13 **Abstract.** Worldwide, the amount of water used for agricultural purposes is rising and the quantification of irrigation is
14 becoming a crucial topic. Because of the limited availability of in situ observations, an increasing number of studies is focusing
15 on the synergistic use of models and satellite data to detect and quantify irrigation. The parameterization of irrigation in large
16 scale Land Surface Models (LSM) is improving, but it is still hampered by the lack of information about dynamic crop rotations
17 or the extent of irrigated areas, and the mostly unknown timing and amount of irrigation. On the other hand, remote sensing
18 observations offer an opportunity to fill this gap as they are directly affected by, and hence potentially able to detect, irrigation.
19 Therefore, combining LSMs and satellite information through data assimilation can offer the optimal way to quantify the water
20 used for irrigation.

21 This work represents the first and necessary step towards building a reliable LSM data assimilation system which, in future
22 analysis, will investigate the potential of high-resolution radar backscatter observations from Sentinel-1 to improve irrigation
23 quantification. Specifically, the aim of this study is to couple the Noah-MP LSM running within the NASA Land Information
24 System (LIS), with a backscatter observation operator for simulating unbiased backscatter predictions over irrigated lands. In
25 this context, we first tested how well modelled Surface Soil Moisture (SSM) and vegetation estimates, with or without
26 irrigation simulation, are able to capture the signal of aggregated 1-km Sentinel-1 backscatter observations over the Po river
27 Valley, an important agricultural area in Northern Italy. Next, Sentinel-1 backscatter observations, together with simulated
28 SSM and LAI, were used to optimize a Water Cloud Model (WCM) which will represent the observation operator in future
29 data assimilation experiments. The WCM was calibrated with and without an irrigation scheme in Noah-MP, and considering
30 two different cost functions. Results demonstrate that using an irrigation scheme provides a better calibration of the WCM,
31 even if the simulated irrigation estimates are inaccurate. The Bayesian optimization is shown to result in the best unbiased

32 calibrated system, with minimal chance of having error cross-correlations between the model and observations. Our time series
33 analysis further confirms that Sentinel-1 is able to track the impact of human activities on the water cycle, highlighting its
34 potential to improve irrigation, soil moisture, and vegetation estimates via future data assimilation.

35 **1 INTRODUCTION**

36 Over the last century, the global water withdrawal grew 1.7 times faster than the population (FAO, 2006). This aggravates the
37 concern over the sustainability of water use as demand for agricultural uses continues to increase (Foley et al., 2011; FAO
38 AQUASTAT http://www.fao.org/nr/water/aquastat/water_use/index.stm, last access 20 May 2021). The strong impact of
39 irrigation on the global water budget is highlighted by many studies and it has been estimated that about 87% of the global fresh
40 water withdrawals have been used for agriculture (Douglas et al., 2009). Accordingly, the quantification of irrigation on a
41 regional to global scale has become a hot research topic.

42 Correctly quantifying irrigation in Earth system models can serve two purposes. On the one hand, it can help improve water
43 management (Le Page et al., 2020, Bretreger et al., 2020), on the other hand, it allows to quantitatively assess its effects on the
44 terrestrial water, carbon and energy cycles (Haddeland et al., 2007; Breña-Naranjo et al., 2014; Hu et al., 2016; Qian et al. 2020).
45 Indeed, results of large-scale irrigation studies using land surface models (LSMs) have demonstrated that irrigation increases
46 soil moisture and evapotranspiration (ET), and consequently latent heat flux with a decrease in sensible heat flux (i.e., Badger
47 & Dirmeyer, 2015; Lawston et al., 2015; Ozdogan et al., 2010b).

48 Despite the significant impact of irrigation on the water and energy cycles, its simulation within LSMs is not yet common
49 practice (Giroto et al., 2017). In earlier studies, attempts to simulate irrigation in LSMs have relied on different
50 parameterizations of well-known irrigation systems (like sprinkler, flood, and drip systems; Ozdogan et al., 2010b; Evans and
51 Zaitchik, 2008), making simplifying assumptions. For instance, in Ozdogan et al. (2010b) irrigation water is not withdrawn from
52 a source (such as a river) but instead added as fictitious rainfall. In contrast, Nie et al. (2018) accounted for source water
53 partitioning, albeit only partially, by considering groundwater irrigation. Irrigation is normally applied when soil moisture drops
54 below a user-defined threshold (Ozdogan et al. 2010b), typically dependent on the soil properties obtained via soil texture maps.
55 Moreover, LSMs equipped with irrigation schemes need to be provided with auxiliary information about crop types and whether
56 or not the crops are irrigated. This is because different crop types are characterized by different rooting depths, which means
57 they require more or less water to restore root zone field capacity. This information is normally gathered from static maps derived
58 from statistical analysis and/or remote sensing (Ozdogan et al., 2010b; Monfreda et al., 2008; Salmon et al., 2015) collected
59 during specific historical periods which are normally different to the desired period of analysis. It is thus clear that the modelling
60 of irrigation is subject to many simplifying assumptions, which span from neglecting the year-to-year crop variability and the
61 irrigation system used to the definition of irrigation application times based on water availability and crop conditions rather than
62 actual farmer decisions.

63 Remote sensing (RS) technologies offer the opportunity to observe directly the Earth surface and its changes, and hence are
64 potentially able to monitor irrigated lands worldwide (Ambika et al., 2016; Gao et al., 2018; Bousbih et al., 2018; Bazzi et al.,
65 2019; Le Page et al., 2020; Dari et al., 2020). In the last decade, some authors used visible and near infrared RS observations
66 jointly with in situ data collected from inventories to map areas equipped for irrigation (Ambika et al., 2016; Ozdogan & Gutman,
67 2008). Kumar et al. (2015a) were the first to propose the use of coarse resolution satellite microwave (MW) sensors to detect
68 irrigation. The authors compared different coarse-scale active and passive MW surface soil moisture (SSM) retrievals with SSM
69 simulations from the Noah LSM (version 3.3; Ek et al., 2003) without activating an irrigation scheme over a continental US
70 domain. Areas where the distributions of model and RS data sets deviated (based on a Kolmogorov-Smirnov test) were assumed
71 to be irrigated. Even though some of the products showed a potential ability to detect irrigation, the authors concluded that the
72 spatial mismatch between the satellite footprint and the irrigated fields, radio-frequency interference (RFI), vegetation, and
73 topography could all deteriorate the accuracy of the results. Similar conclusions were found over the same area by Zaussinger
74 et al. (2019) who compared coarse-scale satellite SSM products with soil moisture predictions from the Modern-Era
75 Retrospective analysis for Research and Applications 2 (MERRA-2) in the absence of precipitation, and Escorihuela and
76 Quintana-Seguí (2016) who additionally compared a downscaled version of the Soil Moisture and Salinity mission (SMOS)
77 SSM to SURFEX LSM simulations. Brocca et al. (2018), Jalilvand et al. (2019) and Dari et al. (2020) used a conceptually
78 different approach with the same coarse scale MW SSM products and estimated irrigation by directly inverting a simple water
79 balance equation (Brocca et al. 2014).

80 The Copernicus Sentinel-1 satellites (Sentinel-1A and Sentinel-1B) offer a new perspective for agricultural applications, thanks
81 to the finer spatial resolution (up to 10-20 m) of the Synthetic Aperture Radar (SAR) backscatter (σ^0) data. For instance, Gao et
82 al. (2018) proposed an approach to map irrigated lands over the Urgell region in Catalonia (Spain), and Le Page et al. (2020)
83 proposed a methodology to detect irrigation timing in south-west France comparing the SSM signal at the plot scale, derived
84 using Sentinel-1 σ^0 and NDVI from Sentinel-2 (El Hajj et al., 2017), with a water budget model forced by Sentinel-2 optical
85 data for the detection of irrigation timing.

86 Despite the high potential demonstrated by RS in detecting, mapping and quantifying irrigation, the uncertainties of the satellite
87 retrievals, the relatively low revisit time of high resolution active MW products and the too coarse spatial resolution of passive
88 MW products with respect to the mean size of irrigated fields represent main limitations for irrigation information retrieval
89 (Romaguera et al., 2010, La Page et al., 2020). Data assimilation (DA) could reduce some uncertainties by optimally integrating
90 LSM estimates and RS observations. Indeed, the LSM estimates resolve processes at desired spatio-temporal scales, while the
91 RS observations can track in a more realistic way human processes like irrigation and their interactions with the water and energy
92 cycles. Contrasting LSM simulations with RS observations offers an opportunity to correct for unmodeled processes or missed
93 events, such as irrigation (Kumar et al., 2015a; Giroto et al., 2017). More generally, DA of satellite-based observations has
94 shown the potential to update soil moisture (De Lannoy & Reichle, 2016; Kolassa et al., 2017) and vegetation (Albergel et al.,
95 2018; Kumar et al., 2020) and important impacts have been reported over agricultural areas (Kumar et al., 2020).

