ABSTRACT

10 Climate resilience is an emerging issue at contaminated sites and hazardous waste sites, since projected climate shifts (e.g., increased/decreased precipitation) and extreme events (e.g., flooding, drought) could affect ongoing remediation or closure strategies. In this study, we develop a reactive transport model (Amanzi) for radionuclides (uranium, tritium, and others) and evaluate how different scenarios under climate change will influence the contaminant plume
15 conditions and groundwater well concentrations. We demonstrate our approach using a two-dimensional reactive transport model for the Savannah River Site F-Area, including mineral reaction and sorption processes. Different recharge scenarios are considered by perturbing the infiltration rate from the base case, as well as considering cap failure and climate projection scenarios. We also evaluate the uranium and nitrate concentration ratios between scenarios
20 and the base case to isolate the sorption effects with changing recharge rates. The modeling results indicate that the competing effects of dilution and remobilization significantly influence pH, thus changing the sorption of uranium. At the maximum concentration on the breakthrough curve, higher aqueous uranium concentration implies that sorption is reduced with lower pH due to remobilization. To better evaluate the climate change impacts in the future, we develop the workflow to include the downscaled CMIP5 (Coupled Model Intercomparison Project) climate
25 projection data in the reactive transport model, and evaluate how residual contamination evolves through 2100 under four climate Representative Concentration Pathway (RCP) scenarios. The integration of climate modeling data and hydro-geochemistry models enables us to quantify the climate change impacts, assess which impacts need to be planned for, and
30 therefore assist climate resiliency efforts and help guide site management.

1. INTRODUCTION

Changing climate may pose a major risk in environmental remediation, especially with regard to the fate, transport, including both hydrologic and reactive processes (Maco et al., 2018). In
35 particular, many sites are managed with monitored natural attenuation strategies where an expanded contamination plume with high concentrations of tritium, uranium and other chemical species remain in the subsurface (Denham et al., 2020). Hydrological shift has been identified as one of the key drivers influencing such risk and uncertainty. In a changing climate, precipitation and evapotranspiration (ET) regimes can change both in magnitude and timing,

Deleted: significant amount of residual contaminants

significantly affecting infiltration. Precipitation regimes are expected to change depending on where the site is located (e.g., Lambert et al., 2008). Increasing ETs usually predicted in climate model projection, due to increasing temperatures under global warming (e.g., Abteu and Melesse, 2013, Milly and Dunne, 2016). Extreme events, such as heavy rain and prolonged droughts, are expected to become more frequent and thus may result in faster plume remobilization (e.g., Rahmstorf and Coumou, 2011).

Deleted: evapotranspiration

Deleted:

We may define climate resilience at contaminated sites as the capacity of individual waste disposal sites to return back to the system's original condition when affected by climate trends, climate variability, extreme events, and other climate-change-related impacts. A critical need exists for understanding climate change impacts on contaminated sites (e.g., U.S. EPA, 2014 and DOE, 2017), however, a quantitative estimation with climate change projection is still missing. Evaluating the effect of climate change on the abundance of water resources has been widely studied (e.g., Gellens and Roulin, 1998; Green et al., 2011; Middelkoop et al., 2001; Pfister et al., 2004), however, water quality and contamination issues were less investigated (Visser et al., 2012). Most previous researches study surface water (Wilby et al., 2006; Van Vliet and Zwolsman, 2008; Van Bokhoven, 2006; Futter et al., 2009; Schiedek et al., 2007), because of the accessibility and data availability (Green et al., 2011). In the limited studies for climate change impacts on groundwater in the subsurface domain, agricultural effluents at the regional scale are the research focus (Bloomfield et al., 2006; Futter et al., 2009; Li and Merchant, 2013; Olesen et al., 2007; Sjoeng et al., 2009; Whitehead et al., 2009; Wilby et al., 2006; Darracq et al., 2005; Destouni and Darracq, 2009; Park et al., 2010).

Deleted: absorb the projected stresses imposed

Deleted: Despite the critical need to evaluate the risks associated with climate change, there is only a limited number of studies that have addressed the effects of climate change on contaminant transport and environmental remediation

Recently, Libera et al. (2019) investigated the potential impact of climate change on residual contaminants in vadose zones and groundwater, using a groundwater flow and transport model. They investigated the complex effect of precipitation and recharge shifts, leading to either dilution and remobilization of residual contaminants. Libera et al (2019) showed that the effects of dilution and remobilization on contaminant concentrations before and after changing precipitation, depending on the well locations, and that surface barrier and source zone monitoring are critical for mitigating the impact. However, Libera et al. (2019) only simulated tritium with decay, but did not couple with a reactive transport model to simulate other chemical species, sorption, and mineral reactions. In this study, we hypothesized that increasing recharge would decrease reactive species concentration further, since increasing the volume of water in the domain would increase pH, which limits the mobility of uranium. The impact of hydrological shifts on reactive contaminants is expected to be more complex, especially redox and pH-sensitive heavy metals. Remobilization would also be affected by additional clean infiltration water. To test those hypotheses and evaluate the impacts, process-based flow and reactive transport models that can characterize sorption and ion exchange processes are essential for quantitatively analyzing the contaminant plume and understanding climate resilience.

Deleted: While the impact of climate change has been investigated extensively from the perspective of water resources (Gellens and Roulin, 1998; Green et al., 2011; Middelkoop et al., 2001; Pfister et al., 2004), only a few studies have addressed water quality issues (Visser et al., 2012). Moreover, most of the scientific literature focuses on surface water (Wilby et al., 2006; Van Vliet and Zwolsman, 2008; Van Bokhoven, 2006; Futter et al., 2009; Schiedek et al., 2007), due to its visibility and accessibility (Green et al., 2011), while studies on groundwater are mostly focused on agricultural effluents at the regional scale (Bloomfield et al., 2006; Futter et al., 2009; Li and Merchant, 2013; Olesen et al., 2007; Sjoeng et al., 2009; Whitehead et al., 2009; Wilby et al., 2006; Darracq et al., 2005; Destouni and Darracq, 2009; Park et al., 2010). ¶

Deleted: appear in different phases

Deleted: ,

Deleted: which is a nonreactive contaminant

Deleted: Large uncertainties still remain, particularly for reactive contaminants, due to complex geochemical processes in the subsurface.

This study aims to evaluate the effects of climate-driven hydrological shifts on (1) reactive contaminants and (2) mineral reactions in vadose zones and groundwater. We assume that the effect of changing precipitation and temperature can be represented by perturbations/shifts in natural recharge through the aquifer system. In our case, climate resilience is evaluated by the

120 concentrations of monitoring wells after climate events in comparison to the background
baseline concentrations. We demonstrate our approach at the Department of Energy (DOE)'s
Savannah River Site (SRS) F-Area Seepage Basins, South Carolina (SC), USA, where soil and
groundwater have been contaminated by various metals and radioactive contaminants. This is
125 the same site studied by Libera et al. (2019). The SRS F-Area seepage basin was chosen
because of the historic contamination monitoring activities, and extensive characterization and
model development (e.g., Flach, 2004; Bea et al., 2013; Sassen et al., 2012; Wainwright et al.,
2014, 2015, 2016; Denham and Eddy-Dilek, 2017; Libera et al., 2019). More importantly, the
130 contamination in F-Area is representative that our study may provide broader insights to other
contamination sites. The vadose zone residual contaminants are quite common (e.g., Stubbs et
al., 2009; Zachara et al., 2005) and also the contaminant export through the wetland region are
fairly common features across many contaminated sites as well (e.g., Mansoor et al., 2006; Li et
al., 2014, Change et al., 2014). Hence, the SRS has become a unique study site for
investigating the potential consequences of climate change on contamination remobilization and
135 mineral reactions/interactions. Our research focuses on the effect of climate change on
progress toward return to natural conditions of the plume between the basins and the funnel-
and-gate. This is important to the timing of the transition of the site from enhanced to monitored
natural attenuation, and hence, important to the overall effectiveness of remediation. More
importantly, this work will support the risk management under changing climate conditions.

