest periods are not included in the current version of Noah-MP, while irrigated
628 areas are defined based on a global dataset (Salmon et al., 2013) which can suffer accuracy limitations. Indeed, the absence of
629 annual dynamic information on irrigated fields, the unknown yearly variability of the crop types and the impact of the
630 meteorological conditions in the stakeholders decision process (i.e., sowing) make the simulation of Noah-MP prone to LAI
631 peak shifts, as compared to observations, when irrigation is simulated. Another important aspect affecting LAI simulations is
632 its sensitivity to root zone soil moisture, which might be more difficult to simulate than SSM during the irrigation season due
633 to larger impacts of the soil texture and transpiration processes along with the high frequency of the wetting and drying phases
634 caused by irrigation events. This results in a significant performance deterioration (often worse than LAI simulation not
635 including irrigation which are mainly driven by seasonality, see Figure 7). By contrast, irrigation modeling helps in reducing
636 the bias of the LAI simulated time series, which, in the cropland area, show a significant underestimation when irrigation is
637 not considered.

638 The limitations found in simulating LAI and vegetation by Noah-MP even when irrigation was simulated could potentially be
639 overcome by assimilating Sentinel-1 σ^0 data. To explore this potential, we compared the LAI from both model runs, and from
640 PROBA-V, with the observed Sentinel-1 σ^0 CR (VH/VV), which should provide information about the vegetation dynamics
641 (Vreugdenhil et al. 2018; Vreugdenhil et al. 2020). We found that the correlation between σ^0 CR and LAI from PROBA-V was
642 much higher than that between σ^0 CR and the simulated LAI by Noah-MP (see Figure 7) suggesting that Sentinel-1 σ^0 DA
643 could help in correcting poor LAI model simulations. Additionally, a higher correlation was found between the σ^0 VV
644 observations and the simulated SSM when irrigation was turned on than in the absence of irrigation, suggesting that the
645 assimilation of σ^0 VV could improve SSM where irrigation is poorly or not ~~modeled~~ modelled. On the other hand, considering
646 the low correlation between the VH signal and SSM in presence of vegetation (Baghdadi et al. 2017), and its close relation

647 with vegetation (Ferrazzoli et al., 1992; Macelloni et al., 2001), future data assimilation experiments will investigate the
648 contribution of VH and CR in improving LAI predictions and irrigation quantification.

649 Finally, by-weekly accumulated irrigation estimates in Figure 7 agree well with real irrigation applications, suggesting that the
650 large-scale LSM irrigation scheme is helpful for intensively irrigated areas. On the other hand, the poor soil and crop
651 parameterization along with other unknown parameters related to the irrigation management (e.g., the farmers can apply more
652 water than actually needed) can cause large biases in these irrigation simulations. Again, ingestion of radar backscatter data
653 could correct for unmodelled processes. More specifically, Sentinel-1 σ^0 could correct: (i) for the magnitude and timing of the
654 irrigation simulations; and (ii) for Noah-MP irrigation predictions over not irrigated regions.

655 **4.2 WCM backscatter simulation**

656 The purpose of the presented WCM observation operator calibration and evaluation was to optimize the parameters for the
657 future assimilation of the Sentinel-1 σ^0 VV and VH into Noah-MP. Such an optimization would ideally minimize the long-
658 term bias between the simulated and observed σ^0 signals. This can be achieved by calibrating the observation operator with
659 long-term observed σ^0 prior to data assimilation, but in this process, it is crucial to avoid potential error cross-correlation
660 between model observation predictions and observations. Furthermore, a good observation operator should not already
661 compensate for missing processes in the LSM by accepting effective, but unrealistic, optimized parameters, because it would
662 then lose its physically-based ability to accurately convert misfits between observations and simulations to LSM updates during
663 the data assimilation. ~~In this line, we considered~~

664 One way to avoid parameters compensation for erroneous LSM input into the WCM would be to use observed time series of
665 e.g. LAI. However, LAI products from different sensors have different biases themselves which can add bias to the σ^0
666 simulations, and more importantly, replacing simulated LAI or SSM with external datasets would undermine the possibility of
667 updating these variables in the future assimilation system. Based on that, we performed the WCM calibration considering SSM
668 and LAI model input from two different experiments: a *Natural* run and an *Irrigation* run, as well as two cost functions, a
669 Bayesian solution J and a KGE solution which resulted in four calibration experiments for each polarization (i.e., eight
670 calibration experiments in total).