96 The assimilation of MW RS observations in LSMs often involves retrieval assimilation. However, assimilating retrievals (i.e.,
97 SSM or vegetation optical depth rather than MW brightness temperature or σ^0 measurements) can be problematic as the retrievals
98 may have been produced with ancillary data that are inconsistent with those used in the LSM (De Lannoy et al. 2016). This is
99 particularly true for passive MW retrievals while active MW retrievals generally rely on change detection methods that lack
100 land-specific ancillary information altogether. An alternative approach, which we follow in this study, is to directly assimilate
101 MW observations and equip the LSM with an observation operator that links land surface variables of interest (e.g., soil moisture
102 and vegetation) with RS data. This allows us to obtain consistent parameters and to reduce the chance of cross-correlated errors
103 between model states and corresponding geophysical satellite retrievals. The direct assimilation of MW observations has already
104 been demonstrated successfully for the update of soil moisture by using Tb derived from the SMOS and SMAP missions (De
105 Lannoy et al. 2016, Carrera et al., 2019, Reichle et al. 2019), as well as using radar σ^0 from ASCAT (Lievens et al., 2017b), and
106 σ^0 from Sentinel-1 in synergy with SMAP Tb (Lievens et al., 2017a). However, to our knowledge, none of these studies
107 considered the joint updating of soil moisture and vegetation, and none specifically focused on the performance over irrigated
108 areas. The σ^0 from Sentinel-1 contains information on both soil moisture (Zribi et al., 2011; Liu and Shi, 2016; Li and Wang,
109 2018; Bauer-Marschallinger et al., 2018) and vegetation (Vreugdenhil et al., 2018; Vreugdenhil et al., 2020) and assimilating
110 this data could allow us to update both soil moisture and vegetation in a land data assimilation system and, in doing so, correct
111 for missed irrigation events.

112 To that end, the LSM needs to be coupled to a backscatter forward model as an observation operator. Different SAR σ^0 models
113 have been proposed to simulate the backscattering contributions of soil and vegetation (Attema & Ulaby, 1978; Oh, 2004; Zribi
114 et al., 2005; Bai et al., 2015; Baghdadi et al., 2017). Most commonly used, the Water Cloud Model (WCM hereafter) developed
115 by Attema and Ulaby (1978) is a σ^0 model that represents the vegetation canopy as a homogeneous cloud containing randomly
116 distributed water droplets. In order to use the WCM as the forward operator in a σ^0 data assimilation system, it first needs to be
117 calibrated to account for biases between the LSM simulations and the satellite observations. However, calibrating a WCM to
118 simulate σ^0 over irrigated areas, is not a straightforward process and it represents a key research problem if the same σ^0 signal is
119 used for the calibration of WCM parameters and later for assimilation and state updating. In fact, if the objective is to assimilate
120 radar σ^0 to realistically inform the model about irrigation applications, the WCM parameters have to maintain a certain degree
121 of independence from the irrigation signal contained in the observed σ^0 as otherwise the assumption of uncorrelated errors
122 between model and observations typical of classical Bayesian-based filters is violated. More specifically, if the LSM provides
123 unrealistic simulations as input (i.e., absence of irrigation), then the WCM calibration with observed σ^0 would compensate for
124 this bias. This would in turn lead to a biased backscatter model with undesirable calibrated parameters for the subsequent data
125 assimilation experiments. Therefore, different strategies can be adopted, for instance calibrating the model during non-irrigated
126 periods or over non-irrigated areas, or equipping the LSM with an irrigation module that makes the WCM less constrained by
127 inconsistencies between simulated and observed σ^0 during irrigation periods. The efficacy of these strategies has so far never
128 been explored.

129 The main objective of this study is to simulate radar σ^0 using a LSM coupled with a WCM and to provide solutions and
130 recommendations for the optimization of the WCM as an observation operator. This is a major stepping-stone towards the
131 development of a reliable system for the assimilation of high-resolution Sentinel-1 σ^0 observations over irrigated areas.
132 Additionally, we aim at:

- 133 1) testing the ability of a sprinkler irrigation system coupled with a LSM to simulate irrigation so as to highlight the
134 potential and limitations of such a tool to optimize a backscatter forward operator over heavily irrigated areas;
- 135 2) demonstrating that Sentinel-1 σ^0 observations contain valuable information to improve both SM and vegetation
136 predictions over irrigated land (i.e., soil moisture and vegetation consistent with human alterations in the water
137 cycle due to intensive irrigation).

138 The analysis is carried out over the Po river valley, one of the most important agricultural areas in Italy and also one of the more
139 intensively irrigated areas in Europe (water withdrawal in the Po basin is estimated to be 20.5 billion m^3/year , of which 16.5
140 billion of m^3/year is withdrawn for irrigation; Po River Watershed Authority, 2006). We use the Noah-MP v.3.6 LSM (Noah-
141 MP hereafter) as part of the NASA Land Information System (LIS) framework together with the WCM from Attema and Ulaby
142 (1978) for the simulation of both σ^0 vertical send and receive (VV) and vertical send and horizontal receive (VH) polarization.
143 Level-1 Sentinel-1 σ^0 observations are used to calibrate the WCM at 1-km resolution, using simulated SSM and Leaf Area Index
144 (LAI) estimates from Noah-MP. The WCM is calibrated for a total of four calibration experiments for each polarization: 1) with
145 or without activating an irrigation scheme within Noah-MP; and, 2) considering two different cost functions. Specifically, we
146 want to demonstrate that activating an -even poor- irrigation scheme is needed to obtain long-term unbiased σ^0 simulations and
147 uncorrelated errors between the WCM and Sentinel-1 and that the calibration process can be sensitive to different cost functions.
148 The manuscript is organized as follows. Section 2 provides information on the study area, the selected datasets, and methods
149 used for our analysis. Specifically, Sections 2.3 and 2.4 provide a detailed description of the Noah-MP LSM and the WCM.
150 Section 2.5 describes the cost functions used for the WCM calibration while Section 2.6 is a description of the experimental set-
151 up designed for the calibration. Finally, Section 2.7 provides insights on the Noah-MP and WCM evaluations. Section 3 presents
152 the results, with an assessment of the Noah-MP evaluation, both regional (Section 3.1) and over the test sites (Section 3.2). The
153 WCM calibration and evaluation results are described in Sections 3.3 and 3.4, respectively. We provide discussion in Section 4
154 while conclusions are reported in Section 5.

155 **2 DATA AND METHODS**

156 **2.1 Study area and in situ data**

157 The analysis was carried out over an area of 24,000 km^2 located within the Po river valley, one of the most important agricultural
158 areas in Europe (Figure 1, left-bottom corner: 44°N, 10.5°W; top-right corner: 45.5°N, 12.2°W). The Po river valley is part of
159 the Po river basin district ($\sim 74,000 \text{ km}^2$), a mountain-fed catchment which extends from the Alps in the West, to the Adriatic
160 Sea in the East. The Po district is one of the eight districts mentioned in the Water Framework Directive (WFD, 2000) initiated

161 by the European Commission and has been hit by seasonal drought events which impacted all water use sectors, in particular
162 agriculture (Strosser et al., 2012). The water assessment and impact evaluation of human activities over the Po river valley is
163 thus a topic of major interest, considering the significant requirements from the agricultural management sector.

164 According to the Köppen-Geiger climate classes (Peel et al., 2007) the study area is classified as "Cfa" (temperate climate,
165 without dry season and with hot summers). From a geographical point of view, the Po river flows from the west to the east,
166 splitting the area of interest in northern and southern areas, respectively. North of the Po river, the agricultural plain area can be
167 additionally subdivided into the Veneto region to the east and the Lombardy region to the west (Figure 1). Lombardy lands have
168 a high water availability, thanks to the presence of several Alpine lakes and reservoirs (Musolino et al., 2017), as does the Veneto
169 region. Wine cultivation plays an important role, especially in the Garda Lake surroundings (located to the north-west side of
170 the study area). In the south, the Emilia Romagna region is an agricultural as well as urbanized-industrialized area. Compared
171 to Lombardy and Veneto, Emilia Romagna is much poorer both in water availability and storage capacity, but its irrigation
172 system is considered the most technologically advanced and efficient in the Po river basin (Musolino et al., 2017). Specifically,
173 it hosts the Canale Emiliano Romagnolo (CER, <https://consorzioцер.it/>, last access 20 May 2021), one of the most important
174 Italian hydraulic systems for agricultural water supply. The main crops in the study region include general summer and winter
175 crops, orchards (i.e., peach, pear, kiwi), olive groves, and vineyards ([https://sites.google.com/drive.arpae.it/servizio-climatico-
176 icolt/home](https://sites.google.com/drive.arpae.it/servizio-climatico-icolt/home), last access 20 May 2021). The plain area is surrounded by a forested hilly and mountainous area of the Tuscan-
177 Emilian Appennine to the south/south-west.

178 In situ data were collected over two test sites, located in the Emilia Romagna region:

- 179 • For an analysis at plot scale we selected the Budrio test site (Figure 1a), an experimental farm managed by the CER
180 authority which includes two plots of 0.39-0.49 ha. The main crops are maize for field 1 (in yellow) and tomatoes in
181 field 2 (red colour). Daily irrigation data, in mm, were collected for the summer 2015-2016 over field 1, whereas
182 daily irrigation water amounts were collected for the summer 2017 over field 2. Additionally, for field 2, hourly in
183 situ soil moisture data, aggregated here at daily scale, were made available from the Department of Physics and Earth
184 Science of the University of Ferrara. The soil moisture data were derived from an innovative Proximal Gamma-Ray
185 (PGR SM hereafter; Filippucci et al., 2020, Strati et al., 2018) station, equipped with a 1L NaI(Tl) detector placed at
186 2.25 m above the ground and a commercial agro-meteorological station (MeteoSense 2.0, Netsen; Strati et al., 2018).
187 The PGR is a nuclear non-invasive and non-contact technique, which allows to overcome the issue connected to in
188 situ point measurements, probing soil moisture with a field scale footprint ($\sim 10^4$ m²) up to a depth of 30 ~ cm. The
189 quantification of PGR soil moisture is derived from measurements of gamma signals emitted by the decay of ⁴⁰K,
190 which is extremely sensitive to different soil water contents in agricultural soils (for more information on the PGR
191 soil moisture deriving procedure the reader can refer to Baldoncini et al., 2019). Finally, daily rainfall data were
192 collected from the national rainfall network managed by the Department of Civil and Environmental Protection (DPC)
193 of Italy, for the irrigated periods.