Deleted: Extensive subsurface characterization and datasets at the SRS F-Area, including groundwater chemistry and water level data from over 100 wells, geophysical data, and various hydrological tests, enabled the development of a subsurface model that can be considered as a testbed for flow and transport studies (Flach, 2004; Bea et al., 2013; Sassen et al., 2012; Wainwright et al., 2014, 2015, 2016; Denham and Eddy-Dilek, 2017; Libera et al., 2019).

2. SITE DESCRIPTION

140 The Savannah River Site F-Area in South Carolina is approximately 100 mi (i.e., 161 km) away
from the Atlantic Ocean and occupies an area of about 800 km² (Figure 1). The site was used to
produce special radioactive isotopes, plutonium, and tritium, for nuclear weapons during the
Cold War Era. The F-Area is located in the north-central part of SRS. There are three
145 hydrostratigraphic units within the Upper Three Runs Aquifer, shown in Figure 1 (B): an Upper
Aquifer zone (UUTRA), a Tan Clay Confining Zone (TCCZ), and a Lower Aquifer zone (LUTRA).
The UUTRA and LUTRA are mainly composed of clean sand, while the TCCZ is a low-
permeability mixed sand-and-clay layer. The piezometric head measurements indicate that the
UUTRA and LUTRA units are hydrologically connected. The bottom of the LUTRA consists of a
150 competent clay layer confining unit that separates the deeper aquifer (Gordon Aquifer) from the
upper two aquifer units (Figure 1). The historical monitoring data collected at the SRS have
shown that the F-Area contaminant plume migrates within the UUTRA and LUTRA (Figure 2),
discharging into a local stream called Fourmile Branch Creek (FMB).

Deleted: - the continuous Gordon Confining Unit - which

Deleted: .

155 Low-level radioactive acidic waste was disposed of in three separate unlined seepage basins
(F-1, F-2, and F-3) and leached into the groundwater. The basins received approximately 7.1
billion liters of waste solutions from processing irradiated uranium between 1955 and 1988.
After the waste discharge operation was terminated in 1988, the F-Area basins were closed and
capped with a low-permeability material. Currently, an acidic contaminant plume extends from
160 the basins approximately 600 m downgradient to the groundwater seepage near the FMB.

Deleted: Fourmile Branch Creek

175 Several measures have been taken to reduce the environmental impacts at the F-Area site,
including capping the basins and pump-and-treat remediation of contaminated groundwater.
Since 2004, the site has been undergoing enhanced natural attenuation using a funnel-and-gate
system, which consists of groundwater flow barriers to decrease the groundwater gradient, and
base injection to neutralize pH and in turn immobilize uranium. The funnel-and-gate system is
operating and requires the periodic injection of base solution to increase pH and immobilize
180 contaminants. Quantitative estimation from the modeling study will provide insights for site
management and stakeholders on when it is appropriate to transition the site to natural
attenuation status without any treatments. Despite the many active remediation measures, the
groundwater remains unnaturally acidic upgradient of the funnel-and-gate and contaminated
with various radionuclides.

185 One characteristic of the SRS F-Area is the high acidity of the plume, making U(VI) highly
mobile. The natural groundwater pH is slightly acidic, between 5.0 and 6.0, and decreases to
values approaching 3.2 in the most contaminated locations. Despite many years of active
remediation, contaminated groundwater still remains highly acidic, and the concentrations of
190 U(VI) and other radionuclides are still significant (Seaman et al., 2007, Savannah River Nuclear
Solution, 2021). It should be noted that in the acidic pH range at the SRS-F-Area, K_d values for
U(VI) could change between 10^2 to 10^6 (Davis et al., 2004; Dong et al., 2012). In addition,
competing sorption between U(VI) and H^+ is important in remediation and has been well studied
in the F-Area site (Davis et al., 2004, Bea et al., 2013, Arora et al., 2018). Because of the
195 difficulty and apparent uncertainty in assessing the adsorption properties and mobility of U(VI)
under complex geochemical conditions in groundwater, several researchers have performed
quantification (UQ) related to U(VI) and H^+ competing sorption in the F-Area site (e.g., Curtis et
al., 2006; Hammond et al., 2011).

3. MODELING METHODS

3.1. Reactive Transport Modeling with Amanzi and PFLOTRAN

250 Groundwater flow and contaminant transport are simulated by the numerical code Amanzi (Moulton et al., 2013, <https://github.com/amanzi/amanzi>), which provides a flexible and extendable parallel flow and reactive transport simulation capability for environmental applications. Amanzi has the capabilities to solve coupled unsaturated and saturated groundwater flow, as well as advection-dispersion transport equations. It includes a general polyhedral mesh infrastructure, and provides multiple advanced nonlinear solvers with open source libraries. The reaction of contaminants and minerals carried by flow through the surrounding rock and soil is modeled by coupling with the geochemistry engine of PFLOTRAN (Lichtner et al., 2015) via the generic interface Alquimia (<https://github.com/LBL-EESA/alquimia-dev>). PFLOTRAN simulates the mineral reactions, adsorption, and ion exchange, while groundwater flow and transport are simulated by Amanzi.

260 3.2. Model Setup and Boundary Conditions

The two-dimensional (2D) flow and transport Amanzi model developed in Libera et al. (2019) was employed and expanded with the coupling of reactive transport model in this study. Our Amanzi simulation used the same conditions of mineral composition and kinetic reactions as the TOUGHREACT model in Bea et al. (2013). The 2D domain is approximately 2600 m long and 100 m deep along the groundwater flow line, passing through the middle of the F-3 basin of the SRS. Bea et al. (2013) calibrated the model and verified it using observational geochemical concentration data from several monitoring wells, and also evaluated the sensitivities of key parameters in the modeling. The model includes the vadose zone and three hydrostratigraphic units (i.e., UUTRA, LUTRA and TCCZ) defined in the previous section. We assume homogeneous average hydrogeological properties within each unit (see Table 2), whose values are compiled from available site investigation reports. Table 1 specifies porosity, permeability, and capillary pressure/saturation data for the vadose zone (Flach et al., 2004; Bea et al., 2013). The system is considered to be advection dominated. Based on the study of scale-dependent advection and dispersion processes in Molz (2015) that states contaminant transport will be typically dominated by advection at scale of 1000 meter, the system is considered to be advection dominated, and mechanical dispersion and molecular diffusion transport processes are neglected.

While Bea et al. (2013) implemented an electrostatic sorption model developed previously by Dong et al. (2012), which is less numerically efficient and requires additional parameterization. Arora et al. (2018) developed a non-electrostatic sorption model (NEM) at the F-Area site, and demonstrated that NEM achieved the same predictive performance as a surface complexation model (SCM) with electrostatic correction terms. The SCM approach is computationally expensive and requires the estimation of additional parameters that describe mineral surface characteristics. On the other hand, NEM does not consider the effects of the development of surface charge on the formation of surface complexes, and it also simplifies the parameters needed in the reactive transport modeling. In Arora et al. (2018), three mineral surface sites with different site densities and acidity constants are developed for modeling H^+ sorption and transport, then further extended to noncompetitive and competitive H^+ and U(VI) . In this paper, we use the competitive H^+ and U(VI) sorption NEM parameters (including site density and surface complexation constant listed in Table 4), which are derived from an inverse analysis and calibration by Arora et al. (2018), and implement them in the model.