671 The calibration experiments using simulations from the *Natural* run as input showed a limited performance and provided
672 presumably bad vegetation parameter estimates which resulted in unrealistic peaks in the simulated σ^0 during the summer,
673 when driven by higher modelled LAI during this period. The inclusion of the irrigation within Noah-MP was very beneficial
674 for all the calibration experiments helping in reducing the bias and increasing the correlation with Sentinel-1 σ^0 as well as
675 removing the anomalous σ^0 increase during warm periods especially for the KGE -based calibration. This corroborates our
676 initial hypothesis that, over intensively irrigated areas, the simulation of irrigation is a mandatory task for an optimal calibration
677 of the WCM. Irrigation modeling, even if only done approximately and perhaps with inaccurate timing, reduces obvious land
678 surface (soil moisture, vegetation) bias and avoids that the WCM needs to compensate for this bias.

679 Our results show overall higher performance in terms of KGE and Pearson-R scores for the *KGE*-based calibration, whereas
680 the long-term bias was better reduced for the *J*-based calibration, which is beneficial in anticipation of future DA. This is
681 because in the *J* cost function i) a target accuracy term which takes into account also the Sentinel-1 observations error is
682 present; and, ii) a parameter deviation penalty based on the prior parameters constraints is used, which avoid parameters to
683 largely deviate to their prior values.

684 In terms of polarization, we found σ^0 VH simulations much more sensitive to the inclusion of the irrigation (vs non inclusion)
685 in Noah-MP, suggesting that observed σ^0 VH might also contain much more information about irrigation (via the influence of
686 the vegetation change due to irrigation) than that contained in σ^0 VV which is normally used for SSM retrieval (Vreugdenhil
687 et al. 2020). We believe that the cause of this is related to a comparatively larger σ^0 of vegetation with respect to that of the
688 soil when the crops are well developed. This was also corroborated by the better agreement between CR and LAI from PROBA-
689 V in one of the study sites mentioned above. Despite this, further investigations are required to confirm this hypothesis and
690 DA will certainly help to test this aspect.

691 5 CONCLUSIONS

692 With the specific focus on intensively irrigated land, the main objective of this work was to define the optimal calibration of
693 the WCM as observation operator for the future ingestion of Sentinel-1 backscatter into the Noah-MP LSM via DA. In this
694 context, we additionally aimed at: 1) unveiling strengths and limitations of irrigation simulation in LSMs from the perspective
695 of a calibrating the WCM; 2) identifying the potential irrigation-related information contained in the Sentinel-1 σ^0 observations
696 to improve soil moisture and vegetation states as well as irrigation estimates in a calibrated DA system.

697 To reach these objectives we coupled the Noah-MP with a sprinkler irrigation scheme within LIS and performed two different
698 simulation experiments, one with and one without irrigation (i.e., *Natural* and *Irrigation* runs). Moreover, we coupled a WCM
699 with Noah-MP and tested different calibration options to prepare for optimal, future, assimilation of σ^0 VV and VH to update
700 both soil moisture and vegetation states.