- The second test site (Figure 1b) is located around the city of Faenza (hereafter Faenza test site) and has a total extent of 1051 ha, consisting of two fields which allow an analysis at the small-district spatial scale. The first one is called San Silvestro (290 ha) and it is located north of the city. The second one is called Formellino (760 ha), located east to the San Silvestro field and north-east to the city of Faenza. Fruit trees are prevalent on the fields; in particular, pear trees and kiwi dominate the area. The water used for irrigation was provided by CER, at hourly time scale and in mm, for the 2-years time period 2016-2017. Daily rainfall data were collected from the national rainfall network managed from the DPC.

201 2.2 Sentinel-1 σ^0 and reference remote sensing products

202 The Copernicus-ESA Sentinel-1 σ^0 observations were used in this study for the calibration of the WCM. The Sentinel-1
203 constellation consists of two satellites, Sentinel-1A and Sentinel-1B, launched in 2014 and 2016, respectively. Each satellite
204 carries a Synthetic Aperture Radar (SAR) operating at C-band (5.4 GHz) in the microwave portion of the electromagnetic
205 spectrum. The processing of the ground-range detected (GRD) Interferometric Wide Swath (IW) observations in VV- and VH-
206 polarization was done using Google Earth Engine's Python interface and included standard techniques: precise orbit file
207 application, border noise removal, thermal noise removal, radiometric calibration, and range-Doppler terrain correction.
208 Furthermore, the σ^0 observations acquired at $5 \times 20 \text{ m}^2$ resolution were aggregated and projected on the 1 km Equal Area Scalable
209 Earth version 2 (EASE-2) grid (Brodzik et al., 2012). After applying an orbit bias-correction (Lievens et al., 2019), the
210 observations from different orbits, either from Sentinel-1A or -1B and ascending or descending tracks, were combined at the
211 daily time-scale.

212 Additionally, RS observations were used for the evaluation of the SSM and LAI simulated in Noah-MP LSM for the period 31
213 March 2015- December 2019:

- The NASA Soil Moisture Active Passive (SMAP; Entekhabi et al., 2010) is an orbiting observatory launched in January 2015 carrying two instruments: a SAR which suffered a failure in early July 2015, and a radiometer measuring Tb at L-band, with a native spatial resolution of 40 km, a revisit time of 2–3 days, and ascending and descending overpasses at 6:00 PM and 6:00 AM (local time), respectively. For this study, the 9-km SMAP Enhanced Level-2 SSM version 4 (0-5 cm; SMAP L2 hereafter) product was used (O'Neill et al., 2020; Chan et al., 2018). The product is derived from SMAP Level-1B (L1B) interpolated antenna temperatures using the Backus-Gilbert optimal interpolation technique. Both ascending and descending tracks were collected.
 - The Metop ASCAT SSM Climate Data Records (CDR) H115 and its extension H116 are provided by the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) Support to Operational Hydrology and Water Management (H SAF; <http://hsaf.meteoam.it/>, last access 20 May 2021). The SSM is retrieved from σ^0 using a change detection algorithm (Wagner et al., 2013), and is characterized by a spatial sampling of 12.5 km and a temporal resolution of one to two observations per day, depending on the latitude.

- The PROBA-V LAI is derived from the PROBA-V satellite mission (Francois et al., 2014; Dierckx et al., 2014) and provided by the Copernicus Global Land Service programme (CGLS, <https://land.copernicus.eu/global/>). The CGLS product at 1 km spatial resolution and 10-day (dekadal) temporal resolution is developed based on the work by Verger et al. (2014).

In order to compare Noah-MP simulations and reference data at the same spatial resolution, Sentinel-1 observations (σ^0 -VV and -VH), as well as ASCAT SSM, SMAP L2 SSM and PROBA-V LAI were extracted over the study domain (left-bottom corner: 44°N, 10.5°W; top-right corner: 45.5°N, 12.2°W) and re-gridded over the LIS grid domain (0.01°) using the nearest-neighbour approach.

2.3 Land surface and irrigation modelling

2.3.1 Noah-MP v.3.6

The analysis was carried out using the Noah-MP (Niu et al., 2011) LSM, running within NASA's LIS 7.2 version (Kumar et al., 2008). LIS is a software framework for terrestrial hydrology modelling and DA, which supports different LSMs that can be conditioned on multiple remote sensing products from active and/or passive microwave sensors. The Noah-MP LSM, which was chosen for this study, is an evolution of the baseline Noah LSM (Mahrt and Ek, 1984; Chen et al., 1996; Chen and Dudhia, 2001) wherein main improvements and augmentations are: 1) the presence of four soil layers; 2) up to three snow layers; 3) one canopy layer which allows to dynamically simulate the vegetation and to compute separately the ground surface temperature; 4) a two-stream radiation transfer scheme based on the canopy layer sub-grid scheme; 5) a Ball-Berry type stomatal resistance scheme; 6) and finally, a simple groundwater model with a TOPMODEL-based runoff scheme (Niu et al., 2005, 2007). The model was set up selecting four soil layers at depths 0–10, 10–40, 40–100 and 100–200 cm, a dynamic vegetation model with a Ball-Berry type canopy stomatal resistance model (Ball et al., 1987), and TOPMODEL-based runoff.

The parameterization followed the recommended options provided in the LIS documentation (<https://modelingguru.nasa.gov/docs/DOC-2634>). A model time step of 15 minutes and a 6 hours output interval were selected together with a spatial resolution of 0.01°. The meteorological forcings used for running Noah-MP LSM were obtained from MERRA-2 (Gelaro et al. 2017). The MERRA-2 original spatial resolution of 0.5°x0.625° was re-mapped to 0.01° through bilinear interpolation. Land model data and parameters were pre-processed and adapted to the LIS longitude/latitude projection using the Land Surface Data Toolkit (LDT; Arsenault et al., 2018) in order to run Noah-MP at the chosen spatial resolution.

For this study, the default LIS Land Cover (LC) map from the University of Maryland (UMD) global land cover product (Hansen et al., 2000) based on the Advanced Very High Resolution Radiometer (AVHRR) data was replaced with the 2015 global LC map, available from the CGLS at 100 m spatial resolution (Buchhorn et al., 2020; available at <https://land.copernicus.eu/global/products/lc>, last access 20 May 2021). The CGLS provides Dynamic Land Cover Layers at 100 m spatial resolution (CGLS-LC100), obtained by combining information derived from the vegetation instrument on board the PROBA-V satellite, a database of high-quality LC reference sites, and several ancillary datasets. For a more detailed

258 explanation of the LC maps generation process we refer to the Algorithm Theoretical Basis Document (ATBD; Buchorn et al.,
259 2020). The 23 classes of the PROBA-V LC map were reclassified to the 14 classes used in the UMD-AVHRR classification
260 supported by LIS. Additionally, the LC map was regrided at 0.01° (Figure 2a) by identifying the most representative class over
261 each LIS grid cell. For additional information on the reclassification process, we refer the reader to Table S1 in the
262 Supplementary Material section. Similarly, the default FAO Soil Map (FAO Soil Map of the World, 1971) was replaced by the
263 Harmonized Soil World Database (HWSD v1.21, 1 km; Figure 2b) and mapped to 5 soil classes over the study region. Other
264 model pre-processed parameters inputs were: i) the Shuttle Radar Topography Mission elevation data (SRTM30, 30 m spatial
265 resolution); 2) climatological global Greenness Vegetation Fraction (GVF) data (0.144°; Gutman and Ignatov, 1998) derived
266 from 5 years (1985-1989) of normalized difference vegetation index (NDVI) data from the AVHRR (Miller et al., 2006); 3) a
267 snow-free albedo and a Noah-specific maximum snow albedo product from NCEP (original resolution 1° and regrided); and
268 finally, 4) soil, vegetation, and other general parameter tables for Noah-MP from the LIS official Data Portal
269 (https://portal.nccs.nasa.gov/lisdata_pub/data/, last access 20 May 2021).

270 **2.3.2 Irrigation modelling**

271 The ability of Noah-MP to dynamically simulate the vegetation and the option to activate irrigation are particularly important
272 considering an extensively irrigated area such as the Po river valley. Indeed, in a recent study by Nie et al. (2018), Noah-MP
273 was coupled with a sprinkler irrigation scheme (Ozdogan et al., 2010b) (where irrigation is applied as supplementary rainfall),
274 which requires three pieces of information:

- 275 • the irrigation location, only occurring over potentially irrigated croplands (expanding over grassland if the intensity
276 exceeds the gridcell's total crop fraction). This information is extracted from a LC map associated with an additional
277 dataset providing information on the percent of irrigated area per grid cell. In this study, the reclassified PROBA-V LC
278 map was coupled with the information contained in the 500 m Global Rain-fed, Irrigated and Paddy Croplands data set
279 (GRIPC; Salmon et al., 2015);
- 280 • the timing of irrigation, which is determined by checking the start and end of the growing season based on a GVF
281 threshold, separately at each grid cell. Following Ozdogan et al.(2010b), we set this threshold to 40% of the GVF;
- 282 • the amount of water used for irrigation. This quantity is derived from the root zone soil moisture (RZSM) availability
283 (MA) as $MA = (RZSM - SM_{WP}) / (SM_{FC} - SM_{WP})$ where RZSM is the current RZSM, SM_{WP} is the wilting point, and SM_{FC}
284 is the field capacity. When the MA falls below a user-defined threshold, irrigation is triggered and the quantity is defined
285 by calculating the amount of irrigation needed to raise the RZSM to the SM_{FC} . For this study, the MA threshold was
286 defined as the 50% of SM_{FC} as in Ozdogan et al. (2010b). MA is calculated at each time step but the irrigation is only
287 applied between 06:00 and 10:00 LT. Following Ozdogan et al. (2010b), this time frame is typically chosen by farmers
288 to reduce evaporative losses. In this context, the maximum rooting depth becomes a crucial information to compute the
289 amount of irrigation water. This information is related to an assigned crop type, cultivated over the study area, through a
290 maximum rooting depth table. Considering the high crop variability over the Po river valley as well as the lack of high

291 resolution dynamic crop maps for the entire study area, a generic crop type with 1 m root depth was selected for the
 292 irrigation simulations. The reference rooting depth was verified to be feasible over the study area based on the European
 293 Soil Data Centre (ESDAC, available at <https://esdac.jrc.ec.europa.eu/content/european-soil-database-derived-data>, last
 294 access 20 May 2021) rooting depths map (Figure S1 in the Supplementary Material).