3.3. CMIP5 Climate Scenarios

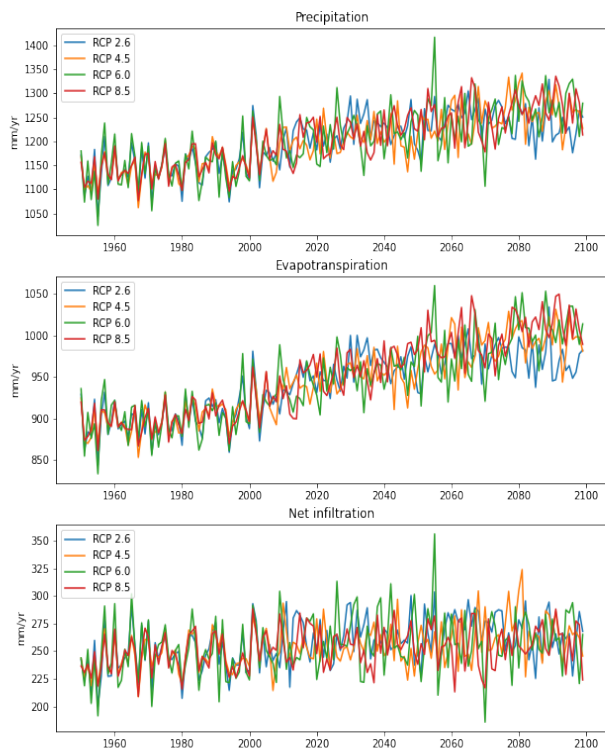

370 CMIP5 (Coupled Model Intercomparison Project, Taylor et al. (2012) is an experimental protocol
with an ensemble of global climate model outputs to improve understanding of climate, and to
provide estimates of future climate change that will be useful to those considering its possible
consequences. The climate forcing in our study used the 1/8-degree downscaled CMIP5
outputs at the F-Area study site from January 1950 to December 2100. The ensemble outputs
include 28 models with four climate scenarios (RCP2.6, 4.5, 6.0 and 8.5) in the future climate
375 projection. The top soil at the F-Area study site is sandy (Wainwright et al., 2014), so we
assume that surface runoff is negligible. In other words, infiltration is calculated by subtracting
evapotranspiration (ET) from precipitation, which are simulated by the atmospheric and land
surface models, respectively, from the coupled climate models. The figure below shows that the
10-year moving average of selected variables demonstrates that both precipitation and ET have
380 increased approximately 6% since the 1950s to the present, and will keep increasing up to an
additional 6% by the end of this century. The differences among climate scenarios are not
statistically significant, but the highest greenhouse gas concentrations (i.e., RCP8.5) ensemble
simulates higher precipitation and ET than others. Although total recharge only slightly
increases as both precipitation and ET are increasing (hence the difference offsets), our
385 simulations focus on gaining the understanding and quantitative estimation of changing climate
impacts on the long-term robustness of contamination remediation in the F-Area.

Deleted: evapotranspiration

Deleted:

Deleted: evapotranspiration

Deleted: Although both precipitation and evapotranspiration are increasing (hence the difference is offset), the total runoff still slightly increases, with significant variability among climate scenarios over time (Figure 3).

400 Figure 3. Simulated precipitation, evapotranspiration, and net infiltration (precipitation - evapotranspiration) at different climate projection scenarios from the CMIP5 datasets.

3.4. Modeling Scenarios

405 The modeling scenarios were developed based on (Libera et al., 2019) are only briefly described here. The modeling scenarios cover two stages of the F-Area historical operation and one additional stage in the future projection. The waste disposal was active during the period 1955-1988, and the basins were capped in 1988, when seepage from the basins into the

410 vadose zone is assumed to have stopped. This study evaluates the effect of climate-change-
induced variations in recharge on contaminant transport after 2020. A base case was developed
with a constant recharge rate throughout the simulation period for assessing climate change
impacts. The uniform recharge rate is 4.743×10^{-6} kg-water/m²/sec (0.15 m/yr infiltration rate),
based on the estimation in Bea et al. (2013). Furthermore, we developed three perturbed
recharge scenarios with respect to the baseline recharge conditions. The three scenarios are:
415 (1) constant positive recharge shift from 2020, i.e., increasing precipitation scenarios; (2)
constant negative recharge shift from 2020, i.e., decreasing precipitation scenarios; and (3) cap
failure and constant positive case from 2020. In both increasing and decreasing scenarios,
recharge changes 10%-50% after 2020. we hypothesize a complete failure of the containment
structure scenario, which is represented by increased source-zone recharge of 10%-50% to the
level of the surrounding region. Multiple studies have demonstrated that increased vegetation or
other mechanisms could threaten or completely damage the integrity of the source-zone
capping structure (Worthy et al., 2013, 2015). In addition to the perturbation scenarios, the
contaminant transport and plume remobilization simulated by Amanzi are also forced by the four
projection scenarios of CMIP5 ensemble climate model data, i.e., climate model scenarios.
420 Instead of the constant recharge rate in those scenarios with changing precipitation, the annual
recharge rate is used in CMIP5 climate scenarios from 1950 to 2100.

4. RESULTS

4.1. Base Case

430 The plume migration is depicted in Figure 4 for the base-case results described in Bea et al.
(2013). The plume migrates through the vadose zone and then infiltrates vertically downward
until it reaches the groundwater table (Figure 4a). The plume then migrates vertically through
the TCCZ into the LUTRA, and also horizontally downstream closer to the FMB (Figure 4b).
Despite the low permeability of the TCCZ, leakage from the UUTRA to the LUTRA is observed
over most of the flow domain. After basin closure and capping, the seepage from the basin is
435 assumed to stop. The uncontaminated groundwater arriving from upgradient increased pH and
reduced the U(VI) concentration (Figure 4c). After the basin closure, because the vadose zone
flow stops, pH remains low and U(VI) concentrations high in the vadose zone. In addition, the
uranium concentration is higher in the TCCZ, where the permeability is low. The vadose zone
below the basin appears to act as a long-term contaminant source for groundwater in the
440 deeper layers (Figure 4d). Although aqueous uranium concentration decreased by several
orders of magnitude after the basin was capped, it is still higher than background concentration.

455 Figure 4. Plume profile of aqueous uranium concentration in the downstream of F-Area study site from 1954 to 2020 in the base case simulation.

