12
13
14 **Key Points**

15 • Young water fractions of Q and ET are correlated to topographic slope negatively and positively,
16 respectively

17 • Flatter landscapes tend to retain more nitrogen mass in the soil and export less nitrogen mass to the stream

18 • A large young streamflow fraction is not sufficient for high in-stream nitrate concentrations.

19
20 **Abstract.** Excess export of nitrate to streams affects ecosystem structure and functions and has been an environmental
21 issue attracting world-wide attention. The dynamics of catchment-scale solute export from diffuse nitrogen sources
22 can be explained by the changes of dominant flow paths, as solute attenuation (including the degradation of nitrate) is
23 linked to the age composition of outflow. Previous data driven studies suggested that catchment topographic slope has
24 strong impacts on the age composition of streamflow and consequently on in-stream solute concentrations. However,
25 the impacts have not been systematically assessed in terms of solute mass fluxes and solute concentration levels,
26 particularly in humid catchments with strong seasonality in meteorological forcing. To fill this gap, we modeled the
27 groundwater flow and nitrate transport for a small agricultural catchment in Central Germany. We used the fully
28 coupled surface and subsurface numerical simulator HydroGeoSphere (HGS) to model groundwater and overland
29 flow as well as nitrate transport. We computed the water ages using numerical tracer experiments. To represent various
30 topographic slopes, we additionally simulated ten synthetic catchments generated by modifying the topographic slope
31 from the real-world scenario. Results suggest a negative correlation between the young streamflow fraction and the
32 topographic slope. This correlation is more pronounced in flat landscapes with slopes $< 1:60$. Flatter landscapes tend
33 to retain more N mass in the soil (including mass degraded in soil) and export less N mass to the stream, due to reduced
34 leaching and increased degradation. The mean in-stream nitrate concentration shows a decreasing trend in response to

35 a decreasing topographic slope, suggesting that a large young streamflow fraction is not sufficient for high in-stream
36 concentrations. Our results improve the understanding of nitrate export in response to topographic slope in a temperate
37 humid climate, with important implications for the management of stream water quality.

41

42 1 Introduction

43 Globally nearly 40% of land is used for agricultural activities [Foley *et al.*, 2005], which constitutes the major source
44 of pollution with nutrients such as nitrate (referred as to N-NO₃ in this study). Excess export of nitrate to streams
45 threatens ecosystem structure and functions, as well as human health via drinking water [Vitousek *et al.*, 2009; Alvarez-
46 Cobelas *et al.*, 2008; Dupas *et al.*, 2017]. This has been an environmental issue attracting attention in Germany and
47 world-wide. The dynamics of nitrate export from diffuse nitrogen (N) sources are regulated by the dominant flow
48 paths that determine the speed at which precipitation travels through catchments before it reaches the stream [Jasechko
49 *et al.* 2016]. The process is subject to both hydrological and biogeochemical influences mediated by various factors
50 (e.g. catchment topography, aquifer properties, redox boundaries). From the perspective of sustainable intensification,
51 process understanding and assessment of potential effects of catchment topography on nitrate export are critical for
52 the management of water quality in connection with agricultural activity.

53 Field observations in central German catchments indicate that in-stream nitrate concentrations (C_Q) show significant
54 differences in mean concentrations and seasonal variations between downstream areas with gentle topography and
55 more mountainous upstream areas [Dupas *et al.*, 2017; Nguyen *et al.*, 2022]. This provides strong evidence that
56 catchment topographic slope can influence the nitrate export. In terms of water age analyses, Jasechko *et al.* [2016]
57 using oxygen isotope data from 254 watersheds worldwide showed significant negative correlation between the young
58 (age < 3 months) streamflow fraction and the mean topographic gradient. They stated that young streamflow is more
59 prevalent in flatter catchments as these catchments are characterized by shallow lateral flow, while it is less prevalent
60 in steeper mountainous catchments as these catchments promote deep vertical infiltration. This statistically significant
61 trend is consistent with the common finding that fast shallow flow paths produce young discharge and potentially
62 influence the in-stream solute concentrations [Böhlke *et al.* 2007; Benettin *et al.* 2015; Hrachowitz *et al.* 2016; Blaen
63 *et al.* 2017]. However, apart from these data-driven analyses, a more mechanistic examination/explanation with the
64 aid of fully resolved flow paths is still required. Wilusz *et al.* [2017] used a coupled rainfall-runoff and transit time
65 model to investigate the young streamflow fraction, with a focus on the effect of rainfall variability rather than on
66 topography and solute export. Zarlenga *et al.* [2022] numerically quantified the relative contributions of hillslopes and
67 the drainage network to age dynamics in streamflow, considering the influences of transmissivity and recharge,
68 without focusing on topographic slope. The effect of topographic slope on C_Q has rarely been subject to systematical
69 testing.

70 Seasonal fluctuation of C_Q is commonplace in catchments under seasonal hydrodynamic forcing. Field observations
71 in mountainous central German catchments indicate that nitrate concentrations, as well as the mass load, in streams
72 vary seasonally, with maxima during the wet winter and minima during the dry summer [Dupas *et al.*, 2017]. Data-
73 driven analyses by Musolff *et al.* [2015] and Dupas *et al.* [2017] suggested the systematic seasonal (de)activation of
74 N source zones as an explanation for such seasonal variability. Under wetter winter conditions the near-surface N
75 source zones in agricultural soils are connected to the stream by fast shallow flow paths. Under drier summer
76 conditions those N source zones are deactivated because their direct hydrologic connectivity to the stream is replaced
77 with deeper flow paths [Dupas *et al.*, 2017]. Based on high-frequency monitoring in the Wood Brook catchment in
78 the UK, Blaen *et al.* [2017] also reported mobilization of nitrate from the uppermost soil layers during high flow
79 conditions via shallow preferential flow paths, which would not occur during base flow in drier periods. This behavior
80 leads to a seasonally-variable nitrate loading due to changing flow paths and the associated variation in transit time
81 that has been observed in many catchments [Benettin *et al.*, 2015; Hrachowitz *et al.*, 2016; Kaandorp *et al.*, 2018;
82 Rodriguez *et al.*, 2018; Yang *et al.* 2018]. However, how this fluctuation behaves in response to catchment land surface
83 topography has not been assessed systematically yet. Such an assessment could improve our understanding of nitrate
84 export from catchments of different topographic slopes not only in terms of the mean concentration but also regarding
85 its temporal variation patterns.

86 Given that most of the above studies used data driven analysis, numerical modeling is an effective tool for the analysis
87 of water flow, age and solute transport, eliminating the need for large amounts of field data. For example, van der
88 Velde *et al.* [2012] constructed a lumped numerical nitrate transport model for the Hupsel Brook catchment in the
89 Netherlands, without resolving the spatially explicit details. Zarlenga and Fiori [2020] presented a physically-based
90 framework to model transient water ages at the hillslope scale, which was later used to investigate the different impacts
91 of hillslopes and the channel network on water ages in catchments [Zarlenga *et al.*, 2022]. A number studies focused
92 on numerically simulating the nitrogen fluxes (or loads) in soil and groundwater [Smith *et al.*, 2004; Rivett *et al.*, 2008;
93 Lindström *et al.*, 2010; van der Velde *et al.*, 2012; Van Meter *et al.*, 2017; X. Yang *et al.*, 2018, 2019; Kolbe *et al.*,
94 2019; Knoll *et al.*, 2020; Nguyen *et al.*, 2021, 2022]. For example, van der Velde *et al.* [2012] constructed a lumped
95 numerical nitrate transport model for the Hupsel Brook catchment in the Netherlands, without resolving the spatially
96 explicit details. Lindström *et al.* [2010] developed HYPE water quality model allowing for simulating the nitrogen
97 fluxes in soil. Van Meter *et al.* [2017] investigated the two-centuries nitrogen dynamics in the Mississippi and
98 Susquehanna River Basins using a TTD (transient time distribution) based transport approach. X. Yang *et al.* [2018]
99 developed the coupled mHM-Nitrate model, which can provide valuable insights into the spatial variability of water
100 and nitrate fluxes in catchment scale. Nguyen *et al.* [2021] further updated that model to the mHM-SAS model by
101 implementing the SAS-function based solute transport module [Harman, 2015, 2019; Rinaldo *et al.*, 2015; van der
102 Velde *et al.*, 2012], allowing for simulating the nitrate export from a Mesoscale Catchment. However, most of these
103 works provided little information on the spatially-explicit details (such as the flow field) for interpreting the nitrate
104 dynamics. Physically-based hydrogeological models (like, e.g., HydroGeoSphere [Therrien *et al.*, 2010]) resolve the
105 spatially-explicit details within a catchment including the full variability of 3D flow paths in the subsurface, helping
106 to understand the seasonally changing flow patterns in response to different catchment topographies. Additionally, the

107 widely used fully-coupled surface-subsurface technology simulates the catchment as an integrated system, providing
108 details of surface water-groundwater exchanges fluxes. These details help to identify paths of rapid discharge to the
109 land surface that can considerably improve the interpretation of nitrate-export patterns.