295 2.4 Water Cloud Model

296 The WCM allows to simulate the top-of-vegetation σ^0 as a function of SSM and vegetation, using empirical fitting parameters.
 297 σ^0 is modeled as the sum of the backscatter from the vegetation (σ_{veg}^0 , in dB) and from the bare soil (σ_{soil}^0 , in dB), attenuated
 298 by the t^2 coefficient that describes the two-way attenuation from the vegetation layer. Scattering interactions between the
 299 ground and the vegetation are not accounted for. As reported in Baghdadi et al. (2018), for a given polarization pq (i.e., VV
 300 and VH), the WCM can be written as follows:

$$301 \quad \sigma_{pq}^0 = \sigma_{veg,pq}^0 + t_{pq}^2 \sigma_{soil,pq}^0 \quad (1)$$

302 where:

$$303 \quad \sigma_{veg,pq}^0 = A_{pq} V_1 \cos\theta (1 - t_{pq}^2) \quad (2)$$

$$304 \quad t_{pq}^2 = \exp\left(\frac{-2B_{pq}V_2}{\cos\theta}\right) \quad (3)$$

$$305 \quad \sigma_{soil,pq}^0 = C_{pq} + D_{pq} \cdot SSM \quad (4)$$

306 Equations 2 and 3 describe the vegetation-related terms. V_1 and V_2 represent two bulk vegetation descriptors, the first one
 307 accounting for the direct vegetation σ^0 , and the second one representing the attenuation. $A_{pq}[-]$ and $B_{pq}[-]$ are the two related
 308 fitting parameters. Common vegetation descriptors used in previous studies are the Vegetation Water Content (VWC, Paloscia
 309 et al., 2013), the NDVI (El Hajj et al., 2016; Li and Wang, 2018) and LAI (Kumar et al., 2015b; Bai and He, 2015), while θ
 310 represents the incidence angle, which is assumed to be 37° for Sentinel-1. Following previous studies (see Lievens et al, 2017b;
 311 Baghdadi et al. 2017; Li and Wang, 2018) we assumed $V_1=V_2$ represented by the dynamically simulated LAI vegetation
 312 descriptor.
 313 descriptor.

314 Equation 4 describes the soil-related term. Following the work by Lievens et al. (2017b), the σ_{soil}^0 can be described, in a simple
 315 linear approach, as a function of the SSM. There are several semi-empirical models (e.g., the Oh model; Oh et al., 1992) or
 316 theoretical models (e.g., the Integral Equation Model (IEM), Fung, 1994) which describe the scattering processes related to
 317 the bare soil, but their application as a forward operator coupled to a LSM has two main limitations: the first one lies in the
 318 difficulty in retrieving soil roughness values over extended reference areas required to parameterize these models; the second
 319 one is their saturation of σ^0 in moist conditions which causes low variability in simulated σ^0 if the LSM soil moisture

320 simulations are biased wet (for more information see Lievens et al., 2017b). Those limitations justify the use of a linear fitted
 321 approach. In Equation 4, the C and D parameters (here fitted in dB and dB/m³/m³, respectively, but σ_{soil}^0 is transformed back
 322 to the linear scale in Equation 1) describe the linear relation between $\sigma_{soil,pq}^0$ and SSM. Those parameters, as well as A and
 323 B (-), need to be calibrated separately for each polarization.

324 2.5 Calibration algorithms

325 We considered two different objective functions to optimize the A, B, C and D parameters:

- 326 • a Bayesian solution, which minimizes the Sum of Squared Errors (SSE) between σ^0 observations from Sentinel-1 and
 327 WCM simulations. The SSE Bayesian calibration solution aims at identifying the optimal parameter vector α which
 328 maximizes the probability of the resulting σ^0 simulations $p(\hat{y}^-) = p(\hat{y}^-|\alpha)p(\alpha)$, where $p(\alpha)$ is the prior parameter
 329 distribution and $p(\hat{y}^-|\alpha)$ is the likelihood. Starting from the assumption of an independent and identically distributed
 330 normal error model, the posterior probability can be maximized by maximizing:

$$331 \quad p(\hat{y}^-|\alpha)p(\alpha) = \prod_i^{N_i} \left\{ \frac{1}{s_i\sqrt{2\pi}} \exp\left(-\frac{(\hat{y}^- - \hat{y}_i^-)^2}{2s_i^2}\right) \right\} \cdot \prod_j^{N_\alpha} \left\{ \frac{1}{s_j\sqrt{2\pi}} \exp\left(-\frac{(\alpha_0 - \alpha_j)^2}{2s_j^2}\right) \right\} \quad (5)$$

332 i.e., the combination of the likelihood and a prior parameter constraint. The latter helps in reducing problems of
 333 equifinality. In Equation (5), \hat{y} represents the observed σ^0 , \hat{y}^- is the simulated σ^0 , i is the timestep and s_i is the standard
 334 deviation of the residual differences between the observed and simulated σ^0 values for N_i time steps. N_α is the number
 335 of parameters to be calibrated, α_0 is the prior parameter constraint and the parameter deviation is limited by s_j^2 , the
 336 variance of a uniform distribution $s_j^2 = (\alpha_{max,j} - \alpha_{min,j})^2/12$ with determined boundaries of the parameters
 337 $[\alpha_{min}, \alpha_{max}]$. The maximum likelihood solution is found by minimizing the following cost function J :

$$338 \quad J = \sum_i^{N_i} \left\{ \ln(s_i) + \frac{(\hat{y}^- - \hat{y}_i^-)^2}{2s_i^2} \right\} + \sum_j^{N_\alpha} \left\{ \frac{(\alpha_0 - \alpha_j)^2}{2s_j^2} \right\} = J_0 + J_\alpha \quad (6)$$

339 where s_i is assumed to be constant in time and represented by a target accuracy of 1 dB, leaving the SSE in the first
 340 term of J_0 to minimize. The second term (J_α) constrains the optimal solution by avoiding strong deviations from initial
 341 parameter guesses.

- 342 • a solution that maximizes the Kling-Gupta Efficiency (KGE; Gupta et al., 2009). Even though this objective function
 343 does not ensure Bayesian optimality, it is a widely used metric which could help to better tune the dynamic σ^0
 344 behaviour:

$$KGE = 1 - \sqrt{(r - 1)^2 + \left(\frac{\langle \hat{y}^- \rangle}{\langle \hat{y} \rangle} - 1\right)^2 + \left(\frac{s[\hat{y}^-]/\langle \hat{y}^- \rangle}{s[\hat{y}]/\langle \hat{y} \rangle} - 1\right)^2} \quad (7)$$

The *KGE* formulation embeds three terms: 1) the first term accounting for the Pearson Correlation (Pearson-R) between the observed (\hat{y}) and simulated (\hat{y}^-) σ^0 time series; 2) a second term accounting for the bias, where the long-term mean is represented as $\langle . \rangle$; and finally, 3) a term accounting for the variability of the simulated and observed signal through the use of the standard deviation $s[.]$. *KGE* = 1 indicates a perfect agreement between simulations and observations. Note that *KGE* redistributes the weight of the bias, variance and correlation components, compared to *J* in Equation 6, which can help in reducing differences between simulated and observed σ^0 also in terms of temporal dynamics during the calibration. On the other hand, in the *KGE* cost function parameters are not constrained by prior values α_0 . This could possibly result in overfitting and a larger prediction uncertainty.

The Particle Swarm Optimization (PSO; Kennedy and Eberhart, 1995) was used to minimize *J* and maximize *KGE*. For our case study the PSO parameters were set as in De Lannoy et al. (2013).

2.6 Experimental setup

An optimal DA system requires long-term unbiased σ^0 simulations (with respect to the assimilated observations). The risk, over an intensively irrigated area, is that an unmodelled irrigation signal would manifest itself as a predominant bias in the σ^0 simulations. The calibration would then inadvertently correct for this supposed bias (i.e., the irrigation signal), thus preventing the DA system from propagating the missing irrigation signal from the observations into the model. Even though existing irrigation schemes are evidently unrealistic and inaccurate, we conjecture that using such a scheme when calibrating the WCM will more likely yield optimal WCM parameters than when neglecting irrigation.

To that end, we considered two different experiment lines (referred to as *Natural* and *Irrigation*, respectively) that produced a total of eight different σ^0 simulation runs (see Figure 3). The *Natural* experiment line differs from the *Irrigation* line by the activation of an irrigation module in Noah-MP, and both are subjected to the calibration algorithms described in Section 2.5. The *Natural* line was used as a diagnostic experiment against which to compare *Irrigation*, which, according to our initial hypothesis, should minimize the impact of the irrigation signal contained in the σ^0 observations on WCM parameters.