701 The main conclusions drawn from our evaluation are as follows:

- 702 • Over highly irrigated areas, the simulation of irrigation in LSMs helps to provide better soil moisture and vegetation
703 simulations which can be used with benefit as input for the WCM calibration. However, the performance of the
704 irrigation simulations is limited by the simplistic model parameterization of this human process and the necessity to
705 consider realistic and updated land cover information (e.g., crop types). This results in poor simulations of the
706 irrigation timing and quantities as well as vegetation dynamics.
- 707 • The Sentinel-1 σ^0 observations contain useful information about SSM and vegetation over highly irrigated areas. This
708 information can be exploited to overcome LSM deficiencies in simulating soil moisture and vegetation over highly
709 irrigated regions, e.g., when irrigation is unmodeled, or poorly modeled because of uncertainties due to crop types,

710 irrigation timing, and farmer agricultural practices. In particular, there is a high chance that the assimilation of
711 Sentinel-1 σ^0 can help in correcting LAI dynamics.

- 712 • The optimal assimilation of Sentinel-1 σ^0 into a LSM must rely upon a well calibrated WCM as observation operator
713 to provide unbiased σ^0 simulations with a minimal chance of having error cross-correlations between model and
714 observations, while ensuring a realistic operator controllability or realistic connection between observed signals and
715 land surface state variables. We demonstrated that calibrating the WCM with inclusion of irrigation modeling
716 consistently led to a better agreement with Sentinel-1 σ^0 . The modeling of irrigation in the LSM simulations, even if
717 not done optimally, avoids that the WCM calibration compensates for LSM biases.
- 718 • We demonstrated that the WCM calibration with a Bayesian cost function, including a prior parameter constraint,
719 provides the optimal WCM parameters, able to generate the lowest bias in the σ^0 simulations for both VV and VH.
720 Although slightly higher correlations are obtained when using a *KGE* cost function, unbiased estimates are
721 particularly beneficial for DA as this minimizes the chance of potential error cross-correlation between model
722 estimates and observations.

723 This study improves the understanding of the LSM limitations in simulating irrigation and highlights the information content
724 in Sentinel-1 σ^0 data. A natural follow up of this study is the assimilation of σ^0 observations within Noah-MP which should
725 enforce our tested evidence and provide new insights for a more realistic description of the water and carbon cycles over
726 irrigated areas.

727 **ACKNOWLEDGEMENT**

728 The authors would like to thank the European Space Agency (ESA) for the funding support as part of the IRRIGATION+
729 project (contract n. 4000129870/20/I-NB). For details please visit <https://esairrigationplus.org/>. Additionally, the authors want
730 to acknowledge the Vlaams Supercomputer Centrum (VSC) High Performance Computing (HPC) for providing the
731 computational resources needed to realize this study (<https://www.vscenrum.be/>). Alexander Gruber has received funding
732 from the Research Foundation Flanders (FWO-1224320N and FWO-1530019N).

Figure 3: Flow chart of the experimental setup used in this study to calibrate the WCM σ^0 signal. A *Natural* and an *Irrigation* experimental line was performed coupling either Noah-MP *Natural* or *Irrigation* simulations with the WCM. For each experimental line σ^0 simulations are driven by the Sentinel-1 signal using two different cost functions (*J* and *KGE*) in order to provide eight different calibration experiments.

Figure 8: Split violin distributions of the calibrated parameters over the entire study area for the eight calibration experiments. For both the *Natural* (blue) and *Irrigation* (orange) experiments, the distributions are shown for the A, B, C, and D parameters, (a, b, c, d) using the *KGE* objective function for VV polarization, (e, f, g, h) *J* objective function for VV polarization, (i, j, k, l) *KGE* objective function for VH polarization, and (m, n, o, p) *J* objective function for VH polarization. Note that the areas under the histograms on both left and right sides of the violins are automatically scaled for optimizing the visualization.