110 Transit time distributions (TTDs) have been widely used to interpret hydrological and chemical responses in catchment
111 outfluxes – both in discharge (Q) and in evapotranspiration (ET) [Botter *et al.*, 2010, 2011; *van der Velde et al.*, 2012;
112 *Heidbüchel et al.*, 2012; *Rinaldo et al.* 2015; *Harman et al.*, 2015; 2019]. They characterize how a catchment stores,
113 mixes and releases water as well as dissolved solutes at large spatial and temporal scales [Benettin *et al.*, 2015; *Harman*,
114 2015; *van der Velde et al.*, 2010, 2012; *Hrachowitz et al.*, 2015; *Van Meter et al.*, 2017]. Given that the nitrate
115 attenuation is linked to the age composition of outflow, the TTDs are ideal tools for interpreting the concentration
116 dynamics with regard to catchment topographic slope. Estimating water ages in natural catchments is still a challenge
117 due to varying climate conditions, as well as the errors in algorithms (e.g. errors in the flow field during particle
118 tracking) and limited computational capacity. *Yang et al.* [2018] used particle tracking to compute the age distributions
119 in the subsurface of a study catchment (while omitting the 4% of total discharge produced by direct surface runoff and
120 ignoring the frequent exchange fluxes that may be important for solute export due to their short transit times). *Zarlunga*
121 *et al.*, [2022] used a physically-based semi-analytical model to compute the transient water ages in a catchment,
122 however, without considering surface runoff and hydrological losses (e.g. ET). In this study we determined the age
123 compositions of Q and ET using numerical tracer experiments, where advective-dispersive transport of the tracers was
124 solved using the fully-coupled surface-subsurface framework of HydroGeoSphere. The computed age dynamics based
125 on the tracer concentrations were representative as the tracers were able to track all the flow processes such as surface
126 runoff, groundwater flow and surface-subsurface interaction.

127 In this study, we attempted to systematically assess the effect of catchment topographic slope on the nitrate export
128 dynamics in terms of mass fluxes, concentration levels and its seasonal variability. We also seek mechanical
129 explanations for the previously found behaviors from data-driven studies (like, e.g., *Jasechko et al.* [2016]) with the
130 help of fully resolved flow paths. First, we selected a real-world small agricultural catchment ‘Schäfertal’ in Central
131 Germany, which is characterized by strong seasonality in hydrodynamic forcing with associated shifts in the dominant
132 flow paths [*Yang et al.*, 2018]. This catchment is typical for many catchments with hilly topography under a temperate
133 humid climate. We created eleven model scenarios by adjusting the mean slope of the real-world catchment while
134 preserving the aquifer heterogeneity. Next, we modeled the water flow and nitrate transport for each catchment. The
135 flow and transport were solved using the fully coupled surface and subsurface numerical simulator HydroGeoSphere,
136 and the water ages were computed using numerical tracer experiments. Finally, the modeled flowpaths, water ages, N
137 mass fluxes and nitrate concentrations under various topographic slopes were analyzed. Through this study, we aimed
138 to (1) examine the relationship between topographic slope and N mass fluxes, and to (2) assess C_Q and its seasonal
139 variation in response to different topographic slopes.

140

141 **2 Data collection**

142 **2.1 Real-world and synthetic catchments**

143 Our study was conducted on the catchment ‘Schäfertal’, situated in the lower part of the Harz Mountains, Central
144 Germany (Figure 1a). The catchment has an area of 1.44 km². The hillslopes are mostly used for intensive agriculture
145 while the valley bottom contains riparian zones with pasture and a small stream draining the water out of the catchment.
146 The gauging station at the outlet of the catchment provides Q records. This gauging station is the only outlet for
147 discharging water from the catchment, because a subsurface wall was erected underneath the gauging station across
148 the valley to block subsurface flow out of the catchment. A meteorological station 200 m from the catchment outlet
149 provides records of precipitation (J), air and soil temperatures, radiation and wind speed. The modeled catchment has
150 a mean topographic slope of ~1:20, estimated using a cross-section perpendicular to the stream (Figure 1a). The aquifer
151 thickness varies from ~5 m near the valley bottom to ~2 m at the top of the hillslope. Groundwater storage is low
152 (~500 mm) in such a thin aquifer and mostly limited to the vicinity of the channel with the upper part of the hillslopes
153 generally unsaturated. The stream bed has a depth of 1.5 m below the land surface. Aquifer properties (e.g. hydraulic
154 conductivity) change from the hillslope, dominated by Luvisols and Cambisols, to the valley bottom, dominated by
155 Gleysols and Luvisols [Anis and Rode, 2015]. Apart from that, the aquifer generally consists of two layers: the top
156 layer of approximately 0.5 m thickness with higher porosity and a developed root zone from crops, and the base layer
157 with smaller porosity due to high loam content [Yang *et al.*, 2018]. Subsequently, ten property zones were used (Figure
158 1b), with zonal parameter values following the model in Yang *et al.*, [2018] listed in Table 1.

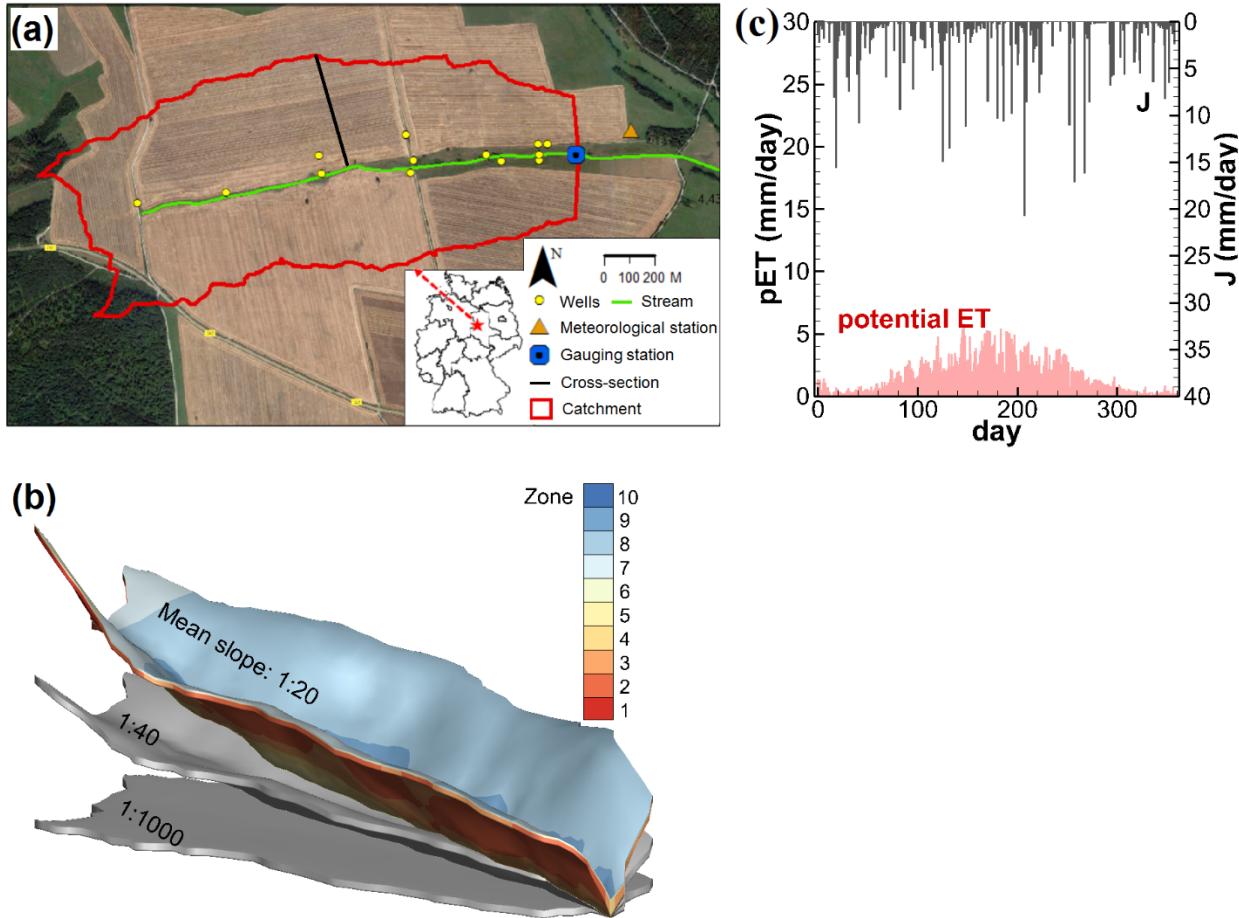

159 Based on this real-world catchment, ten synthetic catchments were generated by adjusting elevations (land surface
160 and aquifer bottom), such that the mean topographic slope ranges from 1:20 (steep) to 1:22, 1:25, 1:30, 1:40, 1:60,
161 1:80, 1:100, 1:200, 1:500 and 1:1000 (flat, Figure 1b). The aquifer depth and heterogeneity were preserved during the
162 adjustments. In total, eleven catchments were used for flow and transport simulations. The catchment with the original
163 topography (1:20) is selected as the base scenario.

164

165 **2.2 Climate**

166 The considered climate for the catchments was derived from the catchment ‘Schäfertal’ located in a region with
167 temperate humid climate and pronounced seasonality. According to the meteorological data records from 1997 to
168 2007, the mean annual J and Q (per unit area) are 610 mm and 160 mm, respectively. Actual mean annual ET based
169 on the ten-year water balance ($J = ET + Q$) is 450 mm. Mean annual potential ET is 630 mm [Yang *et al.*, 2018]. The
170 humid climate is representative for wet regions, quantified by an aridity index (J / potential ET [Li *et al.*, 2019]) of
171 1.0. The ET is the main driver of the hydrologic seasonality as the precipitation is more uniformly distributed across
172 the year (Figure 1c).