As a first step, a model spin up was performed, starting in January 1982 and ending in December 2014. Then, a study period from January 2015 to December 2019 was selected for the different model runs based on the availability of the processed Sentinel-1 σ^0 and reference irrigation data (see Sections 2.1 and 2.2). Daily surface model and irrigation outputs were produced. Considering that the main source of irrigation in the Po river valley is related to surface water abstraction, the sprinkler irrigation scheme did not account for groundwater withdrawals (see Nie et al., 2018).

The A, B, C, and D parameters of the WCM (see section 2.4) were fitted separately to Sentinel-1 σ^0 VV and VH observations, during the period January 2017 - December 2019. Following previous literature (Lievens et al., 2017b; De Lannoy et al., 2014; De Lannoy et al., 2013), we performed a grid cell-based calibration to account for the spatial variability in the simulated and

376 observed σ^0 signals that stems from specific features within the observed footprints as well as from the soil and vegetation
 377 parameterization of Noah-MP. Both the calibration using the SSE with prior constraint (Bayesian J) and the KGE were applied
 378 to the *Natural* and *Irrigation* runs providing eight different experiments named *J-VV Natural*, *J-VH Natural*, *J-VV Irrigation*,
 379 *J-VH Irrigation*, *KGE-VV Natural*, *KGE-VH Natural*, *KGE-VV Irrigation* and *KGE-VH Irrigation*.

380 Lower and upper boundaries as well as prior guess values of the WCM parameters were defined based on the work of Lievens
 381 et al. (2017b) and on a sensitivity analysis (not shown here). The selected values are displayed in Table 1. Finally, it should be
 382 noted that all the calibration experiments were realized by considering daily values of σ^0 simulations and observations.

383 **Table 1: Lower boundaries (LB), upper boundaries (UB), and prior guess values of the WCM parameters for both VV and VH**
 384 **polarization**

	A-VV[-]	A-VH[-]	B-VV[-]	B-VH[-]	C-VV[dB]	C-VH[dB]	D-VV[dB/m ³ /m ³]	D-VH[dB/m ³ /m ³]

385

386 2.7 Noah-MP LSM and WCM evaluations

387 The validation aims at i) evaluating the performance of Noah-MP in simulating irrigation, soil moisture, and vegetation and
 388 the ability of the WCM to simulate radar σ^0 , and ii) unveiling the information about irrigation contained in Sentinel-1 radar σ^0
 389 in order to assess its potential to improve both soil moisture and vegetation representation within Noah-MP.

390 The evaluation was carried out on both the regional scale (i.e., over the entire study area) and on the two selected sites, Faenza
 391 (small-district scale) and Budrio (plot scale), where irrigation data were available. Considering the lack of benchmark data for
 392 irrigation evaluation (Foster et al., 2020) we decided to use in situ data for the small Budrio fields spatial scale (i.e., 0.45-049
 393 Ha) even though model simulations are made at a much coarser resolution (i.e., ~1 km). We are aware that differences in
 394 spatial scale can increase the uncertainty of our evaluation, but 0.01° LSM spatial resolution is still a good compromise for an
 395 analysis at regional, small-district and plot scale. Additionally, limitations are partly reduced by the low chance of including
 396 non-irrigated fields within the 1 km LIS grid cells within the Po River Valley, as the latter is almost entirely irrigated (Salmon
 397 et al., 2015). We compared Noah-MP (with and without using the irrigation module) SSM and LAI simulations with satellite
 398 SSM from ASCAT and SMAP, and LAI from PROBA-V, respectively, during the period 2015-2019. Furthermore, these land
 399 surface simulations were compared to Sentinel-1 σ^0 to understand how much of the SSM and LAI signal was captured by
 400 Sentinel-1.

401 As the irrigation timing is often driven by the stakeholders' turns to withdraw water and by water availability rather than by
402 the conditions of the soil and crops themselves, the comparisons between simulated SSM and satellite SSM were carried out
403 by aggregating the two variables over a bi-weekly time window. On the other hand, the LAI from Noah-MP was aggregated
404 to ten-daily values in order to match the dekadal PROBA-V LAI values. We used the Pearson-R for SSM and LAI evaluation.
405 For SSM, we also computed the Root Mean Square Error (RMSE), calculated considering the original temporal resolution of
406 the satellite products, while for LAI, we also tested the ratio bias, i.e., the ratio between the long-term mean of the simulations
407 and the long-term mean of observations. In particular, this additional score for LAI was used to provide a further evaluation
408 of the ability of the Noah-MP to simulate crop phenology during the irrigated vs non-irrigated periods so as to not rely solely
409 on the evaluation of temporal dynamics, which, due to the uncertainty in the Noah-MP crop type parameterization, could be
410 affected by time shifts in the LAI climatology. This parameterization uncertainty comes from the lack of knowledge of the
411 spatial crop type information and is difficult to be reduced without additional information. Our assumption is that radar σ^0
412 assimilation can also correct for this with future data assimilation.

413 Following Vreugdenhil et al. (2018) and Vreugdenhil et al. (2020), Noah-MP LAI and PROBA-V LAI were also compared
414 with the Sentinel-1 σ^0 VH/ σ^0 VV cross ratio (CR), which was demonstrated to have a high agreement with the vegetation
415 signal. Though the σ^0 VH was demonstrated to increase with the vegetation signal (Macelloni et al., 2001), the CR will be
416 more sensitive to vegetation changes as the ratio is less sensitive to changes in soil moisture and soil-vegetation interaction
417 (Veloso et al., 2017; Vreugdenhil et al., 2020).

418 To evaluate WCM simulations, we used bi-weekly values of σ^0 simulations and observations considering a two-years period
419 independent from the calibration period: 2015-2016. Statistical metrics such as grid-based temporal Pearson-R, KGE, and bias
420 were calculated between Sentinel-1 σ^0 and calibrated WCM simulations. The analysis of the parameters was restricted to the
421 cropland area as no difference between our experiment lines exists over other land cover types (i.e., the irrigation module is
422 active only over grid points classified as crop).

423 **3 RESULTS**

424 **3.1 Noah MP regional evaluation**

425 Figure 4 shows maps of the Pearson-R between bi-weekly Noah-MP SSM *Natural* and *Irrigation* simulations and bi-weekly
426 ASCAT and SMAP L2 SSM retrievals, respectively, for April 2015 to December 2019. The Noah-MP SSM *Irrigation* run
427 provides a higher agreement with both satellite SSM data sets compared to the *Natural* run. Indeed, the median Pearson-R
428 between SMAP L2 SSM and Noah-MP SSM increases from 0.68 to 0.73, for the *Natural* run (Figure 4a) and the *Irrigation*
429 run (Figure 4b), respectively. A similar improvement can be observed considering the ASCAT reference SSM, with an
430 improvement in the median Pearson-R of 0.08 when irrigation is activated in the model (from 0.7 to 0.78; Figure 4e). Areas
431 characterized by higher correlation when irrigation is simulated are represented in blue in the Pearson correlation difference
432 map of Figure 4f (obtained by subtracting the map in Figure 4d from the map in Figure 4e). Almost all cropland areas are

433 characterized by a higher agreement between observations and simulations for the *Irrigation run*. Note that for the evaluation
434 of Noah-MP against SMAP, we relaxed retrieval quality flags, which would otherwise mask out almost the entire study area.
435 The Supplementary material (Figure S2) shows the coverage when using the recommended quality flags. Results in Figure 4
436 were confirmed by analyzing the RMSE between satellite SSM products and Noah-MP simulations for both the *Natural* and
437 *Irrigation* runs, after rescaling them based on their mean and standard deviation, because SSM retrievals and SSM simulations
438 do not have the same units. Results are displayed in Figure S3 of the Supplementary material and show, for both the satellite
439 products, a general reduction in RMSE when compared with the *Irrigation* run. An improvement in performances can be
440 observed over the entire cropland area, in particular over the central triangle feature where sandy-loam soil texture is present
441 and where, consequently, more irrigation is simulated in the model due to the higher permeability of the soil.
442 The evaluation of the LAI simulation was limited to the regional scale analysis due to a lack of in situ vegetation data over the
443 selected test sites. The comparison between dekadal values of Noah-MP LAI, from both model runs, and the PROBA-V LAI
444 product was carried out over the reference period January 2015 to October 2019 using the temporal Pearson-R and the ratio
445 bias, shown in Figure 5.
446 Figure 5a and 5b show that the Pearson-R for vegetation has a lower median value of 0.67 when irrigation is simulated in
447 Noah-MP, whereas this value equals 0.72 for the *Natural* run. The difference between the two Pearson-R maps is shown in
448 Figure 5c, providing evidence of the areas facing a deterioration of the performance in terms of Pearson-R related to the
449 *Irrigation* run. This deterioration is particularly strong over cropland areas south to the Po river (red colour) while the northern
450 area also shows grid cells where the performance improves (blue colour).
451 By contrast, the ratio bias evaluation score (Figures 5d, 5e, 5f) highlights an improvement in long-term mean vegetation
452 simulations when irrigation is included (Figure 5e). Here the optimal condition is represented by a ratio bias equal to 1 when
453 the mean of the simulated LAI is equal to the mean of the observed LAI. In this context, Figure 5d displays ratio bias values
454 lower than one over a large central triangle-shaped cropland area and median ratio bias value of 0.73, highlighting an
455 underestimation of the LAI simulation related to the *Natural* run. Conversely, Figure 5e shows ratio bias values close to one
456 when irrigation is simulated over an extended cropland area and a median bias value of 0.99. The improvement given by the
457 *Irrigation* run is emphasized in Figure 5f where the histograms of the ratio bias distributions related to both model runs show
458 the higher performance of the *Irrigation* run (red) compared to the *Natural* run (blue) for which the distribution is more skewed
459 to the zero value.