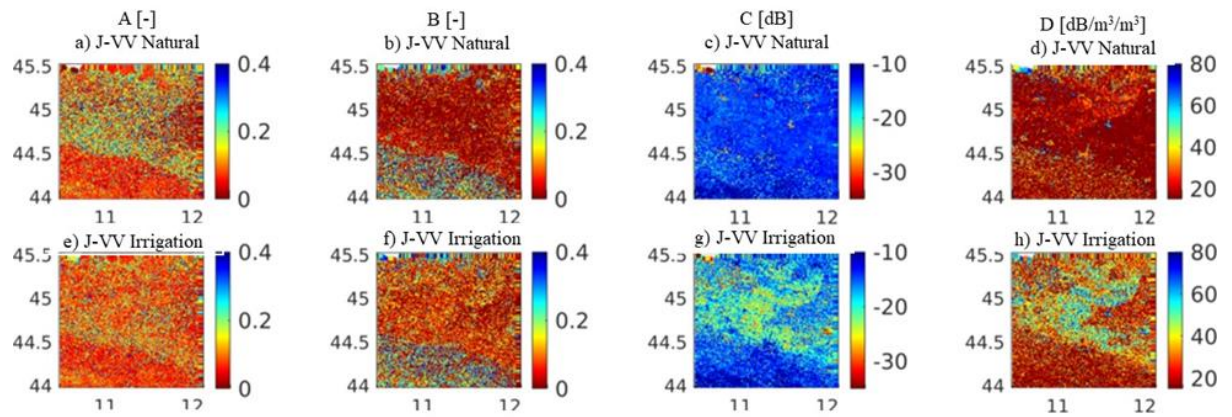

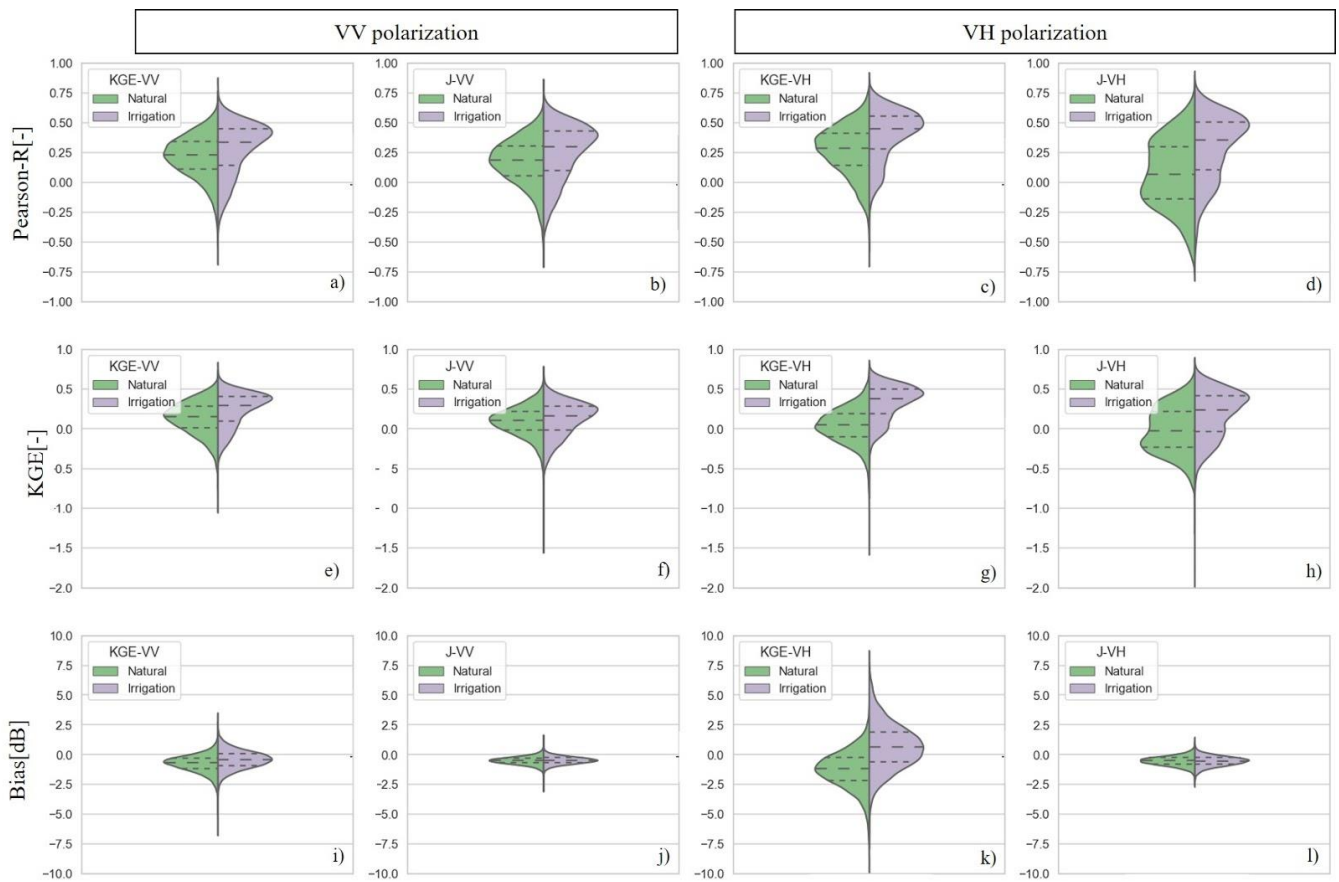

Figure 9

Figure 9. Maps of: a) A parameter; b) B parameter; c) C parameter; d) D parameter for the J-VV Natural calibration experiment. Maps of: e) A parameter; f) B parameter; g) C parameter; h) D parameter for the J-VV Irrigation calibration experiment.

Figure 10: Split violin distributions of (a, b, c, d) Pearson-R, (e, f, g, h) KGE and (i, j, k, l) bias calculated between σ^e simulations and observations for the validation period, for all the calibration experiments and considering only the cropland areas, using simulations from the *Natural* run (left, green) and the *Irrigation* run (right, violet). The results are shown for VV (first two columns) and VH (right two columns), and alternating for both the calibration with a *J* and *KGE* cost function. Note that the areas under the histograms on both left and right sides of the violins are automatically scaled for optimizing the visualization.

Figure 1047: Comparisons between σ^0 observations (VV polarization in blue dots and VH polarization light blue dots) and simulations (VV polarization in red and VH polarization in green) in the Faenza San Silvestro field, after calibration with a *KGE* cost function for a) the *Natural* run, b) *Irrigation* run, and after calibration with the *J* cost function for c) the *Natural*, and d) *Irrigation* run.

1050

1051 **Code and Data availability.**

1052 Data from SMAP can be downloaded at https://nsidc.org/data/SPL2SMP_E/versions/4