460 Figure 5 shows the base-case breakthrough curves of pH, aqueous uranium, tritium, and nitrate at the source-zone well (FSB-95DR) and the downgradient well (FSB-110D) for the full simulation period (1956-2100). Both wells are located in the UUTRA layer. The simulated pH values rapidly decrease to 3.3 at both the source-zone well (Figure 5a) and the downgradient well (Figure 5c). In general, tritium concentrations (Figure 5c) decrease faster and more dramatically than aqueous uranium and nitrate, owing to its radioactive decay. The uranium concentrations (Figure 5b) increased from the background level $1.25 \times 10^{-10} \text{ mol kgw}^{-1}$ to $3.0 \times 10^{-5} \text{ mol kgw}^{-1}$ at both wells in less than a few years, and remained constant until basin closure in 1988. After the basin closure, pH rebounds to 4.0 in 2000 and gradually increases throughout the end of simulation. Similarly, uranium concentration (Figure 5b) decreases by two orders of magnitude in 20 years and keeps decreasing to approximately $1.0 \times 10^{-7} \text{ mol kgw}^{-1}$ by the end of the simulation period. Compared to the downgradient well, the source-zone well consistently has lower pH (Figure 5a) and higher aqueous uranium (Figure 5c) concentrations throughout the simulation period. By the end of 2100, pH (Figure 5a) is higher than 5.0 and aqueous uranium concentration lower than $2 \times 10^{-7} \text{ mol kgw}^{-1}$ (Figure 5b) in most of the vadose zone at the source-zone well. Overall, our simulation has a similar fit to the observations as Bea et al (2013) as the same parameters in Bea et al (2013) are used.

4.2. Increasing Recharge Scenarios

485

The breakthrough curves under the increasing recharge scenarios are shown in Figure 6. When recharge is increased, pH at the source-zone well (Figure 6a) is significantly lower compared to the base-case scenario. pH values are changed with different recharge rates as relatively high pH infiltrated rainwater dilutes the low-pH contaminated environment in the subsurface system.

490

However, the relationship between recharge and pH is nonlinear, with thresholds such that pH is the lowest at +20% recharge, while pH is higher in the cases with +30% to +50% recharge.

495

Nitrate concentrations at the source-zone well (Figure 6b) increase immediately after 2020, and spike 5 years after perturbation, with the highest concentration in the greater recharge (+50%) case. After 2050, nitrate concentration is the highest with +20% recharge, and decreases from +30% to +50% recharge (Figure 6b). The tritium concentrations (Figure 6c) peak similarly to nitrate, although tritium decreases significantly after 2040 due to radioactive decay. The uranium concentrations (Figure 6d) are also similar to the breakthrough curves for the nitrate concentrations and show negative correlation with pH oscillation. At downgradient locations, pH (Figure 6e) is not influenced by the recharge increase up to +30%. Above the 40% increase, pH

decreases significantly after 2040. Nitrate concentrations at the downgradient well (Figure 6f) decrease immediately after 2020 due to dilution, but increase afterwards, with peaks around 2040. Similar to the source-zone well (Figure 6b), the concentration peaks are higher with greater recharge rates and remain higher than the base case throughout the end of the simulations. The tritium concentrations (Figure 6g) keep decreasing after 2020 with the peaks in 2040, with the similar behavior of sudden increase showing in nitrate concentration (Figure 6f), and higher concentrations in the high recharge scenarios. The uranium concentrations (Figure 6h) also exhibit patterns similar to those of nitrate (Figure 6f), in that both the peak and remaining concentrations are higher in the greater recharge scenarios.

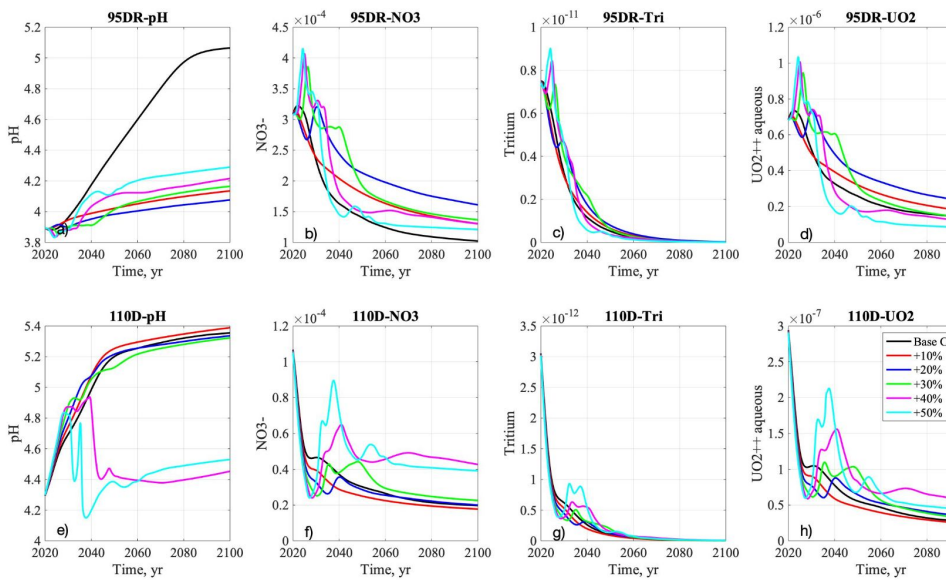

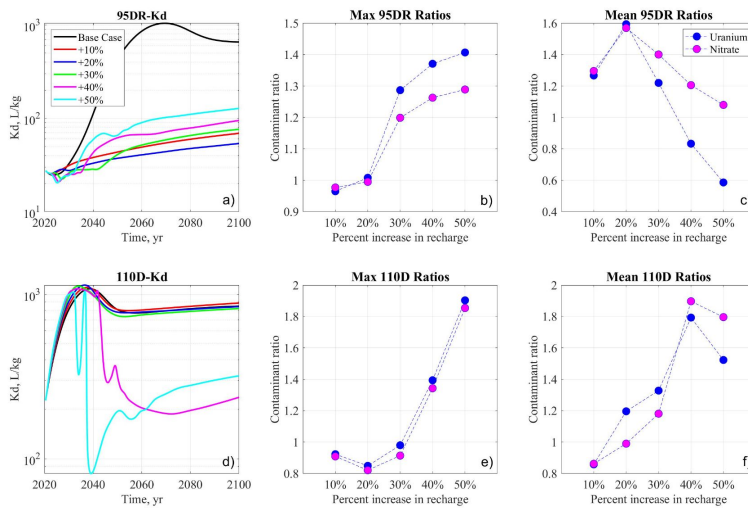

Figure 6: Breakthrough curves of pH, nitrate, tritium, and aqueous uranium at the source-zone well (a-d) and downgradient well (e-h) in the base case and increasing precipitation scenarios from 2020 to 2100.

The reactive (uranium) and non-reactive (nitrate) species are compared in Figure 7. K_d values are computed by sorbed uranium concentration in the solid phase with the aqueous uranium concentration from the model outputs. Figure 7a shows that K_d values at the source-zone well are lower in the increasing recharge cases than the base case, which is consistent with pH breakthrough curves (Figure 6a). The +20% case has the lowest K_d at the source-zone well, while the K_d values are higher in the smaller recharge case (+10%) and greater recharge cases beyond +30%. In contrast, at the downgradient well (Figure 7d), the K_d values are lower in the +40% to +50% scenarios echoing the downgradient pH breakthrough curves in Figure 6e. In

525 addition, we compare uranium and nitrate concentrations with respect to the maximum
 concentration (i.e., the peak concentrations that occur after a few years in the increasing
 recharge scenarios) as well as the average concentration from 2040 to 2100, which illustrates
 the long-term contamination trend. Figure 7 (b-c) presents the ratio of uranium and nitrate,
 defined as the concentration in each scenario compared to the baseline case. In the maximum
 concentration at the source-zone well (Figure 7b), the ratios are mostly higher than 1,
 530 demonstrating that the maximum concentration is higher in the greater increasing recharge
 scenarios. The uranium maximum concentration ratio is higher than the nitrate; therefore, the
 increasing recharge affects the uranium concentrations more than the nitrate concentrations at
 the peaks (Figure 7b). For average concentrations at the source-zone well (Figure 7c), the ratio
 increases in the +20% recharge case, but decreases at greater recharge values. Different from
 535 the maximum concentrations, the mean uranium ratio becomes lower than the mean nitrate
 ratio, and falls below 1.0 in the greater recharge scenarios (Figure 7c). At the downgradient
 well, the maximum concentration ratios are less than 1.0 in the (+10% ~ +30%) recharge
 scenarios but higher than the base case in greater recharge (+40~50%) scenarios, while nitrate
 and uranium ratios are similar (Figure 7e). The average concentration ratios at the
 540 downgradient well after 2040 are generally higher with increasing recharge, and reach their
 highest at the +40% scenario (Figure 7f). The nitrate concentration ratios are lower than
 uranium in the smaller (+10% ~ +30%) recharge scenarios, but are higher in those scenarios of
 above +40% recharge.