460 **3.2 Noah MP site evaluation**

461 The Noah-MP SSM was evaluated at the Budrio test site field 2 (Figure 1a), using the daily reference PGR SM for the year
462 2017. Comparisons between the SSM simulations of the *Natural* and *Irrigation* runs with in situ PGR SM are shown in Figure
463 6a, while daily observed irrigation and rainfall data are compared with daily irrigation simulations in Figure 6b. Soil moisture
464 data are plotted at their original temporal resolution (i.e., daily) to illustrate an issue related to the irrigation timing: SSM
465 simulations in Figure 6a show the ability of the sprinkler irrigation scheme to simulate irrigation in the summer season, but

466 there is an inevitable problem in reproducing the correct timing and magnitude of irrigation. Indeed, the total amount of
467 simulated irrigation is 604 mm for the 2017 summer season, which overestimates the total amount of observed irrigation, being
468 349.5 mm. Furthermore, the model simulations not only miss irrigation, but also suffer from erroneous precipitation input,
469 such as on the 11th of July 2017, where the observed precipitation event in the growing season is not found in the model SSM
470 simulations. In any case, bi-weekly Pearson-R between simulated SSM and in situ PGR SM are higher for the *Irrigation* run
471 than for the *Natural* run (0.54 vs 0.42) suggesting the benefit in activating irrigation.

472 For the Budrio field 1 test site (Figure 1a), two summer seasons of irrigation data were available. To assess the irrigation
473 information contained in Sentinel-1 σ^0 observations (and the potential added value for a forthcoming DA experiment) we
474 compared bi-weekly values of Sentinel-1 σ^0 VV and VH with SSM estimates from both the *Natural* run and *Irrigation* run
475 (Figure 7a) for this site. Although the σ^0 VV is generally used to retrieve SSM (Wagner et al., 2013; Gruber et al., 2013; Bauer-
476 Marschallinger et al., 2018), data at both polarizations were analyzed in order to understand the soil contribution contained in
477 the two signals. Information related to the irrigation periods are shown in Figure 7c, where irrigation observations and irrigation
478 simulations from Noah-MP are compared. Figure 7a indicates that the SSM simulations are better reflected in the Sentinel-1
479 σ^0 VV than σ^0 VH data, particularly when irrigation is simulated (orange line). The SSM estimates from the *Natural* run (light
480 blue line) agree poorly with the Sentinel-1 data, with Pearson-R values equal to 0.32 and -0.1 for the σ^0 VV (blue dots) and σ^0
481 VH (cyan dots), respectively. When irrigation is simulated, the σ^0 VV data better follow the modelled SSM signal (Pearson-R
482 of 0.53) especially during the summer irrigation season when the backscatter signal remains higher and stable. On the other
483 hand, σ^0 VH seems to provide poor performances also when irrigation is simulated, with a Pearson-R value equal to 0.06,
484 confirming findings by Baghdadi et al. (2017) which highlighted how the use of VH alone to retrieve SSM is suboptimal when
485 vegetation cover is well developed.

486 In Figure 7b, the Sentinel-1 σ^0 CR (VH/VV) is compared with Noah-MP LAI from the *Natural* run (light-blue line) and
487 *Irrigation* run (orange line). The performance in terms of Pearson-R decreases from 0.76 to 0.65, when the irrigation is
488 simulated. This is due to a time shift of the Noah-MP LAI growing season in the *Irrigation* run. PROBA-V LAI (in green) was
489 additionally compared with the Sentinel-1 CR (blue dots) showing a Pearson-R of 0.84. The higher agreement between the RS
490 products (Sentinel-1 and PROBA-V) highlights the strong relation between the σ^0 CR and the vegetation signal, suggesting a
491 potential benefit of Sentinel-1 assimilation to correct the simulated vegetation phenology.

492 Finally, Figure 7c shows a comparison between 15-days accumulated mm of simulated irrigation (in orange) and observed
493 irrigation (in green). The Pearson-R is equal to 0.77, indicating that the sprinkler irrigation scheme can provide acceptable
494 irrigation estimates at this temporal resolution though absolute irrigation amounts are overestimated.

495 **3.3 WCM calibration**

496 The WCM parameters A and B (vegetation parameters), and C and D (soil parameters) were calibrated for each grid cell
497 separately during the reference period January 2017 to December 2019 (Figure 3), using daily σ^0 simulations and observations.
498 The calibrated parameters related to the entire study area for each of the eight experiments are shown in Figure 8 where the

499 blue left parts of the violin plots identify experiments of the *Natural* run, while the orange right parts of the violin plots are
500 related to the *Irrigation* run.

501 Generally, the *J*-calibration provides parameter distributions closer around their prior guess as compared to the *KGE*-
502 calibration for which the distributions are often multimodal, especially for the C and D parameters (i.e., Figure 8d, 8h). This
503 is due to the prior parameter penalty, which is included in the Bayesian solution but not in the *KGE*. In general, the calibration
504 of the two functions using the *Natural* run provides wider distributions between lower and upper boundaries for the A
505 vegetation parameter with a high number of grid cells characterized by A-values higher than 0.1 (see *KGE-VV Natural* and *J*-
506 *VV Natural* experiments in Figures 8a and 8e respectively). Conversely, the *Irrigation* run provides A distributions more
507 skewed to the lower boundary (being also the guess value in each calibration experiment), with a smaller number of grid cells
508 characterized by high A values compared to the *Natural* run. In a preliminary sensitivity study (not shown), we observed that
509 high values of the vegetation parameters A and B, as obtained for the *Natural* run, have the tendency to generate high peaks
510 in the simulated σ^0 during the growing season. Indeed, in the summer, the *SSM Natural* signal is low and not consistent with
511 the Sentinel-1 σ^0 , which observes irrigation. In order to follow the temporal dynamics of the Sentinel-1 σ^0 , the calibration
512 algorithms attribute a relatively higher weight (higher A values) to the LAI than to SSM to compensate for the underestimated
513 SSM in the *Natural* run. By contrast, the *Irrigation* run provides vegetation parameter distributions more skewed to the lower
514 boundaries (see also Section 3.4.2). The C and D parameter distributions feature a better sensitivity to soil moisture dynamics
515 using the *Irrigation* run input data, which is the expected behaviour considering that they describe the σ^0_{soil} . This is true
516 especially when using the *J* cost function (see parameters distributions for the *J-VV Natural* and for the *J-VV Irrigation*
517 experiments in Figures 8g and 8h), which results in more spread in the calibrated C and D distributions for the *Irrigation*
518 simulations (especially in VV polarization), whereas the mode of the C and D parameter distributions for the *Natural*
519 experiments is more shifted to the upper and lower boundaries, respectively.

520 Figure 9 shows the spatial pattern of the parameters over the study area to better understand the differences between the *Natural*
521 and *Irrigation* calibration runs. We found a connection between the WCM parameters distribution and model parameters, in
522 particular with the HWSD soil texture map (shown in Figure 2). For both the *J-VV Natural* and *J-VV Irrigation* experiments,
523 the activation of the irrigation scheme reduces the dependency of the vegetation-related parameters A and B on soil texture
524 (Figures 9a-b for the *J-VV Natural* and Figures 9e-f for the *J-VV Irrigation* experiment). This is also shown in the parameter
525 maps of the *KGE* calibration experiments (Figure S5 in the Supplementary material). Additionally, the activation of the
526 irrigation scheme, more realistically, shifts the soil texture dependency towards the soil parameters C and D (Figures 9g and
527 9h), highlighting another important reason for simulating irrigation.

528 Finally, the different polarization experiments generally provided similar distributions for the vegetation A and B parameters
529 and the D soil parameter. The largest differences between the VV and VH polarizations are identified for the C parameter
530 distributions. This is due to the lower σ^0 signal associated with the VH polarization. Indeed, Figure 8c and 8g are characterized
531 by higher values of the C in VV polarization, as compared to the distributions for VH polarization in Figures 8k and 8o. In the

532 latter, the C-VH distributions are generally more skewed to the lower boundary of the parameters, with median values closer
533 to the defined guess parameter value.

534 **3.4 WCM evaluation**

535 **3.4.1 Regional evaluation**

536 The regional evaluation of the calibration experiments was carried out during the period January 2015 to December 2016 for
537 agricultural areas within the study domain (almost 15,000 km²), by comparing bi-weekly σ^0 simulations with Sentinel-1 σ^0 in
538 terms of Pearson-R, KGE, and bias. The distribution of the evaluation metrics for the eight experiments is shown in Figure 10.
539 A comparison of the metrics for the *Irrigation* and *Natural* runs confirms better results when irrigation is activated, with violin
540 plots skewed towards more positive values for both KGE and Pearson-R. When stratified by the cost function, the Pearson-R
541 distribution in Figure 10a-d indicates slightly higher performance for the *KGE* (Figures 10a and 10c) than for *J* (Figure 10b
542 and 10d). In terms of the KGE score, simulations are naturally closer to the observations when the *KGE* cost function is used.
543 On the other hand, in terms of bias, generally better performances are found when the Bayesian solution is used (Figures 10i-
544 l). The latter is particularly evident for the VH polarization when comparing the *KGE-VH* and *J-VH* experiments (Figure 10k
545 and 10l).