173

174 **Figure 1.-** (a) The catchment ‘Schäfertal’, Central Germany (background image from © Google Maps). (b) The
 175 catchments with mean topographic slopes of 1:20, 1:40 and 1:1000. (c) The measured precipitation J and the
 176 estimated potential evapotranspiration ET for the year 2005 under the [the](#) humid climate [Yang *et al.*, 2018]. Ten
 177 aquifer property zones in (b) were defined in the subsurface of the catchment for zonal parameter values (e.g.
 178 hydraulic conductivity).
 179

180

181 **3 Methods**

182 **3.1 Flow and nitrate transport**

183 **Flow model**

184 It is necessary to solve both groundwater and surface water flow because the spatially-explicit details in the catchment
 185 including the specific flow paths and exchange fluxes are necessary to interpret the effect of varying topographic slope
 186 on nitrate transport. We simulated the flow system using the fully coupled surface and subsurface numerical model
 187 HydroGeoSphere, which solves for variably saturated groundwater flow with the Richards’ equation and for surface
 188 flow with the diffusion-wave approximation of the Saint-Venant equations [Therrien *et al.*, 2010]. Additionally, the
 189 exchange flux between groundwater and surface water can be implicitly simulated. The nitrate transport is simulated

190 in the groundwater flow, surface flow and exchanges fluxes by solving the advection-dispersion-diffusion equation
191 describing the conservation of nitrate mass. HydroGeoSphere has been successfully used to simulate catchment
192 hydrological processes and solute transport in many studies [e.g. *Therrien et al.*, 2010; *Yang et al.*, 2018], therefore
193 governing equations and technical details are not explicitly repeated here.

194 In our previous work *Yang et al.* [2018], a hydrological flow model has already been established for the catchment
195 'Schäfertal'. It was calibrated against measured groundwater levels and stream discharge Q . The optimized parameter
196 values are listed in Table 1. In this work, we performed our simulations based on that flow model, with the nitrate
197 transport process being added while maintaining the model setup. We provide a brief review of that flow model here.
198 Readers may refer to *Yang et al.* [2018] for a full description of the model and its calibration.

199 The modeled subsurface of the catchments was discretized into 9 horizontal layers between the land surface and the
200 aquifer base, with thinner layers in the upper part (0.1 m) to better represent the unsaturated zone and compute the ET.
201 In total, the subsurface was discretized by a mesh of 13860 prisms, with the horizontal size of the prisms ranging from
202 30 to 50 m. The topmost 1540 triangles were used to discretize the surface domain, where surface flow was simulated.
203 Ten property zones for the subsurface were defined (Figure 1b), being assigned with the zonal hydraulic conductivity
204 and porosity values (Table 1). ET was simulated as a combination of plant transpiration from the root zone (top 0.5 m
205 soil) and evaporation down to the evaporation depth (0.5 m), which are both constrained by soil water saturation.
206 Regarding the flow boundary conditions, spatially uniform and temporally variable J was applied to the land surface.
207 Spatially constant and temporally variable potential ET was applied to the aquifer top to calculate the actual ET. The
208 bottom of the aquifer was considered an impermeable boundary. A critical depth boundary condition was assigned to
209 the catchment outlet to simulate the stream discharge Q , which was compared to the measured Q during the calibration.
210 The software PEST [Doherty and Hunt, 2010] was used for the transient calibration. After calibration, the time-
211 variable groundwater levels were well replicated by the flow model for most of the wells, with mean coefficients of
212 determination (R^2) of 0.43. The fit between the simulated and measured Q was satisfactory with a R^2 of 0.61. The
213 calibrated model successfully simulated the flow system from 1997 to 2007.

214 In this study, we continued to use the above-described model setup, including the mesh, the parameters and the flow
215 boundary conditions, for the eleven catchments with different topography. Note that the mesh was adapted to the
216 change of the topography by changing node elevations vertically. However, to simplify the flow simulation and the
217 age computation (described in section 3.2), we selected the year 2005 as a representative year and assumed that all the
218 years have the identical climate (J and potential ET) as the year 2005. Therefore, J and potential ET of 2005 (Figure
219 1c) were cycled and applied to the catchments for all the simulated years.

220

221 **Table 1.** The key flow parameters and their values following *Yang et al.*, [2018].

Parameter	Process	Type	Value
Hydraulic conductivity	Subsurface	zonal	Zonal values (refer to Yang et al., [2018])
Porosity	Subsurface	zonal	Zonal values (refer to Yang et al., [2018])
Residual saturation	Subsurface	uniform	0.08 [-]

223

224

225

226 **Transport boundary conditions and parameters**

227 The nitrogen (N) pool is formed in the soil zone of the catchments, representing a nitrate source zone. The N pool is
 228 controlled by various complex processes. It is replenished by external inputs from atmospheric deposition, biological
 229 fixation, animal manure from the pasture area, and fertilizer from the farmland on the hillslopes. Nitrate that can be
 230 transported with water is formed and leached from this N pool by a microbiological immobile-mobile exchange
 231 process [Musolff et al., 2017; Van Meter et al., 2017]. In our study, we employed the simplified framework by Yang
 232 et al., [2021] to track the fate of N in the N pool (Figure 2a). This framework was derived from the ELEMent
 233 approach (Exploration of Long-tErM Nutrient Trajectories, Van Meter et al., 2017), which uses a parsimonious
 234 modeling framework to estimate the biogeochemical legacy nitrate loading in the N pool and the N fluxes leaching
 235 from the N pool to the groundwater. This framework assumes that total N load in the N pool is comprised by inorganic
 236 N (SIN) and organic N (SON). Two types of SON are distinguished: active organic N (SON_a) with faster reaction
 237 kinetics and protected organic N (SON_p) with slower reaction kinetics. It is assumed that the external N input
 238 contributes only to the SON. The SON is mineralized into SIN. The SIN is further consumed by plant uptake and
 239 denitrification, and finally leaches to groundwater as dissolved inorganic N (DIN, representing mainly nitrate in the

240 studied catchment [Yang *et al.*, 2018; Nguyen *et al.*, 2021]). The framework is acceptable due to the fact that most of
 241 the nitrate fluxes from source zones has undergone biogeochemical transformation in the organic N pool [Haag and
 242 Kaupenjohann, 2001]. The framework simplifies complexities of different N pools and transformations via
 243 mineralization, dissolution, and denitrification within the soil zone [Lindström *et al.*, 2010], while preserving the main
 244 pathway for nitrate leachate.

245 The governing equations to calculate these N fluxes follow the ones in Yang *et al.*, [2021]. A specific portion (h) of
 246 the external N input contributes to the SON_p pool, and the rest contributes to the SON_a pool. The portion h is the land-
 247 use dependent protection coefficient [Van Meter *et al.*, 2017]. The mineralization and denitrification are described as
 248 first order processes with rate coefficients k_a , k_p , and λ_s respectively, using:

$$249 \quad MINE_a = k_a \cdot f(\text{temp}) \cdot SON_a \quad (1)$$

$$250 \quad MINE_p = k_p \cdot f(\text{temp}) \cdot SON_p \quad (2)$$

$$251 \quad DENI_s = \lambda_s \cdot SIN \quad (3)$$

252 where $MINE_a$, $MINE_p$, $DENI_s$ ($\text{kg ha}^{-1} \text{ day}^{-1}$) are the mineralization rates for SON_a and SON_p , and denitrification rate
 253 for SIN . k_a , k_p , and λ_s (day^{-1}) are coefficients for the first order processes. $f(\text{temp})$ is a factor representing a constraint
 254 by soil temperature [Lindström *et al.*, 2010]. Note that the mineralization and plant uptake occur in the N pool.
 255 Denitrification can occur in both the N pool and later in groundwater. The plant uptake rate UPT follows the equation
 256 used in the HYPE model [Lindström *et al.*, 2010]:

$$257 \quad UPT = \min (UPT_p, 0.8 \cdot SIN) \quad (4)$$

$$258 \quad UPT_p = p1/p3 \cdot \left(\frac{p1-p2}{p2} \right) \cdot e^{-(DNO-p4)/p3} / \left(1 + \left(\frac{p1-p2}{p2} \right) \cdot e^{-(DNO-p4)/p3} \right)^2 \quad (5)$$

259 where UPT and UPT_p ($\text{kg day}^{-1} \text{ ha}^{-1}$) are the actual and potential uptake rates. The computation of UPT_p considers a
 260 logistic plant growth function. DNO is the day number. $p1$, $p2$, $p3$ are three parameters depending on the crop/plant
 261 type, they are in the units of (kg ha^{-1}), (kg ha^{-1}), and (day), respectively. $p4$ is the day number of the sowing date. The
 262 leaching process allows for SIN to leach from the soil (N pool) to the groundwater. The leaching rate LEA ($\text{kg ha}^{-1} \text{ day}^{-1}$)
 263 is defined as a first order process as:

$$264 \quad LEA = f \cdot SIN / \Delta t \quad (6)$$

$$265 \quad f = (1 - \exp^{-a \frac{wal}{\theta d}}) \quad (7)$$

$$266 \quad wal = q \cdot \Delta t \quad (8)$$

267 where f is a factor, ranging between [0, 1], to determine the portion of SIN that leaches into groundwater during a time
 268 step Δt . a is unit-less leaching factor. θ is the soil porosity. d is the soil depth. wal [L] is the water available for
 269 leaching during Δt . wal can be estimated using the Darcy fluxes q [LT^{-1}], which are provided by the flow simulations
 270 for each cell of the mesh. Physically, f is a function of the ratio between wal and the volume of soil voids $\theta \cdot d$,
 271 representing the ability of water to flush the SIN . This formulation of LEA is modified from the ones used in Pierce
 272 *et al.*, [1991], Shaffer *et al.* [1991] and Wijayantiati *et al.* [2017], to comply with the spatially-distributed
 273 HydroGeoSphere model.