545 Figure 7: Breakthrough curves for K_d at the source-zone well (a-c) and the downgradient well (d-f) for the increasing recharge scenario from 2020 to 2100. Maximum and average ratios of base case to increased recharge case for uranium and nitrate concentrations at both well locations.

4.3. Decreasing Recharge Scenarios

550

Although decreasing recharge has little impact on pH at the source-zone well up to -30% (Figure 8), pH increases significantly in the -40% ~ -50% recharge scenarios. The nitrate concentrations (Figure 8b) increase immediately after the perturbation of recharge, then decrease throughout the end of the simulation. Similar to pH, nitrate concentrations (Figure 8b) do not change significantly in smaller decreasing recharge scenarios, but decrease two orders of magnitude in the greater (-40 ~ -50%) decreasing recharge scenario. Tritium concentrations (Figure 8c) also increase immediately after 2020, then decrease; the rate of decrease is more rapid than the nitrate concentrations due to radioactive decay, and exhibit few differences among decreasing recharge scenarios. The uranium concentration (Figure 8d) breakthrough curves are similar to the nitrate curves. At the downgradient well, the pH values have a similar trend to the source-zone well in all decreasing recharge scenarios before 2040. However, the breakthrough curves diverge after 2040 and increase more in the greater decreasing recharge scenarios. The pH values are higher than the source-zone well and reach as high as 7.0 in the -50% recharge scenario in 2100 (Figure 8e). The nitrate concentrations in the down gradient well (Figure 8f) keep decreasing in the first 10-15 years after 2020. Concentrations peak around 2025-2035; the decrease is more significant in all the decreasing recharge scenarios than the base case. In general, the peak concentrations occur earlier and higher in the greater decreasing recharge scenarios, and the breakthrough curves decrease faster and lower in the long-term projection to 2100. Spikes were observed in the tritium concentration breakthrough curves (Figure 8g), as well as with smaller magnitudes at the down gradient well 10-15 years after the perturbation. The uranium concentration breakthrough curves (Figure 8h) are similar to the nitrate, but decrease more rapidly in all cases.

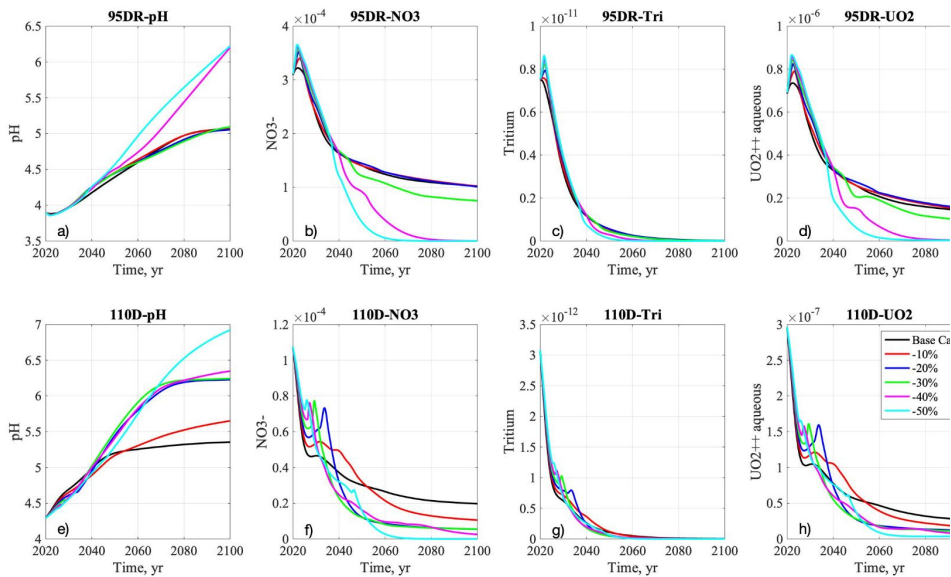

Figure 8: Breakthrough curves of pH, nitrate, tritium, and aqueous uranium at the source-zone well (a-d) and downgradient well (e-h) in the base case and decreasing precipitation scenarios from 2020 to 2100.

580

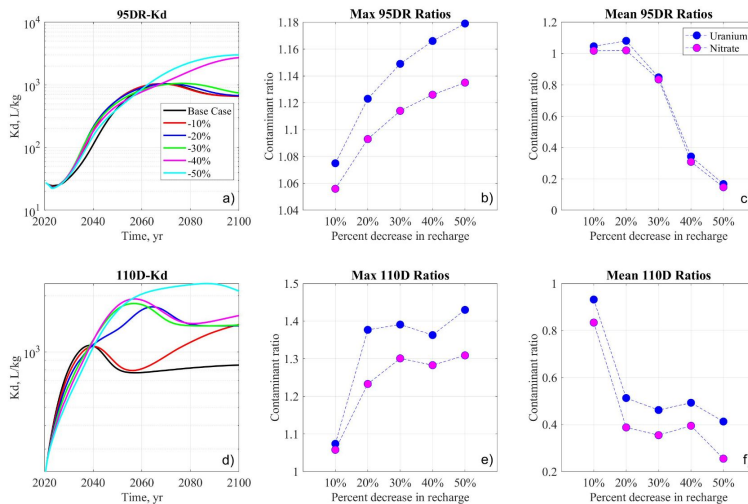

K_d breakthrough curves generally reflect the pH breakthrough curves in Figure 8 and are higher in the decreasing recharge scenarios at both well locations. Figure 9a shows that at the source-zone well, the base case ~ -30% cases have relatively similar K_d values throughout the simulation period. After 2060, the -40% and -50% recharge scenarios both significantly increase. At the downgradient, K_d values are generally higher than source-zone well, and the difference in K_d values among cases are more pronounced (Figure 9d). K_d value is the lowest in the higher recharge (base case and -10%) scenarios, and largest in the significantly decreasing recharge (-50%) case. The -10% and -20% recharge scenarios significantly diverge at 2040 and converge at 2100. Similar to the increasing recharge scenarios, maximum uranium and nitrate concentrations at the source-zone well occur immediately a few years after the perturbation (Figure 8). With decreasing recharge from -10% to -50%, maximum concentration ratios are generally lower than 1.0 and increase with decreasing recharge, while average concentration ratios are generally higher than 1.0. In Figure 9b, the uranium maximum concentration ratios are slightly higher than nitrate, with greater difference in the -50% recharge case. In Figure 9c, the ratios of long-term average concentrations show that both uranium and nitrate concentration are nearly the same as the base case in smaller decreasing recharge scenarios (-10% ~ -20%), but decrease quickly and are significantly lower in the greater decreasing recharge scenarios (-30% ~ -50%). Compared to the results at the source-zone well, the maximum and average

585

590

595

600 concentration ratios at the downgradient well (Figure 9e and f) have similar trends. Nitrate maximum concentration ratios are higher than nitrate (Figure 9e), and their differences are the greatest in the -20% and -30% recharge case. The average concentration ratios (Figure 9f) decrease with decreasing recharges, and uranium ratios are consistently higher than nitrate.