546 The VH simulations exhibit a better performance in the *Irrigation* run than VV simulations (Figure 10c-d and Figure 10a-b).
547 Indeed, considering all the statistical scores, the VV polarization is characterized by more similar distributions between the
548 *Natural* and *Irrigation* run for both cost functions. This suggests a higher sensitivity of the VH polarization to the change of
549 vegetation introduced by irrigation, confirming the Sentinel-1 σ^0 VH to be strongly influenced by irrigation as witnessed by
550 the larger score improvement obtained for the calibration experiments *KGE-VH Irrigation* (Figure 10g) and *J-VH Irrigation*
551 (Figure 10h), compared to the *Natural* runs experiments.

552 In summary, i) VH polarization is more sensitive to the change in the cost function and input data (*Irrigation* or *Natural* run)
553 than VV polarization likely due to its higher sensitivity to vegetation change (Vreugdenhil et al., 2018; Macelloni et al. 2001)
554 which, in the area, is related to the crop development after irrigation, ii) the combination of *J* with activation of the irrigation
555 scheme is able to provide the best unbiased estimates of simulated σ^0 for both VV and VH (*J-VV Irrigation* and *J-VH irrigation*
556 experiments) at the price of generally lower correlations (compared to the *KGE* cost function). This is, however, beneficial for
557 DA as it minimizes the chance of potential error cross correlation between model estimates and observations. Indeed, the match
558 of the temporal dynamic of the signals induced by the correlation term is stronger in the *KGE* than in *J*, which additionally
559 includes a parameter constraint. The higher weight of the correlation in the *KGE* cost function can negatively impact the
560 parameter calibration even when irrigation is turned on in Noah-MP because the simulated irrigation applications are in general
561 not temporally consistent with those seen by Sentinel-1 (see Figure 6).

562 **3.4.2 In situ evaluation**

563 The WCM simulations are further analysed in detail at the Faenza test site (specifically for the San Silvestro field), because it
 564 has a larger extent than the Budrio site (see Figure 1), although the same overall conclusions were found for Budrio. Figure 11
 565 shows simulated and observed σ^0 time series for the different experiments highlighted in Figure 3, and Table 2 summarizes the
 566 statistics (i.e., Pearson-R, KGE and bias) of each experiment.

567 The agreement between simulated and observed σ^0 measured by the Pearson-R and KGE in Table 2 generally gives better
 568 performances after calibration with the *KGE* cost function than with the *J* cost function. An example is in the higher correlations
 569 found for the *KGE-VH Irrigation* experiment as compared to the *J-VH Irrigation* (Figures 11b and 11d respectively). On the
 570 other hand, in terms of bias the cost function *J* significantly outperforms the calibration with *KGE* in all experiments with
 571 surprisingly comparable values between *Natural* and *Irrigation* runs (Table 2).

572 One undesirable feature of *Natural* runs is the presence of high σ^0 peaks during the summer, clearly detectable over the Faenza
 573 test site, especially in the VH polarization, which are less evident in the *Irrigation* run (see Figure 11b and 11d). A similar
 574 behaviour was found for Budrio (not shown). These peaks are likely attributed to the poor estimation of model vegetation
 575 parameter values, previously discussed in section 3.3, when the WCM attempts to compensate for bias in SSM and vegetation
 576 input, i.e., input that is not consistent with observations over irrigated areas. This is particularly true for the *KGE* calibration,
 577 which does not use a prior parameter constraint. In contrast, the *J* calibration still provides reasonable σ^0 simulations that are
 578 closer to the ones of the *Irrigation* run due to the Bayesian technique itself.

579 **Table 2: Results of the site WCM evaluation considering the test site Faenza San Silvestro for each WCM experiment**

	<i>KGE-VV</i> <i>Natural</i>	<i>KGE-VV</i> <i>Irrigation</i>	<i>J-VV</i> <i>Natural</i>	<i>J-VV</i> <i>Irrigation</i>	<i>KGE-VH</i> <i>Natural</i>	<i>KGE-VH</i> <i>Irrigation</i>	<i>J-VH</i> <i>Natural</i>	<i>J-VH</i> <i>Irrigation</i>

580

581 **4 DISCUSSION**

582 **4.1 Noah-MP irrigation modelling**

583 The Noah-MP LSM, used as input for the WCM calibration, was evaluated in two configurations, either with a sprinkler
 584 irrigation scheme activated or without irrigation (i.e., *Irrigation* run and *Natural* run). Although not all of the Po river valley

585 is irrigated by sprinkler systems, it most likely still leads to more realistic LSM simulations than not considering irrigation at
586 all.

587 The main limitation found in the irrigation simulations was related to the irrigation timing and magnitude that was inconsistent
588 with observations. Although this finding is based on only a single study site, it is very likely that it is a widespread issue within
589 the study area for several reasons. In LSMs, the irrigation application is driven by the RZSM availability and consequently by
590 the soil type and the rooting depth parametrizations. Moreover, it is also influenced by the accuracy of the meteorological
591 forcings (especially precipitation, Reichle et al. 2017) which can determine errors in the soil moisture representation. The main
592 reason, however, is likely that irrigation is often the result of subjective farmer decisions rather than objective rules based on
593 the soil state and crop conditions. In theory, the irrigation timing issue could be partly solved by using temporally consistent
594 high-resolution crop maps which should provide a more realistic information of crop phenology and rooting depth. However,
595 in practice, this is unfeasible over many areas of the world given the absence of this information on a large scale. Also, given
596 that irrigation applications are mainly linked to unmodelled processes like rotation schedules for farmers to withdraw water,
597 the correct simulation of the timing can be unsolvable when using models only.

598 Despite the potential problems related to the unrealistic assumptions in the simulation of irrigation, our results demonstrated
599 that even the use of simple irrigation schemes within Noah-MP can be beneficial. In the regional evaluation, SSM simulations
600 of the *Natural* and *Irrigation* runs were compared with RS SSM from SMAP and ASCAT (Figure 4) on a bi-weekly temporal
601 scale. For both products, we found large improvements in temporal Pearson-R when irrigation was simulated, confirmed by a
602 decrease in the RMSE values over croplands, suggesting that the activation of irrigation modelling provides more realistic
603 SSM estimates. Our findings further confirm the potential of coarse resolution datasets for providing irrigation-related
604 information over intensively irrigated and relatively large agricultural areas, as was shown by Kumar et al. (2015a).

605 While the impact of irrigation was clear in terms of SSM, the regional evaluation of the simulated LAI against the PROBA-
606 V-based LAI provided contradicting results. In this case, the Pearson-R analysis suggested a deterioration of the Noah-MP
607 simulated LAI when irrigation was activated over the cropland area. We interpreted this correlation deterioration by the
608 absence of specific information about the crop phenology in the model parameterization. In practice, information about the
609 specific crop type is not available and the rooting depth is the sole parameter controlling water uptake from the soil layers.
610 Additionally, information on sowing and harvest periods are not included in the current version of Noah-MP, while irrigated
611 areas are defined based on a global dataset (Salmon et al., 2013) which can suffer accuracy limitations. Indeed, the absence of
612 annual dynamic information on irrigated fields, the unknown yearly variability of the crop types and the impact of the
613 meteorological conditions in the stakeholders decision process (i.e., sowing) make the simulation of Noah-MP prone to LAI
614 peak shifts, as compared to observations, when irrigation is simulated. Another important aspect affecting LAI simulations is
615 its sensitivity to root zone soil moisture, which might be more difficult to simulate than SSM during the irrigation season due
616 to larger impacts of the soil texture and transpiration processes along with the high frequency of the wetting and drying phases
617 caused by irrigation events. This results in a significant performance deterioration (often worse than LAI simulation not
618 including irrigation which are mainly driven by seasonality, see Figure 7). By contrast, irrigation modeling helps in reducing

619 the bias of the LAI simulated time series, which, in the cropland area, show a significant underestimation when irrigation is
620 not considered.

621 The limitations found in simulating LAI and vegetation by Noah-MP even when irrigation was simulated could potentially be
622 overcome by assimilating Sentinel-1 σ^0 data. To explore this potential, we compared the LAI from both model runs, and from
623 PROBA-V, with the observed Sentinel-1 σ^0 CR (VH/VV), which should provide information about the vegetation dynamics
624 (Vreugdenhil et al. 2018; Vreugdenhil et al. 2020). We found that the correlation between σ^0 CR and LAI from PROBA-V was
625 much higher than that between σ^0 CR and the simulated LAI by Noah-MP (see Figure 7) suggesting that Sentinel-1 σ^0 DA
626 could help in correcting poor LAI model simulations. Additionally, a higher correlation was found between the σ^0 VV
627 observations and the simulated SSM when irrigation was turned on than in the absence of irrigation, suggesting that the
628 assimilation of σ^0 VV could improve SSM where irrigation is poorly or not modelled. On the other hand, considering the low
629 correlation between the VH signal and SSM in presence of vegetation (Baghdadi et al. 2017), and its close relation with
630 vegetation (Ferrazzoli et al., 1992; Macelloni et al., 2001), future data assimilation experiments will investigate the contribution
631 of VH and CR in improving LAI predictions and irrigation quantification.

632 Finally, by-weekly accumulated irrigation estimates in Figure 7 agree well with real irrigation applications, suggesting that the
633 large-scale LSM irrigation scheme is helpful for intensively irrigated areas. On the other hand, the poor soil and crop
634 parameterization along with other unknown parameters related to the irrigation management (e.g., the farmers can apply more
635 water than actually needed) can cause large biases in these irrigation simulations. Again, ingestion of radar backscatter data
636 could correct for unmodelled processes. More specifically, Sentinel-1 σ^0 could correct: (i) for the magnitude and timing of the
637 irrigation simulations; and (ii) for Noah-MP irrigation predictions over not irrigated regions.