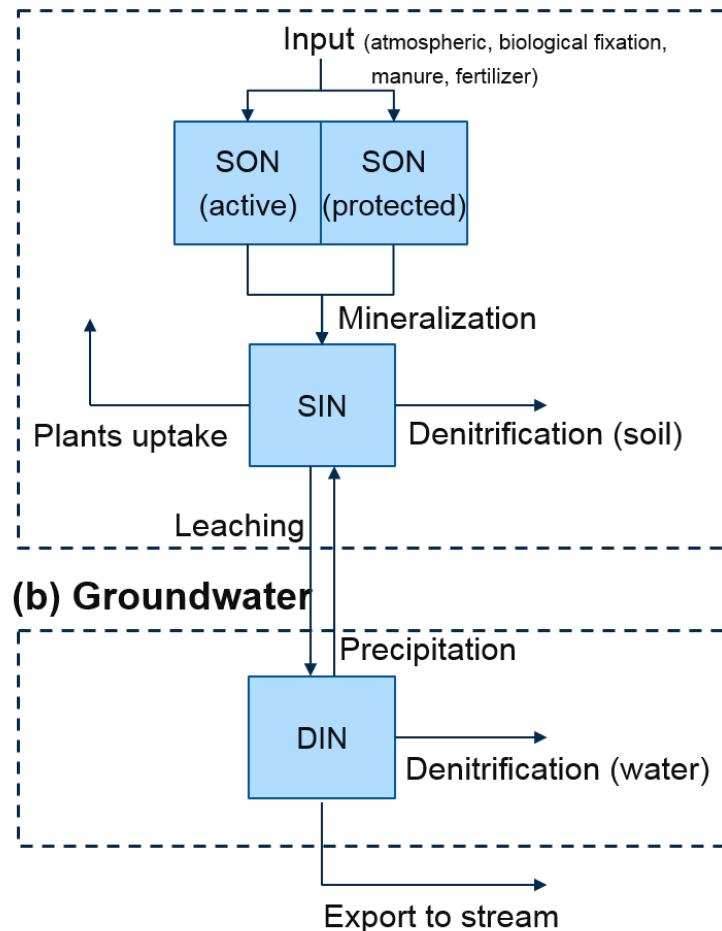

274 **Table 2.** The parameters for the N pool and nitrate transport. The parameters with a range are calibrated. The
 275 adjustable ranges are selected to cover the values that the parameters can potentially take on or the values reported
 276 by the referred literature.

Parameter	Description	Range	Reference	Best-fit value
<u>N pool</u>				
d	Soil depth	Fixed	<i>Yang et al.</i> [2018]	0.5 m
N_{Input}	N external input	Fixed	<i>Nguyen et al.</i> [2021]	180 kg ha ⁻¹ yr ⁻¹
h	protection coefficient	Fixed	<i>Van Meter et al.</i> [2017]	0.3 [-]
k_a	Mineralization coef. (DON _a)	[0 - 0.7]	<i>Yang et al.</i> [2021]	0.011 day ⁻¹
k_p	Mineralization coef. (DON _p)	[0 - 0.7]	<i>Yang et al.</i> [2021]	0.0008 day ⁻¹
λ_s	Denitrification coef. (soil)	[0 - 0.7]	<i>Yang et al.</i> [2021]	0.0007 day ⁻¹
$p1$	Parameter for plants-uptake	[60 - 160]	<i>Van Meter et al.</i> [2017]	160 kg ha ⁻¹
$p2$	Parameter for plants-uptake	[0 - 10]		9.8 kg ha ⁻¹
$p3$	Parameter for plants-uptake	[1 - 60]		25.6 day
$p4$	Parameter for plants-uptake	Fixed		63 day
a	Leaching factor	[0 - 100]		0.154 [-]
<u>Transport</u>				
λ	Denitrification coef. (water)	[0 - 0.7]	<i>Yang et al.</i> [2021]	0.0072 day ⁻¹
a_L	Longitudinal dispersity	Fixed		8 m
a_T	Transverse dispersivity	Fixed		0.8 m

277
 278 The N pool is positioned on the top part of the aquifer, used as a boundary condition for the DIN (nitrate) transport.
 279 Advective-dispersive transport of DIN in the flow system is simulated using HydroGeoSphere (Figure 2b).
 280 Degradation (denitrification in groundwater) during transport is considered as a first order process. Degradation is not
 281 considered on the land surface (denitrification in surface flow), where aerobic conditions likely deactivate
 282 denitrification and residence time is short. To implement the evapoconcentration effect in the transport model, ET is
 283 assumed to remove DIN mass without altering the DIN concentration of the water, and to inject that mass back to the
 284 SIN pool. This represents a precipitation process from DIN to SIN, which is the inverse process of leaching (Figure
 285 2b). There are two reasons for doing that: (i) the physical process of ET causing the immobilization of DIN can be
 286 mathematically considered, and (ii) the N mass balance can be conserved as the plants-uptake is already considered
 287 in the N pool according to the plant growth function (Equation 4 and 5), being independent from the ET flux.
 288 Regarding the parameters, the soil depth, within which the N pool is implemented, is set to 0.5 m. N external input is
 289 180 kg ha⁻¹ yr⁻¹ according to Nguyen et al. (2021), where the nitrate balance was simulated for the larger upper Selke
 290 catchment that contained our studied catchment. The external N input is assumed to be spatiotemporally constant due
 291 to the limited information on its variation in space and time. The protection coefficient h is fixed as 0.3 according to
 292 the values reported in *Van Meter et al.* [2017]. The sowing date $p4$ is fixed as 63 days according to the fact that sowing

293 activities and plant growth start in early March. Longitudinal and transverse dispersivity values were 8 m and 0.8 m,
294 respectively. Other parameters were set to be adjustable and calibrated (Table 2).

297 groundwater.

298

299

300 *Transport calibration*

301 As the flow parameters (e.g., hydraulic conductivity and porosity) were already calibrated in *Yang et al. [2018]* using
302 data sets of discharge and groundwater levels. In this study, the calibration was only performed for the transport. To
303 get reasonable parameter values for the N pool and N transport, a calibration was performed for the transport. The
304 software package PEST [Doherty and Hunt, 2010] was used. PEST uses the Marquardt method [Marquardt, 1963] to
305 minimize a target function by varying the values of a given set of parameters until the optimization criterion is reached.
306 We used the measured C_d and N surplus as the data sets target variables for comparison with the simulated ones. The
307 N surplus, which is the annual amount of N remaining in the soil after consumption by plant-uptake, was estimated as

308 $48.8 \text{ kg ha}^{-1} \text{ yr}^{-1}$ [Yang et al., 2021]). As two different data sets (C_O and N Surplus) were used, a weighting scheme
309 was used such that the defined multi-objective function was not dominated by one data set.

310 Note that the entire model calibration (for flow and transport) actually followed a procedure of two steps: first for
311 flow, and second for transport. Alternatively, the flow and transport parameters can be calibrated at one step by
312 defining the multi-objective function using all the data sets (discharge, groundwater levels, C_O and N surplus). The
313 potential effect of the two different calibration procedures on the modeling results should be further explored, however,
314 being out of the main focus of this study. We consider the two-step calibration procedure to be acceptable, because
315 our result showed that it was sufficient to reach an acceptable model performance for both flow and transport
316 (described later).

317 Several transport parameters were fixed at the values selected according to prior information, such that the degree of
318 freedom in the calibration can be reduced as much as possible (Table 2). In total eight parameters were adjustable and
319 calibrated (Table 2), because they were the key parameters to determine the N fluxes in soil and groundwater. Their
320 adjustable ranges were selected according to the literature or to cover the values that the parameters can potentially
321 realistically reach (Table 2). The calibration was carried out for the period from Jul 1999 to Jul 2003, during which
322 the data sets are available. First, the flow and transport were simulated in the catchment of the base scenario (original
323 topography, section 2.1), for the period from Jul 1999 to Jul 2003. Secondly, PEST was used to obtain a best fit
324 between the simulated results and the data sets by varying the parameter values. We used the measured C_O and N
325 surplus as the data sets. The N surplus, which is the annual amount of N remaining in the soil after consumption by
326 plant uptake, was estimated as $48.8 \text{ kg ha}^{-1} \text{ yr}^{-1}$ (Yang et al., 2021). Note that the simulation period from Jul 1999 to
327 Jul 2003 was only used for model calibration, rather than for the actual simulations with the eleven catchments of
328 different topographic slope. After calibration, the model with the best-fit parameter values can well replicate the
329 measured C_O with a Nash-Sutcliffe efficiency (NSE) of 0.75 (see Figure S1 in the supporting information). The
330 simulated N surplus was $50.7 \text{ kg ha}^{-1} \text{ yr}^{-1}$, comparable to the measured value.