1053 Data from ASCAT are available at the website <http://hsaf.meteoam.it/>

1054 The Sentinel-1 backscatter data processing was done using Google Earth Engine’s Python interface and including standard
1055 processing techniques

1056 Data from PROBA-V are available at <https://land.copernicus.eu/global/>

1057 MERRA-2 data are available at MDISC, managed by the NASA Goddard Earth Sciences (GES) Data and Information Services
1058 Center (DISC, <https://disc.gsfc.nasa.gov/datasets?project=MERRA-2>)

1059 LIS input and general parameters tables are provided at https://portal.nccs.nasa.gov/lisdata_pub/data/

1060 In situ data are available under request to the original providers.

1061

1062 **Author contributions:** Sara Modanesi designed, coordinated the study and made the analyses. Christian Massari, Gabrielle
1063 De Lannoy and Alexander Gruber designed, coordinated and helped in the data analysis and interpretation. Hans Lievens,
1064 Angelica Tarpanelli and Renato Morbidelli helped in the result interpretation and data processing and collection. All authors
1065 contributed to the editing of the manuscript.

1066

1067 **Competing interests.** The authors declare no competing interest

Supplementary Material

Table S1: The UMD-AVHRR 14 classes (Map code) classification (on the left) was used to reclassify the 23 classes-based PROBA-V LC map. On the right side of the table the PROBA-V land uses are displayed, together with the map codes for each land use. Additionally, the number of pixels, related to each class are shown, together with the UMD-AVHRR reclassification map code.