605 Figure 9: Breakthrough curves for K_d at the source-zone well (a-c) and the downgradient well (d-f) for the increasing recharge scenario from 2020 to 2100. Maximum and average ratios of base case to increased recharge case for uranium and nitrate concentrations at both well locations.

Deleted:

4.4. Cap-Failure Scenarios

610 In the cap-failure scenarios, pH is always lower than the base case across +10% to +50% recharge rates (Figure 10a). At the source-zone well, these pH values dip below 3.5 in 2030, rebound to 4.0 after 2045, and then slightly increase to 4.3 by the end of the simulation. The +50% cap-failure scenario has the highest pH value compared to the +10 ~ +40% cap-failure cases. Nitrate concentrations spike and increase one order of magnitude in 2030, then decrease to the same level as the base case in 2050 (Figure 10b). The pattern of tritium and uranium breakthrough curves (Figure 10 c-d) look very similar to nitrate. Among the breakthrough curves of nitrate, tritium, and uranium across all cap-failure scenarios, the +50% cap-failure scenario simulates the earliest peak, while the +20% scenario simulates the highest peak. At the downgradient well, pH values at all cap-failure scenarios increase with the base case in the first ten years, then decrease around 2035 and remain lower than the base case (Figure 10e). pH values only decrease from 5.5 to 5.0 in the smaller +10 ~ +20% recharge rates. However, they decrease significantly with greater recharge rates (+30% ~ +50%) in those cap-failure scenarios. The breakthrough curves of pH increase in the first ten years after 2020, dip to 3.6 around 2040, and then slightly increase, but require several decades to rebound to

615

620

Deleted: ~

630

the same pH level as in 2020. Compared to the nitrate concentration breakthrough curves at the source-zone well (Figure 10b), the peaks at the downgradient well are simulated in 2040 with a 10-year delay (Figure 10f). The nitrate concentrations in those greater (+30% ~ 50%) recharge rates occur earlier and are higher than in the smaller (+10% ~ 20%) recharge rates. The tritium concentration shows similar peaks as nitrate, but the earliest peak with +50% cap failure has the highest values, and the later peaks with smaller (+10% ~ 20%) recharge rates will be lower because of tritium radioactive decay (Figure 10g). Uranium concentration breakthrough curves show similar behaviors to nitrate in both wells (Figure 10bd and fh).

635

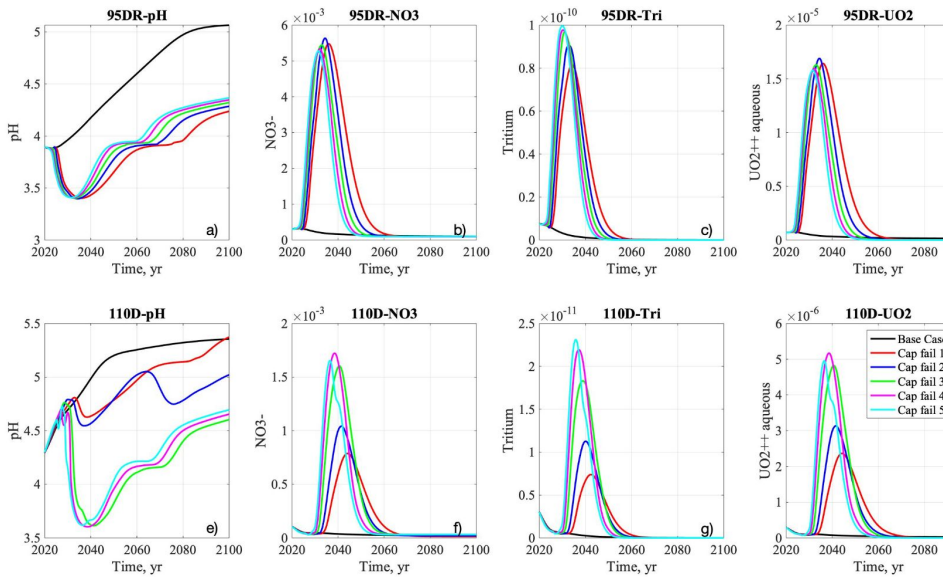

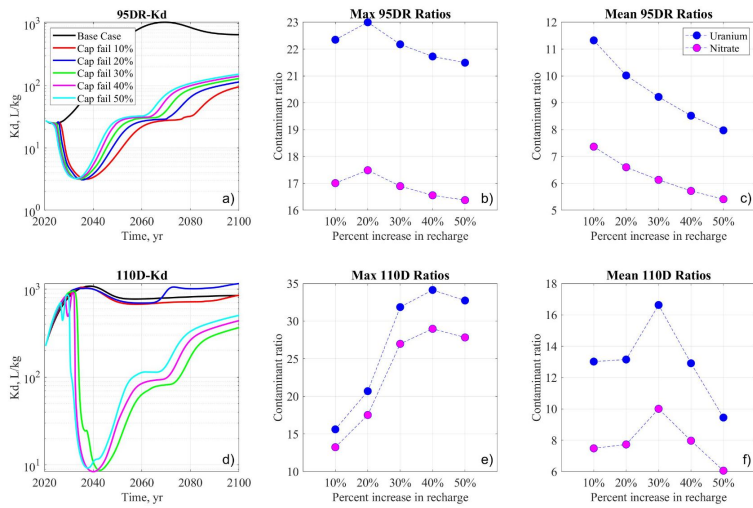

Figure 10. Breakthrough curves of pH, aqueous uranium, tritium, and nitrate at the source-zone well (a-d) and downgradient well (e-h) in the base case and cap-failure scenarios from 2020 to 2100.

640

K_d breakthrough curves are highly correlated with pH at both monitoring wells (Figure 10ae), K_d decreases by 2035 and 2040 at both wells, respectively, returns to the 2020 level around 2050, then keeps increasing until 2100. At the source-zone well, K_d values decrease and rebound fastest in the +50% recharge case, and the smallest +10% recharge rate case shows a similar trend but is delayed by nearly 10 years (Figure 11a). At the downgradient well, the K_d breakthrough curves at higher recharge cases (+30% ~ +50%) are more closely correlated with pH and decrease around 2040, while smaller recharge cases (+10% ~ +20%) are more similar to the base case (Figure 11d). A turning point occurs in 2040, when the +30% case switches places with the +50% case and has the lowest K_d value until 2100, similar to the behavior of

645

650 aqueous uranium breakthrough curves in 2040 (Figure 10h). When comparing Figure 11d and
 Figure 10e, it is clear that although pH is not the highest in the +20% cap-failure scenario, after
 2070, that scenario has the highest K_d value and more adsorption. In cap failure scenarios, the
 maximum and average uranium concentration ratios are consistently greater than nitrate in both
 wells, and follow the same trend with increasing recharge rates (Figure 11b-c, e-f). Both ratios
 655 of uranium and nitrate maximum and average concentration are one order of magnitude greater
 than the base case. The maximum concentrations of uranium and nitrate are observed in 2030
 and 2040 at the source-zone well and downgradient well, respectively (Figure 10bf), although it
 is difficult to tell the difference from the breakthrough curves because of the magnitude of peak
 concentrations. The uranium and nitrate maximum concentration ratios are highest in the 20%
 660 cap-failure scenarios (Figure 11b), and decrease with greater increasing recharge rate. The
 ratios of uranium average concentrations against base case are also persistently higher than
 nitrate in the long term throughout 2100, and decrease with greater recharge rate (Figure 11c).
 At the downgradient well, the maximum concentration ratio against the base case generally
 increases with greater recharge rate, and is the largest in the +40% recharge case (Figure 11e).
 665 The average concentration ratio increases with the smaller (+10% ~ +30%) recharge rates, then
 decreases with the greater (+40% ~ +50%) recharge rates (Figure 11f).