331 The best-fit parameter values from the base scenario were also used for the all other scenarios with catchments of
332 different topographic slope, assuming that the parameters do not change with the change of topographic slope. In total,
333 we simulated the flow and nitrate transport for eleven scenarios (11 catchments of different topographic slope). For
334 each scenario, the simulations were run for 100 years with identical boundary conditions for each year. The first 99
335 years were used as a spin-up phase to assure a dynamic equilibrium (i.e. to achieve simulated variables, such as heads
336 and concentrations, that are identical between years), and the last year was used for actual observation and analysis.
337 The CPU time of each simulation was ~4 hours.

338 3.2 Water ages

339 The water stored in a catchment (storage), Q and ET can all be characterized by age distributions, for they comprise
340 water parcels of different age from precipitation events that occurred in the past. The age distributions need to be
341 calculated for each aforementioned scenario to assess the responses of water ages on catchment topographic slope.

342 Our model setup (with virtual catchments and identical climate for each year) allowed us to perform long-term
343 numerical tracer experiments and to extract the age distributions.

344 We assumed that inert tracers of uniform concentration existed in precipitation. The tracers were applied to the land
345 surface as a third-type (Cauchy) boundary condition and were subjected to transport modeling. Tracer can exit the
346 aquifer via the outfluxes Q and ET. We considered a period of 200 years for the tracer experiments, which was
347 sufficiently long to ensure convergence of the computed water ages. The 200 years period was partitioned into 2400
348 months ($\Delta t = 1$ month). A different tracer was used for each of the periods resulting in a total of 2400 distinct tracers.

349 The injection of tracer i started with the precipitation at the beginning of its associated period t_0^i and lasted throughout
350 the period. The advective-dispersive multi-solute transport was simulated using HydroGeoSphere. The first 199 years
351 of the simulation period were used as a spin-up phase to ensure a dynamic equilibrium of the calculated ages,
352 minimizing the influence of the initial conditions. The last year was used for the actual observations and the
353 computation of age distributions. Solving the transport of the 2400 tracers would be computationally expensive.
354 However, because the climate (flow boundary conditions) was identical for each year, the transport simulation was
355 performed only for the first 12 tracers that covered the course of a year. Based on these results, the results for the other
356 2388 tracers were manually reproduced (e.g., by shifting the concentration breakthrough curves of the 12 tracers in
357 time while maintaining the shapes).

358 For each tracer, the breakthrough curves of the mass-fluxes of Q and ET, as well as the mass in storage were reported.
359 For a specific time t , the age distributions for Q/ET/storage were computed by calculating the mass fraction of each
360 tracer using:

$$361 \quad p_{Q/ET/S}(T, t) = \frac{M^i(t)}{\Delta t \sum M^i(t)} \quad (9)$$

362
363 where $p_Q(T, t)$, $p_{ET}(T, t)$ are the age distributions of Q, ET (equivalent to backward transit time distributions - TTDs),
364 and $p_S(T, t)$ is the age distributions of water in storage (equivalent to the residence time distribution - RTD). $M^i(t)$ is
365 the mass-flux of the tracer i in Q or ET, or the mass stored in catchment at time t , $\sum M^i(t)$ is the sum of $M^i(t)$ over
366 all tracers. T is the age ranging within $[t - t_0^i - \Delta t, t - t_0^i]$ for tracer i .

367 For each scenario, the CPU time of the tracer experiment was ~8 hours. Based on the age distributions, we calculated
368 the mean discharge age $T_Q(t)$, which is equivalent to the mean discharge transit time (simply referred to as ‘discharge
369 age’ in the following sections). We calculated the young water fraction in streamflow $YF_Q(t)$, which is the fraction of
370 streamflow with an age younger than three months (also referred to as ‘young streamflow fraction’ [Jasechko *et al.*
371 2016]). Similarly, the ET age $T_{ET}(t)$ and the young water fraction in ET $YF_{ET}(t)$ can be calculated as well (more
372 details are described in Text S1 of the supporting information). Their responses to changes in topographic slope were
373 analyzed.

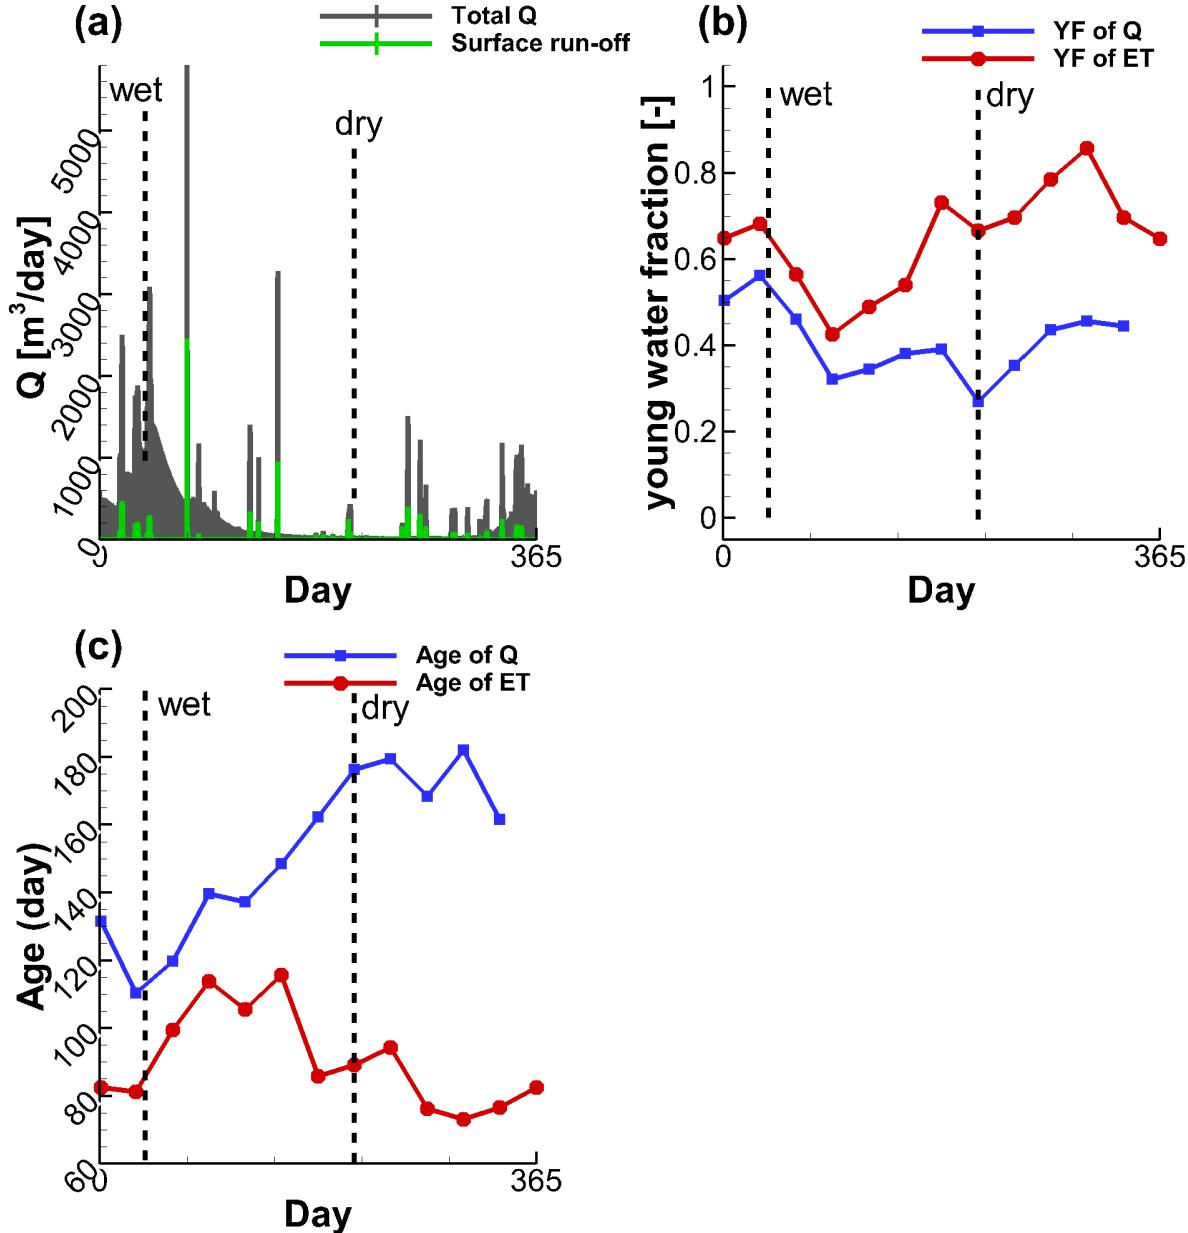

374

375 **4 Results and discussion**

376 **4.1 Dynamics of water ages and nitrogen fluxes**

377 Driven by the seasonality of the climate, the simulated Q , the young water fractions YF , and the water ages all show
378 seasonal fluctuations. Figure 3 shows these fluctuations for the base scenario (original topography). Q reaches its
379 maximum towards the end of the wet winter in late February and reaches its minimum during the drier late summer
380 in mid-September. Total Q consists of a portion of groundwater discharge (including the flow via vadose zone) and a
381 portion generated via surface-runoff during events of high precipitation (Figure 3a). The calculated YF_{ET} is smallest
382 in April and largest in November (Figure 3b), while YF_Q is smallest in August and largest in February. ET generally
383 has larger young water fractions than Q as ET has a higher probability to remove young water from the shallow soil
384 rather than the older water from the deeper aquifer. Especially during the dry season (summer), most precipitation can

385 be quickly removed by ET. The water ages of Q and ET show generally opposite fluctuation patterns for YF (Figure
 386 3c). The ET age ranges from 70 to 115 days, being younger than Q that has the age ranging from 109 to 180 days.