638 **4.2 WCM backscatter simulation**

639 The purpose of the presented WCM observation operator calibration and evaluation was to optimize the parameters for the
640 future assimilation of the Sentinel-1 σ^0 VV and VH into Noah-MP. Such an optimization would ideally minimize the long-
641 term bias between the simulated and observed σ^0 signals. This can be achieved by calibrating the observation operator with
642 long-term observed σ^0 prior to data assimilation, but in this process, it is crucial to avoid potential error cross-correlation
643 between model observation predictions and observations. Furthermore, a good observation operator should not already
644 compensate for missing processes in the LSM by accepting effective, but unrealistic, optimized parameters, because it would
645 then lose its physically-based ability to accurately convert misfits between observations and simulations to LSM updates during
646 the data assimilation.

647 One way to avoid parameters compensation for erroneous LSM input into the WCM would be to use observed time series of
648 e.g. LAI. However, LAI products from different sensors have different biases themselves which can add bias to the σ^0
649 simulations, and more importantly, replacing simulated LAI or SSM with external datasets would undermine the possibility of
650 updating these variables in the future assimilation system. Based on that, we performed the WCM calibration considering SSM
651 and LAI model input from two different experiments: a *Natural* run and an *Irrigation* run, as well as two cost functions, a

652 Bayesian solution J and a KGE solution which resulted in four calibration experiments for each polarization (i.e., eight
653 calibration experiments in total).

654 The calibration experiments using simulations from the *Natural* run as input showed a limited performance and provided
655 presumably bad vegetation parameter estimates which resulted in unrealistic peaks in the simulated σ^0 during the summer,
656 when driven by higher modelled LAI during this period. The inclusion of the irrigation within Noah-MP was very beneficial
657 for all the calibration experiments helping in reducing the bias and increasing the correlation with Sentinel-1 σ^0 as well as
658 removing the anomalous σ^0 increase during warm periods especially for the KGE -based calibration. This corroborates our
659 initial hypothesis that, over intensively irrigated areas, the simulation of irrigation is a mandatory task for an optimal calibration
660 of the WCM. Irrigation modeling, even if only done approximately and perhaps with inaccurate timing, reduces obvious land
661 surface (soil moisture, vegetation) bias and avoids that the WCM needs to compensate for this bias.

662 Our results show overall higher performance in terms of KGE and Pearson-R scores for the KGE -based calibration, whereas
663 the long-term bias was better reduced for the J -based calibration, which is beneficial in anticipation of future DA. This is
664 because in the J cost function i) a target accuracy term which takes into account also the Sentinel-1 observations error is
665 present; and, ii) a parameter deviation penalty based on the prior parameters constraints is used, which avoid parameters to
666 largely deviate to their prior values.

667 In terms of polarization, we found σ^0 VH simulations much more sensitive to the inclusion of the irrigation (vs non inclusion)
668 in Noah-MP, suggesting that observed σ^0 VH might also contain much more information about irrigation (via the influence of
669 the vegetation change due to irrigation) than that contained in σ^0 VV which is normally used for SSM retrieval (Vreugdenhil
670 et al. 2020). We believe that the cause of this is related to a comparatively larger σ^0 of vegetation with respect to that of the
671 soil when the crops are well developed. This was also corroborated by the better agreement between CR and LAI from PROBA-
672 V in one of the study sites mentioned above. Despite this, further investigations are required to confirm this hypothesis and
673 DA will certainly help to test this aspect.

674 **5 CONCLUSIONS**

675 With the specific focus on intensively irrigated land, the main objective of this work was to define the optimal calibration of
676 the WCM as observation operator for the future ingestion of Sentinel-1 backscatter into the Noah-MP LSM via DA. In this
677 context, we additionally aimed at: 1) unveiling strengths and limitations of irrigation simulation in LSMs from the perspective
678 of a calibrating the WCM; 2) identifying the potential irrigation-related information contained in the Sentinel-1 σ^0 observations
679 to improve soil moisture and vegetation states as well as irrigation estimates in a calibrated DA system.

680 To reach these objectives we coupled the Noah-MP with a sprinkler irrigation scheme within LIS and performed two different
681 simulation experiments, one with and one without irrigation (i.e., *Natural* and *Irrigation* runs). Moreover, we coupled a WCM
682 with Noah-MP and tested different calibration options to prepare for optimal, future, assimilation of σ^0 VV and VH to update
683 both soil moisture and vegetation states.

684 The main conclusions drawn from our evaluation are as follows:

- 685 ● Over highly irrigated areas, the simulation of irrigation in LSMs helps to provide better soil moisture and vegetation
686 simulations which can be used with benefit as input for the WCM calibration. However, the performance of the
687 irrigation simulations is limited by the simplistic model parameterization of this human process and the necessity to
688 consider realistic and updated land cover information (e.g., crop types). This results in poor simulations of the
689 irrigation timing and quantities as well as vegetation dynamics.
- 690 ● The Sentinel-1 σ^0 observations contain useful information about SSM and vegetation over highly irrigated areas. This
691 information can be exploited to overcome LSM deficiencies in simulating soil moisture and vegetation over highly
692 irrigated regions, e.g., when irrigation is unmodeled, or poorly modeled because of uncertainties due to crop types,
693 irrigation timing, and farmer agricultural practices. In particular, there is a high chance that the assimilation of
694 Sentinel-1 σ^0 can help in correcting LAI dynamics.
- 695 ● The optimal assimilation of Sentinel-1 σ^0 into a LSM must rely upon a well calibrated WCM as observation operator
696 to provide unbiased σ^0 simulations with a minimal chance of having error cross-correlations between model and
697 observations, while ensuring a realistic operator controllability or realistic connection between observed signals and
698 land surface state variables. We demonstrated that calibrating the WCM with inclusion of irrigation modeling
699 consistently led to a better agreement with Sentinel-1 σ^0 . The modeling of irrigation in the LSM simulations, even if
700 not done optimally, avoids that the WCM calibration compensates for LSM biases.
- 701 ● We demonstrated that the WCM calibration with a Bayesian cost function, including a prior parameter constraint,
702 provides the optimal WCM parameters, able to generate the lowest bias in the σ^0 simulations for both VV and VH.
703 Although slightly higher correlations are obtained when using a *KGE* cost function, unbiased estimates are
704 particularly beneficial for DA as this minimizes the chance of potential error cross-correlation between model
705 estimates and observations.

706 This study improves the understanding of the LSM limitations in simulating irrigation and highlights the information content
707 in Sentinel-1 σ^0 data. A natural follow up of this study is the assimilation of σ^0 observations within Noah-MP which should
708 enforce our tested evidence and provide new insights for a more realistic description of the water and carbon cycles over
709 irrigated areas.

710 **ACKNOWLEDGEMENT**

711 The authors would like to thank the European Space Agency (ESA) for the funding support as part of the IRRIGATION+
712 project (contract n. 4000129870/20/I-NB). For details please visit <https://esairrigationplus.org/>. Additional acknowledgements
713 go to the Canale Emiliano Romagnolo (CER; Emilia Romagna, Italy) for providing irrigation data over the irrigated test sites.
714 For the Proximal Gamma Ray soil moisture data at the Budrio test site the Authors would like to thank the Department of
715 Physics and Earth Sciences, University of Ferrara Polo Scientifico e Tecnologico, and in particular Dr. Martina Natali, Dr.

716 Virginia Strati, Dr. Alberi Matteo, Dr. Kassandra Giulia Raptis and Prof. Fabio Mantovani. Additionally, the authors want to
717 acknowledge the Vlaams Supercomputer Centrum (VSC) High Performance Computing (HPC) for providing the
718 computational resources needed to realize this study (<https://www.vscenrum.be/>). Alexander Gruber has received funding
719 from the Research Foundation Flanders (FWO-1224320N and FWO-1530019N).

Figure 11: Comparisons between σ^0 observations (VV polarization in blue dots and VH polarization light blue dots) and simulations (VV polarization in red and VH polarization in green) in the Faenza San Silvestro field, after calibration with a *KGE* cost function for a) the *Natural* run, b) *Irrigation* run, and after calibration with the *J* cost function for c) the *Natural*, and d) *Irrigation* run.

1019

1020

1021 **Code and Data availability.**

1022 Data from SMAP can be downloaded at https://nsidc.org/data/SPL2SMP_E/versions/4

1023 Data from ASCAT are available at the website <http://hsaf.meteoam.it/>

1024 The Sentinel-1 backscatter data processing was done using Google Earth Engine's Python interface and including standard
1025 processing techniques

1026 Data from PROBA-V are available at <https://land.copernicus.eu/global/>

1027 MERRA-2 data are available at MDISC, managed by the NASA Goddard Earth Sciences (GES) Data and Information Services
1028 Center (DISC, <https://disc.gsfc.nasa.gov/datasets?project=MERRA-2>)

1029 LIS input and general parameters tables are provided at https://portal.nccs.nasa.gov/lisdata_pub/data/

1030 In situ data are available under request to the original providers.

1031

1032 **Author contributions:** Sara Modanesi designed, coordinated the study and made the analyses. Christian Massari, Gabrielle
1033 De Lannoy and Alexander Gruber designed, coordinated and helped in the data analysis and interpretation. Hans Lievens,
1034 Angelica Tarpanelli and Renato Morbidelli helped in the result interpretation and data processing and collection. All authors
1035 contributed to the editing of the manuscript.

1036

1037 **Competing interests.** The authors declare no competing interest