670 Figure 11: Breakthrough curves for K_d at the source-zone well (a-c) and the downgradient well (d-f) for the increasing recharge scenario from 2020 to 2100. Maximum and average ratios of base case to increased recharge case for uranium and nitrate concentrations at both well locations.

Deleted:

4.5. Climate Model Scenarios

675 Recharge rates are calculated by subtracting evapotranspiration (ET) from precipitation in the
four CMIP5 climate projection scenarios. The highest greenhouse gas concentration pathway
RCP8.5 scenario has the maximum simulated precipitation and evapotranspiration. However,
the differences in recharge rate are small across those four scenarios as both precipitation and
680 ET increase in the projection (Figure 3). Therefore, the concentration breakthrough curves are
similar under those climate scenarios. The average recharge rate in those scenarios is around
8.0 x 10⁻⁶ kg-water/m²/sec (0.253 m/yr), or approximately 1.68 times higher than the base case.
In general, simulated contaminant concentrations in those climate scenarios are lower than the
base case due to dilution effects with greater recharge rate, except that pH values are also
685 lower than the base case (Figure 12). The breakthrough curves decrease faster before 2020
(not shown in Figure 12) and reach background concentration sooner than the base case.

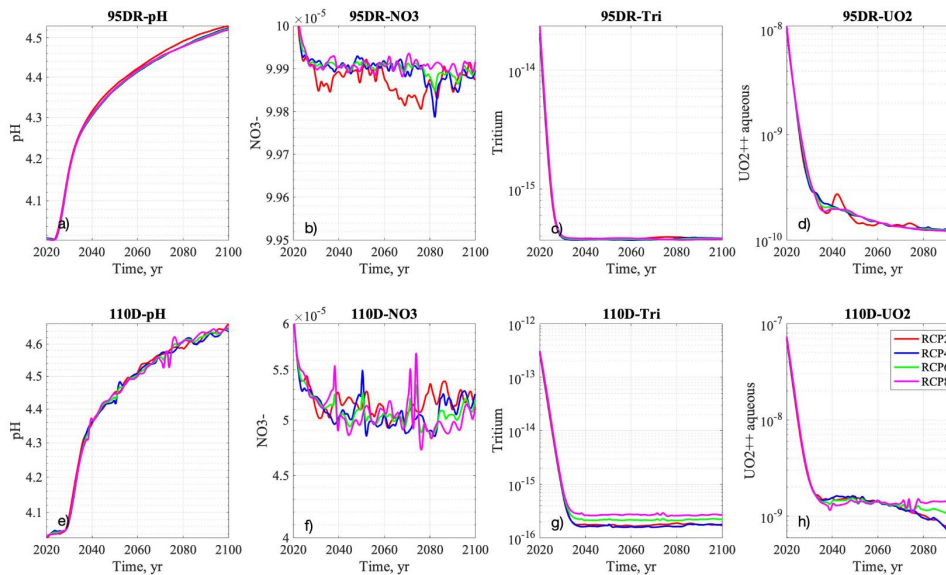

At the source-zone well, the pH breakthrough curve gradually rebounds from 4.0 to 4.5 by the
end of the simulation (Figure 12a). Both nitrate and uranium concentrations show annual
variability after 2020, as recharge rates are changing annually (Figure 12bd). Specifically, nitrate
690 breakthrough curves (Figure 12b) become steady state sooner than the uranium, as nitrate
background concentration is higher. The oscillation is hardly observed in tritium concentration
breakthrough curves, as it decreases faster due to decay. At the downgradient well, pH values
across climate scenarios are consistently lower than the base case with annual variability
(Figure 12e). Compared to the results at the source-zone well, the nitrate concentrations at the
695 downgradient well (Figure 12f) are lower than the background level with greater annual
variability, and become steady state a few years later. The tritium concentration becomes
extremely low below 1.0 x 10⁻¹⁵ mol kgw⁻¹ (Figure 12g), while uranium concentrations return to
background level after 2030 (Figure 12h).

5. DISCUSSION

710

A balance between dilution and remobilization is a key factor determining the contaminant concentration depending on recharge rates, as discussed in Libera et al. (2019). In the increasing recharge scenarios, contaminant concentrations decrease first due to dilution, and then increase because the mobilized contaminants migrate from the source zones to the wells.

715

The highest recharge scenario has the earliest and highest peak in contaminant concentrations due to a stronger remobilization effect, but it has the lowest concentrations and highest pH later due to dilution. In the later period, the increasing recharge again causes dilution due to flushing, resulting in a concentration level below the base case. Because of long-term dilution, the

720

aqueous uranium concentration in greater increasing recharge scenarios is even lower than the base case at the source-zone well after 2035. The relationships between concentrations and recharge are nonlinear and nonmonotonic, depending on different times and locations.

725

Changing recharge rate has less impact at the downgradient well where the spikes are delayed for approximately 10 years since its location is further from the seepage basin, and it takes time for the remobilized plume to reach it. The breakthrough curves of smaller (+10% ~ +30%) increasing recharge scenarios are similar to those of the base case, with slight dilution effects

Deleted: Generally i

Deleted: Additionally, i

throughout 2100, while concentration spikes due to remobilization in 2040 are observed with the larger (+40 ~ +50%) increasing recharge scenarios (Figure 6eh).

730

In the early stage of decreasing recharge scenarios, contaminant concentrations increase because of diminished flushing and a low flow rate of clean groundwater. Later in the simulation period, contaminant concentrations decrease significantly in the greater decreasing recharge scenarios, when the groundwater table declines and isolates the residual contaminants in the vadose zone. This was not observed in the previous tritium simulation (Libera et al., 2019) because of tritium's radioactive decay. In general, this means that decreasing precipitation and droughts are effective in sequestering contaminants in the vadose zone. At the same time, it implies less flushing and an increase in residence time of the contaminants at the site. The uncontaminated groundwater from the upgradient also migrates more slowly in the aquifer. The larger volume of residual contaminants could potentially increase risk, particularly considering extreme precipitation events, which are projected to happen more frequently in many climate models (USGCRP, 2017). Also, there is more interest in groundwater resources during a drought, which leads to increased pumping in the contaminated aquifer. Although such pumping activities are strictly regulated at our study site, such trade-offs require attention at other sites.

735

740

745

To investigate the impact on reactive species such as uranium, we compared reactive (uranium) and nonreactive (nitrate) concentration ratios to assess the impacts of reaction and sorption. We originally hypothesized that increasing recharge would decrease reactive species concentration further, since increasing the volume of water in the domain would increase pH, which limits the mobility of uranium. However, Figure 7 shows that the uranium-concentration ratios compared to the base case increase more significantly than the nitrate concentrations. This is because the remobilization occurs when the pH is still low, and also because remobilization happens to both uranium and protons (Figure 6). In addition, the amount of the residual contaminants is larger for uranium than nitrate due to sorption. Later in the simulation period, the uranium average concentrations are lower than for nitrate and decrease with greater recharge scenarios, because increasing pH, due to long-term dilution by additional recharge, immobilizes uranium.