387
 388 **Figure 3.** Simulated (a) Q, (b) young water fractions in streamflow (YF_Q) and evapotranspiration (YF_{ET}), and (c) water
 389 ages for the catchment of the base scenario. The YF and water ages are monthly averages.

390
 391 The simulated C_Q shows strong seasonality with maxima in the wet and minima in the dry period, fitting the measured
 392 C_Q data well (Figure 4a). Figure 4b lists the calculated annual N mass balance in the catchment of the base scenario.
 393 The organic (SONa + SONp) and inorganic (SIN) N load in the soil are 470 kg ha⁻¹ and 43 kg ha⁻¹, respectively. The
 394 SON accounts for 92% of the total N load, which is consistent with the study of Stevenson [1995] where the organic

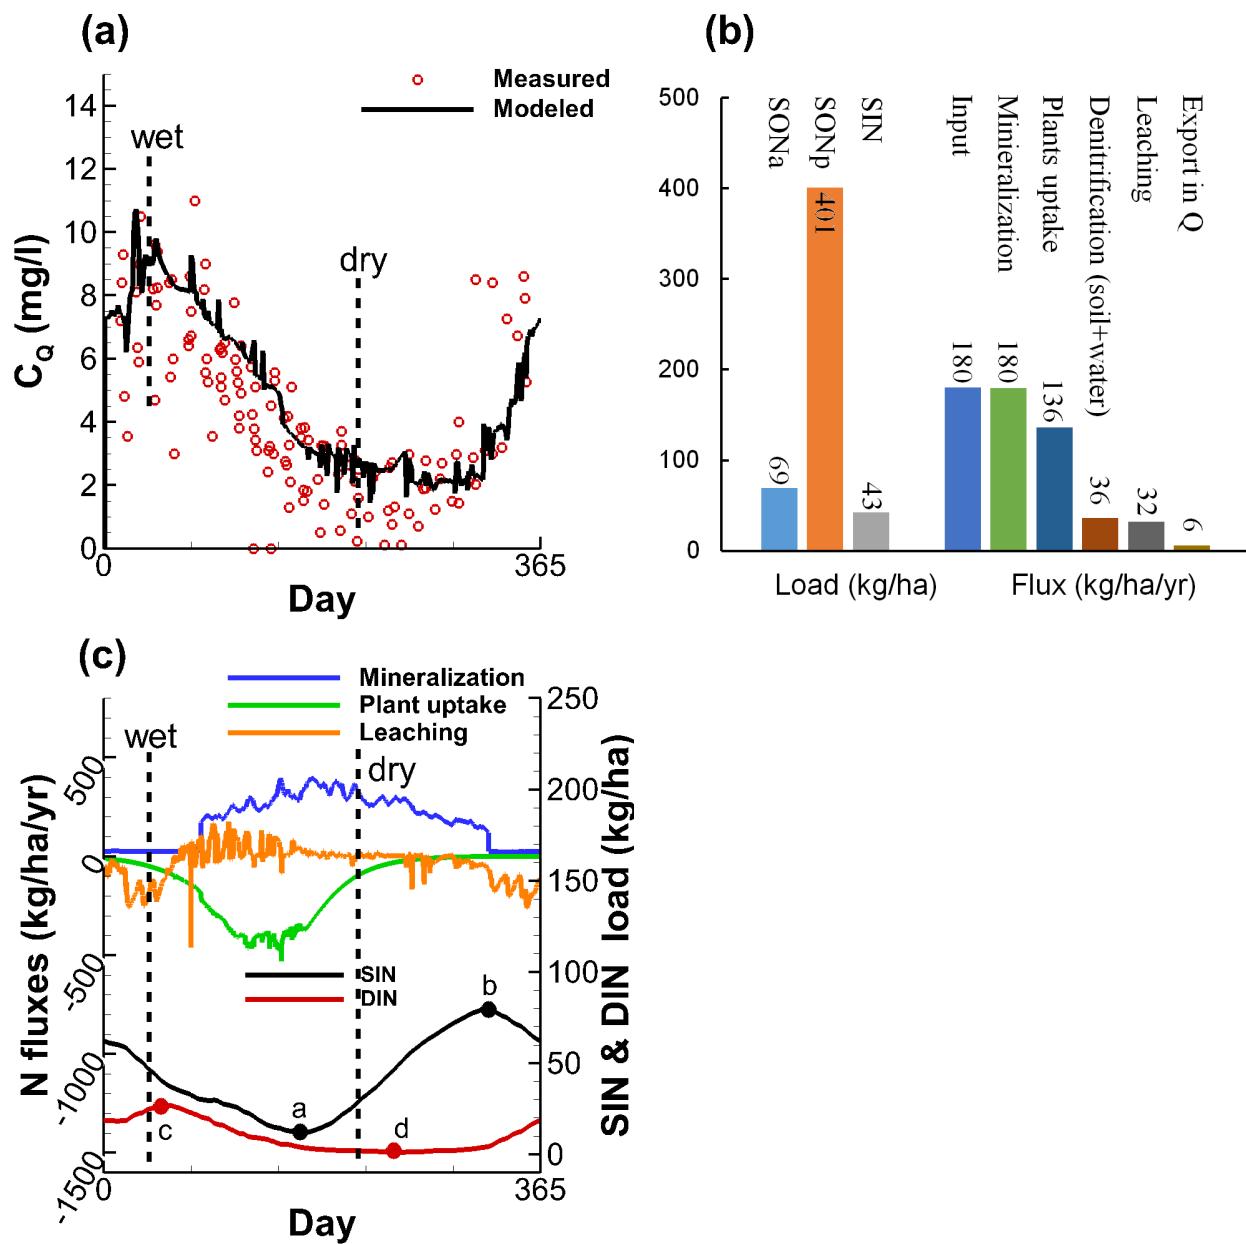

395 N fraction was reported to be greater than 90%. The mineralization converts SON into SIN with a rate of $180 \text{ kg ha}^{-1} \text{ yr}^{-1}$.
396 This rate is equal to the external N input because this way a steady-state of the annual N mass balance was reached
397 in the simulations. About 76% of the input N flux is taken up by the vegetation ($136 \text{ kg ha}^{-1} \text{ yr}^{-1}$). 20% is consumed
398 by denitrification ($36 \text{ kg ha}^{-1} \text{ yr}^{-1}$), either in the soil (before leaching) or in the groundwater (after leaching). The
399 remaining 4% reaches the stream water and is exported out of the catchment ($6 \text{ kg ha}^{-1} \text{ yr}^{-1}$). The simulated
400 mineralization flux is within the range of $[14\text{--}187] \text{ kg ha}^{-1} \text{ yr}^{-1}$ reported by *Heumann et al.* [2011] for their study sites
401 in central Germany. The simulated plant uptake and leaching fluxes are comparable to the values suggested in *Nguyen*
402 et al. [2021] for the same area ($120 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for plant uptake and $[15\text{--}60] \text{ kg ha}^{-1} \text{ yr}^{-1}$ for leaching). The simulated
403 denitrification rate is within the range $[8\text{--}51] \text{ kg ha}^{-1} \text{ yr}^{-1}$ reported in *Hofstra and Bouwman* [2005] for 336 agricultural
404 soils located worldwide. Moreover, 80% and 20% of the leaching N are consumed by denitrification during transport
405 in the groundwater and exported to stream water, respectively. These portions are generally comparable to those
406 reported in *Nguyen et al.* [2021] (61% and 39%, respectively). Therefore, the simulated N loads and fluxes for the
407 catchment of the base scenario are considered to be acceptable.

408 Figure 4c shows the temporal variation of the N load and fluxes. It demonstrates that low levels of SIN are maintained
409 by high plant-uptake before the dry summer arrives (May – June), such that there is little SIN available for leaching.
410 The SIN load reaches its minimum when plant uptake reaches its maximum (marker a in Figure 4c). The cessation of
411 plant-uptake during the dry period leads to the increase of the SIN load as well as the increase of the leaching rate.
412 The mineralization in winter is significantly reduced due to the dropping temperatures, cutting the SIN supply. This
413 results in the SIN load reaching its high peak in the middle of November (marker b in Figure 4c) and subsequent
414 decrease due to increased leaching and eventually plant uptake. These seasonal fluctuation patterns are generally
415 consistent with the knowledge of N fluxes reported in previous studies [Dupas et al., 2017; *Nguyen et al.*, 2021]. For
416 DIN load in water, it reaches its maximum generally when the leaching weakens in the beginning of March (marker c
417 in Figure 4c), and reaches the minimum just before the leaching process becomes active again in the end of August
418 (marker d in Figure 4c). These low and high peaks of SIN and DIN loads can also be identified by their spatial
419 distributions in the catchment (see Figure S2 in the supporting information).

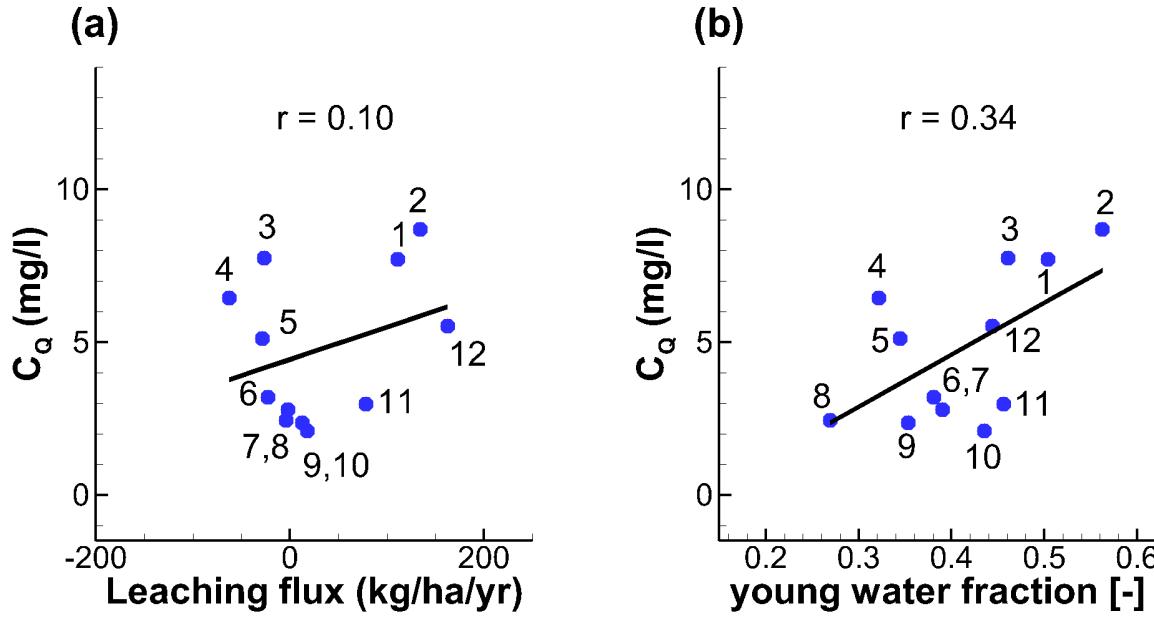

420 Seasonal variations of C_Q can be directly influenced either by the fluctuation of the nitrate leaching into groundwater,
421 or by fluctuations in the degradation in groundwater associated with varying transit times (quantified by the young
422 water fraction in streamflow YF_Q). These two influences represent the effect from the variability in N source and in N
423 transport, respectively. Linear regression analysis shows that C_Q is correlated with leaching flux rate and YF_Q with
424 Spearman rank-correlation coefficients of 0.1 and 0.34, respectively (Figure 5). The seasonal fluctuations of C_Q and
425 leaching flux are temporally out of phase. The maximum leaching occurs in December, while the maximum C_Q is
426 reached two months later in February (Figure 5a). The minimum leaching occurs in April, while the minimum C_Q is
427 reached around September. This behavior indicates that C_Q responds later to the changes in N leaching, which is
428 reasonable because the leaching nitrate needs time to travel from the shallow soil to streamflow. The fluctuation of
429 C_Q and YF_Q are more synchronized, proven by the fact that both maxima are reached in February (wet, Figure 5b) and
430 minima occur generally in the dry summer time. Field observations in mountainous central German catchments also
431 indicate that C_Q varies seasonally, with maxima during the wet winter and minima during the dry summer [Dupas et

432 al., 2017]. These seasonal fluctuations of C_Q and YF_Q were frequently explained using the “inverse storage effect”
433 [Harman, 2015; Yang *et al.* 2018]: during the wet season Q has a strong preference for young water associated with
434 higher concentrations, which would not occur during dry periods due to the deactivation of the shallow fast flow
435 processes. These patterns generally suggest that the C_Q fluctuation is more attributed to the variability in the N
436 transport rather than to the variability in the N source, echoing previous observations that 80% of the leaching N mass
437 is degraded during transport. However, it is still hard to tell whether the N source or the N transport is dominating the
438 C_Q fluctuation.

439

442 **Figure 4.** Simulated (a) In-stream nitrate concentration C_Q , (b) N loads and fluxes, and (c) time-variable N fluxes for
 443 the catchment of the base scenario. Note that the measured C_Q in (a) includes all the measurements from 2001 to 2010.

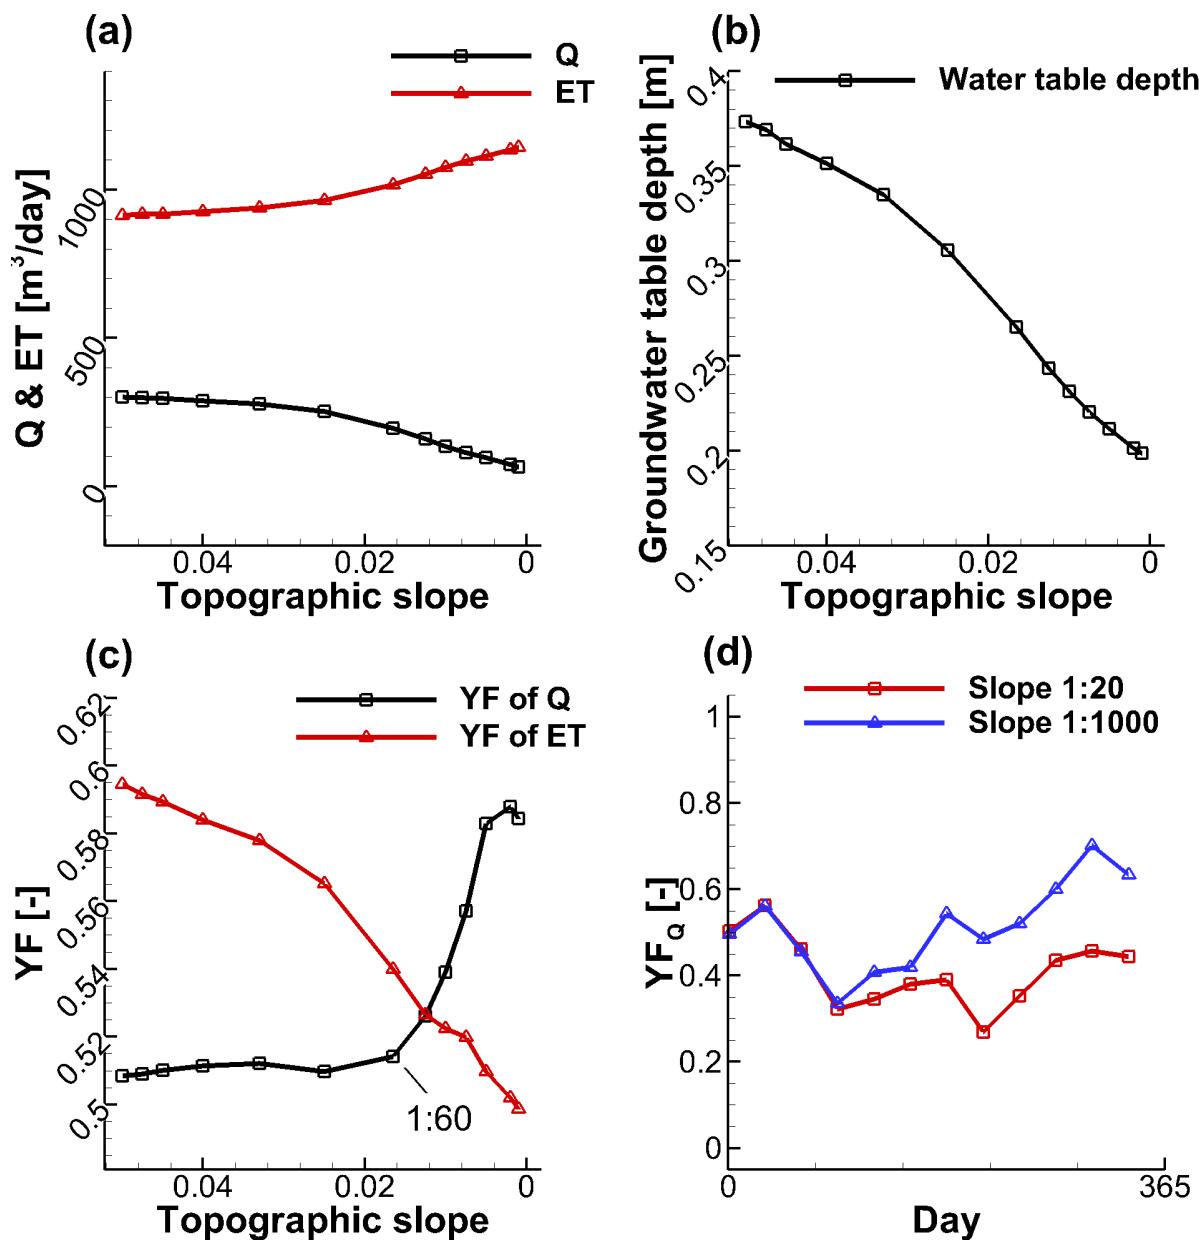

445

446 **Figure 5.** Comparing the monthly averaged C_Q with (a) the leaching flux and (b) the young water fractions of Q. The
 447 black lines are linear fits of the two variables, with r being the Spearman rank-correlation coefficient. The numbers
 448 refer to the months.