750

755

In cap-failure scenarios, sorption of uranium is reduced with increasing infiltration, because K_d is sensitive to lower pH due to remobilization through the basin. At the downgradient well, the greater recharge cases (+30% ~ +50%) have a more closely correlated K_d and pH, and have a higher aqueous uranium concentration, than the lower recharge scenarios. In our scenarios, there is a clear change in the balance of aqueous and sorbed uranium concentration in the transition from +20% to +30% recharge, where the system's sorption in the downgradient fundamentally changes. The cap-failure cases indicate that changing recharge and cap-failure levels can trigger dramatic changes in pH and sorption. Similar to Libera et al. (2019), this study confirms the importance of cap or surface barriers to limit the impacts of cap failure under extreme climate regimes. Uniquely, the uncertainty of K_d value was constrained to 10^2 to 10^3 in our study, compared to the greater range (10^2 - 10^6) in the previous studies (Bea et al., 2013)

765

770

Deleted: , when there is a drought,

Deleted: could

Deleted: Consistent with

775 At this site, pH and uranium concentration fronts are retarded, because they are affected by the
adsorption and ion exchange processes onto kaolinite and goethite (Bea et al., 2013). Limited
sites for adsorption/exchange are saturated by the elevated H⁺ and uranium loading, and their
concentrations eventually reach steady state at the end of the projection period. Overall in our
scenarios, the change in recharge has a similar impact on uranium and nonreactive species,
780 which is largely attributed to pH buffering due to mineral precipitation. The increase in pH due to
dilution encourages the precipitation of kaolinite, but the precipitation reaction of kaolinite
produces H⁺ ions, which then decreases pH. At low pH, the hydroxyl groups on the octahedral
structures of aluminosilicates like kaolinite become protonated, effectively creating a net positive
charge on the mineral. This means that uranium cannot sorb to the clay and is therefore mobile
785 in the system. Previous experimental (Dong et al. 2012) and modeling (Arora et al., 2018)
studies also reaffirmed that percent U(VI) sorption is greater with a higher, neutralized pH,
because U(VI) and H⁺ are competing in sorption. This is the process of dissolution and
precipitation of kaolinite:

790 A similar reaction occurs with gibbsite. Dong et al. (2012) showed that there was an insignificant
weight percent or volume fraction of gibbsite at F-Area, since it only forms at pH>5.4. However,
in the decreasing recharge scenarios, all the recharge cases at the downgradient well have a
pH between 5.4 and 7 after 2070, and pH at the two greater recharge cases at the source-zone
well also surpass 5.4. Decreasing recharge would likely trigger the formation of gibbsite, which
could increase pH buffering. Additionally, according to Bea et al. (2013), this mechanism, as
795 well as cation exchange and adsorption processes on kaolinite and goethite, explain some
buffering of pH. The pH buffering effect is the major mechanism for pH remaining low for an
extended period of time in climate resilience studies with reactive transport modeling.

800 Nevertheless, our model is built upon more than 10 years of site characterization, sorption
experiments and reactive transport models (Dong et al., 2012; Bea et al., 2013; Sassen et al.,
2013; Wainwright et al., 2019). The non-electrostatic sorption model (NEM) sorption model used
in this study is based on Arora et al. (2018), which is calibrated with long-term monitoring
datasets and considered competitive H⁺ and uranium sorption.

805 In addition to understanding the impact of a range of recharge scenarios, this study has
established a pipeline to use the CMIP5 climate model projections as input to the hydrology and
reactive transport modeling simulations. Although increasing precipitation is projected over time,
we found that the increasing ET associated with temperature can reduce the recharge rates. We
found that, compared to the base case and hypothetical scenarios, the CMIP5 climate data
projects a small increase or no change of recharge rate over time, indicating that the changing
810 climate has minor effects on the contamination plume and breakthrough curves in our study site.
This is similar to the behaviors observed in the increasing precipitation scenarios in Figure 6:
that smaller recharge increases have little impact on the concentration breakthrough curves,
because the increasing recharge is below the threshold that may cause significant
remobilization. Contaminant migration is more controlled by the transport process. Our reactive
815 transport modeling with CMIP5 projection recharge shows that contaminant migration is
sensitive to recharge rate. In our study, ET is prescribed from the ensemble average of CMIP5
datasets and is not computed in our simulations. The annual variability of precipitation and ET,

Deleted: . While it was thought to be irrelevant for this particular study area within F-Area, some recharge scenarios suggest that there could be more gibbsite formation than previously thought.

Deleted: The reactive transport modeling with CMIP5 projection also reveals the sensitivity of recharge rates, and indicates that the uncertainty associated with simulated ET and precipitation could significantly affect the assessment of waste disposal and contaminant transport.

830 in other words net infiltration, is more significant in RCP8.5 than other scenarios. The uncertainty in the estimation of ET as well as the annual variability in CMIP5 scenarios could significantly affect the assessment of waste disposal and contaminant transport.

4. CONCLUSION

835 The climate resilience of residual contamination at the SRS F-Area waste disposal site throughout the projection period from 2020 to 2100 is investigated in this study. Groundwater flow, mineral reactions, surface complexation sorption, and ion-exchange processes are simulated by the Amanzi and PFLOTRAN flow and reactive transport model. We illustrate four scenarios characterized by a range of variable recharge values: (1) increasing recharge after 2020, (2) decreasing recharge after 2020, (3) cap failure and constant positive recharge shift, and (4) recharge rate under different RCP scenarios from the CMIP5 climate model projection. 840 Although exaggerated in the first three cases, this systematic study using changing recharge rates was useful in identifying the phased impacts of increasing or decreasing recharge rates, as well as the difference between the reactive and nonreactive species. Plume distribution and breakthrough curves of chemical species are evaluated to assess the impacts of changing 845 recharge rate and flow conditions. The ratios of maximum and average reactive and nonreactive species concentrations between scenarios and base case are used to understand how climate change affects the adsorption and ion exchange of residual contaminants in the subsurface domain. Furthermore, K_d breakthrough curves are evaluated to understand the pH effects on sorption with different recharge rates in those scenarios.

850 With increasing recharge rates, pH decreases and residual contaminant concentrations increase, because of the remobilization of protons and reactive species. The impact on uranium or pH-dependent species is the same as nonreactive contaminants. K_d values are correlated with pH and behave differently when changing recharge rates beyond certain thresholds. In 855 most cases, uranium-maximum concentration ratios against the base case are higher than the nitrate concentration ratios, owing to remobilization, while the uranium concentration breakthrough curves in the later period depend on long-term flow conditions. The results of cap-failure scenarios suggest that reactive transport modeling and analysis of pH effects on reactive species are important for the risk assessment of such engineering failures.

860 Our results highlight that climate change impacts may not be intuitive, and must be analyzed quantitatively by models. ET projection has great uncertainty, but is particularly important in determining the recharge rates in reactive transport modeling for climate resilience studies. Reactive transport models which consider pH dependency for reactive species are essential for 865 analyzing the impacts of pH with changing recharge rates. Although this study is focused on one site, we developed the pipeline to use climate projection datasets in reactive transport modeling and thereby demonstrated the capability for assessing climate change impacts on waste disposal sites. We expect that our approach and insights are transferable to other sites that have large amounts of residual contaminants in the vadose zones or in the groundwater.