449

450 4.2 Effect of topographic slope on flow

451 With the help of our simulations, it is possible to systematically explore the influence of topographic slope on the
 452 water flow and N fluxes. Figure 6 shows the responses of temporally-averaged Q and ET, the groundwater table depth,
 453 and flow weighted mean YF_Q and YF_{ET} to the changes of topographic slope. Under a constant climate, the changes of
 454 topographic slope can reshape the water flow via influencing flow partitioning between Q and ET. More water is taken
 455 up by ET and less water becomes Q in flatter landscapes (Figure 6a). These patterns can be explained by the change
 456 of groundwater table depth (Figure 6b), as shallower groundwater tables can be reached by the vegetation in flatter
 457 landscapes where ET therefore has a higher chance to remove water from the subsurface. The simulated YF_Q and YF_{ET}
 458 show generally increasing and decreasing patterns, respectively, when the topographic slope decreases (Figure 6c),
 459 demonstrating that young streamflow is more prevalent in flatter landscape and young ET is more prevalent in steeper
 460 landscapes. However, the increasing pattern of YF_Q does not continue in steep catchments with slopes $> 1:60$.
 461 Topographic slope changes YF_Q not only in terms of its mean value, but also in terms of its temporal variation. Figure
 462 6d indicates that the maximum and minimum YF_Q are reached in February and August for the steepest catchment
 463 (slope 1:20), respectively, and in November and April for the flattest catchment (slope 1:1000).

466 **Figure 6.** The simulated (a) Q and ET, (b) spatially-averaged depth of the groundwater table from the land surface,
 467 (c) young water fraction in streamflow YF_Q and evapotranspiration YF_{ET} , in relation to the topographic slope for the
 468 simulated catchments. (d) temporal variations of YF_Q for a steep landscape (slope 1:20) and a flat landscape (slope
 469 1:1000).

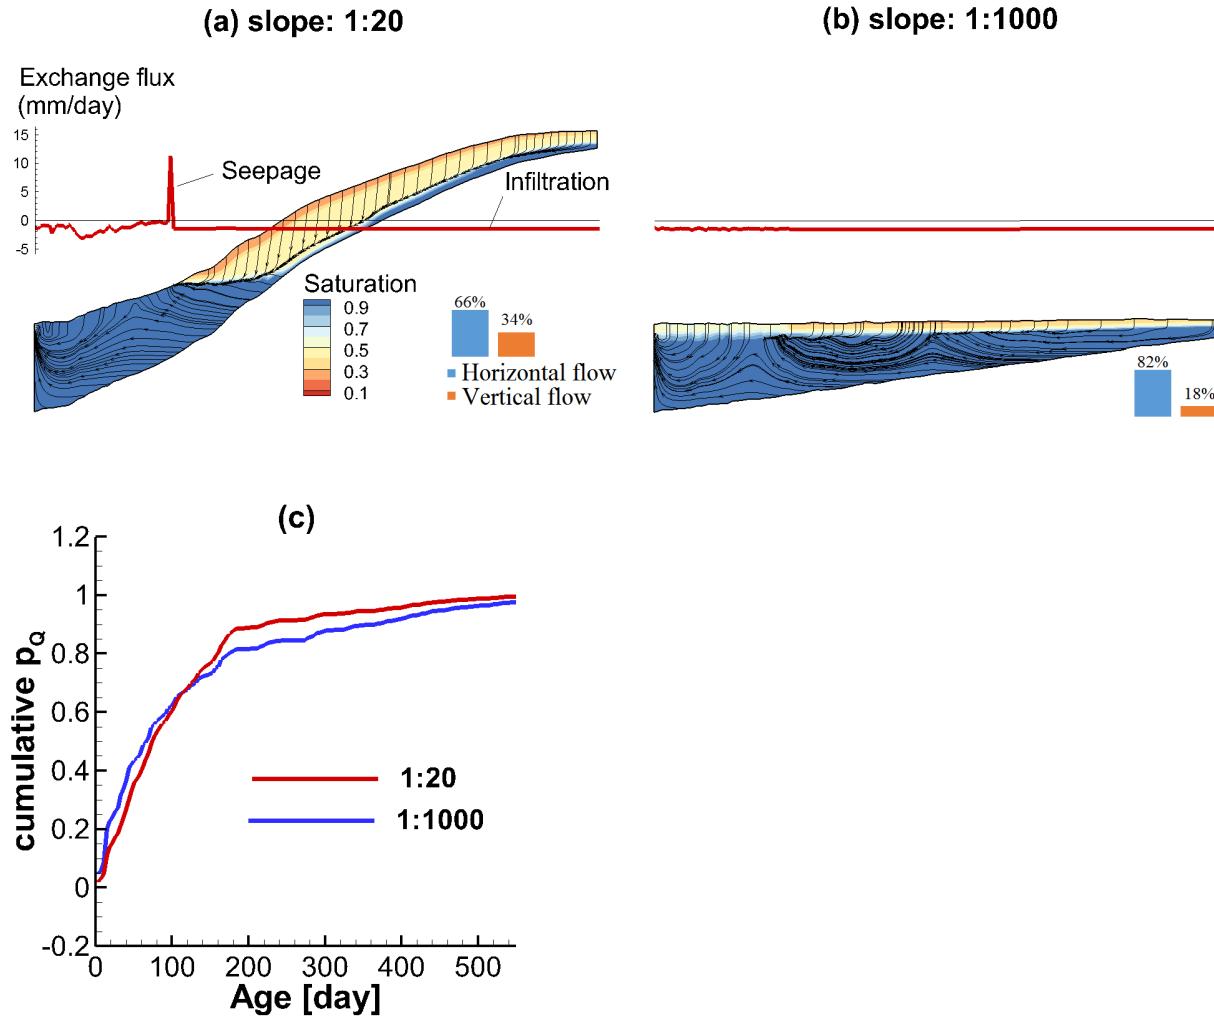

471 Interpreting the response of the YF_Q to topographic slope mechanistically requires a closer look at the flow processes
 472 using a cross-sectional view. We plotted the subsurface flow fields for the wet season at a cross-section of the
 473 catchments with slopes 1:20 and 1:1000 (Figure 7).

474 Figure 7a reveals that the hillslope part of the catchment with a slope of 1:20 is largely unsaturated so that the flow
475 paths in this area are characterized by vertical infiltration. In contrast, the valley bottom is fully saturated. Overall,
476 34% of the subsurface domain is characterized by vertical flow (flow in 34% of the total aquifer volume is more
477 vertical than horizontal). For this scenario two main discharge routes to the stream can be identified: (i) A fraction of
478 the groundwater flows through the fully saturated zone and exits the aquifer to the stream, and (ii) another fraction
479 exits the aquifer via seepage near to where the groundwater table intersects the land surface, indicated by a large
480 exchange flux (from subsurface to surface, positive). The seepage represents a preferential flow path allowing for
481 discharge via overland flow instead of discharge via the sub-surface with longer transit times. Note that both of the
482 discharge routes provide the pathways for the rainfall falling on the top hillslope to reach the stream.

483 When the slope is reduced to 1:1000, the flow pattern experiences significant changes (Figure 7b) compared to the
484 catchment with a slope of 1:20. Several hydrologic studies have described two different flow systems in aquifers: (i)
485 a recharge-limited system where the thickness of the unsaturated zone is sufficient to accommodate any water-table
486 rise and thus the elevation of the groundwater table is limited by the recharge, and (ii) a topography-limited system
487 where the groundwater table is close or connected to the land surface such that any fluctuation in groundwater table
488 can result in considerable change in surface runoff [Werner and Simmons, 2009; Michael et al., 2013]. In the selected
489 cross sections, the steeper one (slope 1:20) is a partially topography-limited system (Figure 7a) (the hillslope is
490 recharge-limited while the valley bottom is topography-limited). The flat one (slope 1:1000) is transformed into a
491 fully recharge-limited system (from Figure 7b) due to the reduced hydraulic head gradients. This transformation leads
492 to three main effects: (i) The seepage flow vanishes because the groundwater table disconnects from the land surface.
493 The seepage route that would discharge water from the top of hillslope to the stream is cut off, (ii) the infiltration
494 processes is weakened, indicated by the fact that the portion of subsurface domain characterized by vertical flow is
495 reduced from 34% to 18%, and (iii) local flow cells are more likely to form, where water infiltrates to the aquifer and
496 eventually exits the aquifer via ET rather than via flow to the stream (Figure 7b, the local flow cells are more
497 pronounced in the dry season, see Figure S3-b in the supporting information).

498 Because of the three aforementioned effects, the connectivity between the stream and the more distant hillslopes is
499 significantly reduced. Precipitation falling farther from the stream has a lower chance to reach the stream and a higher
500 chance to be intercepted by ET on its way to the stream. The hillslope that used to generate old streamflow does not
501 contribute to streamflow anymore. While precipitation water close to the stream has a higher chance to contribute to
502 streamflow. We concluded that the increase of the YF_Q in flat landscapes is due to this reduction of the longer flow
503 paths and the persistence of shorter flow paths, as indicated by the computed TTDs (Figure 7c).

504

505
506 **Figure 7.** Cross-sectional view of saturation, flow paths, and exchange fluxes between the surface and the subsurface
507 in the wet season (February) for catchments with topographic slope (a) 1:20, and (b) 1:1000. The cross-section is
508 marked in Figure 1a. The black lines represent the flow paths. The red curves show exchange fluxes (along the cross-
509 sectional profiles), positive values indicate seepage to the land surface and negative values indicate infiltration to the
510 subsurface. (c) The computed cumulative TTDs for Q during the wet season (February), for the catchment with
511 topographic slope of 1:20 and 1:1000.

512
513 In summary, we identified a generally increasing pattern of YF_Q in response to the decreasing topographic slope. When
514 the landscape becomes flatter, the hydraulic head gradient as the main driving force changes the aquifer from a
515 partially topography-limited system to a recharge-limited system that is more likely to form local flow cells.

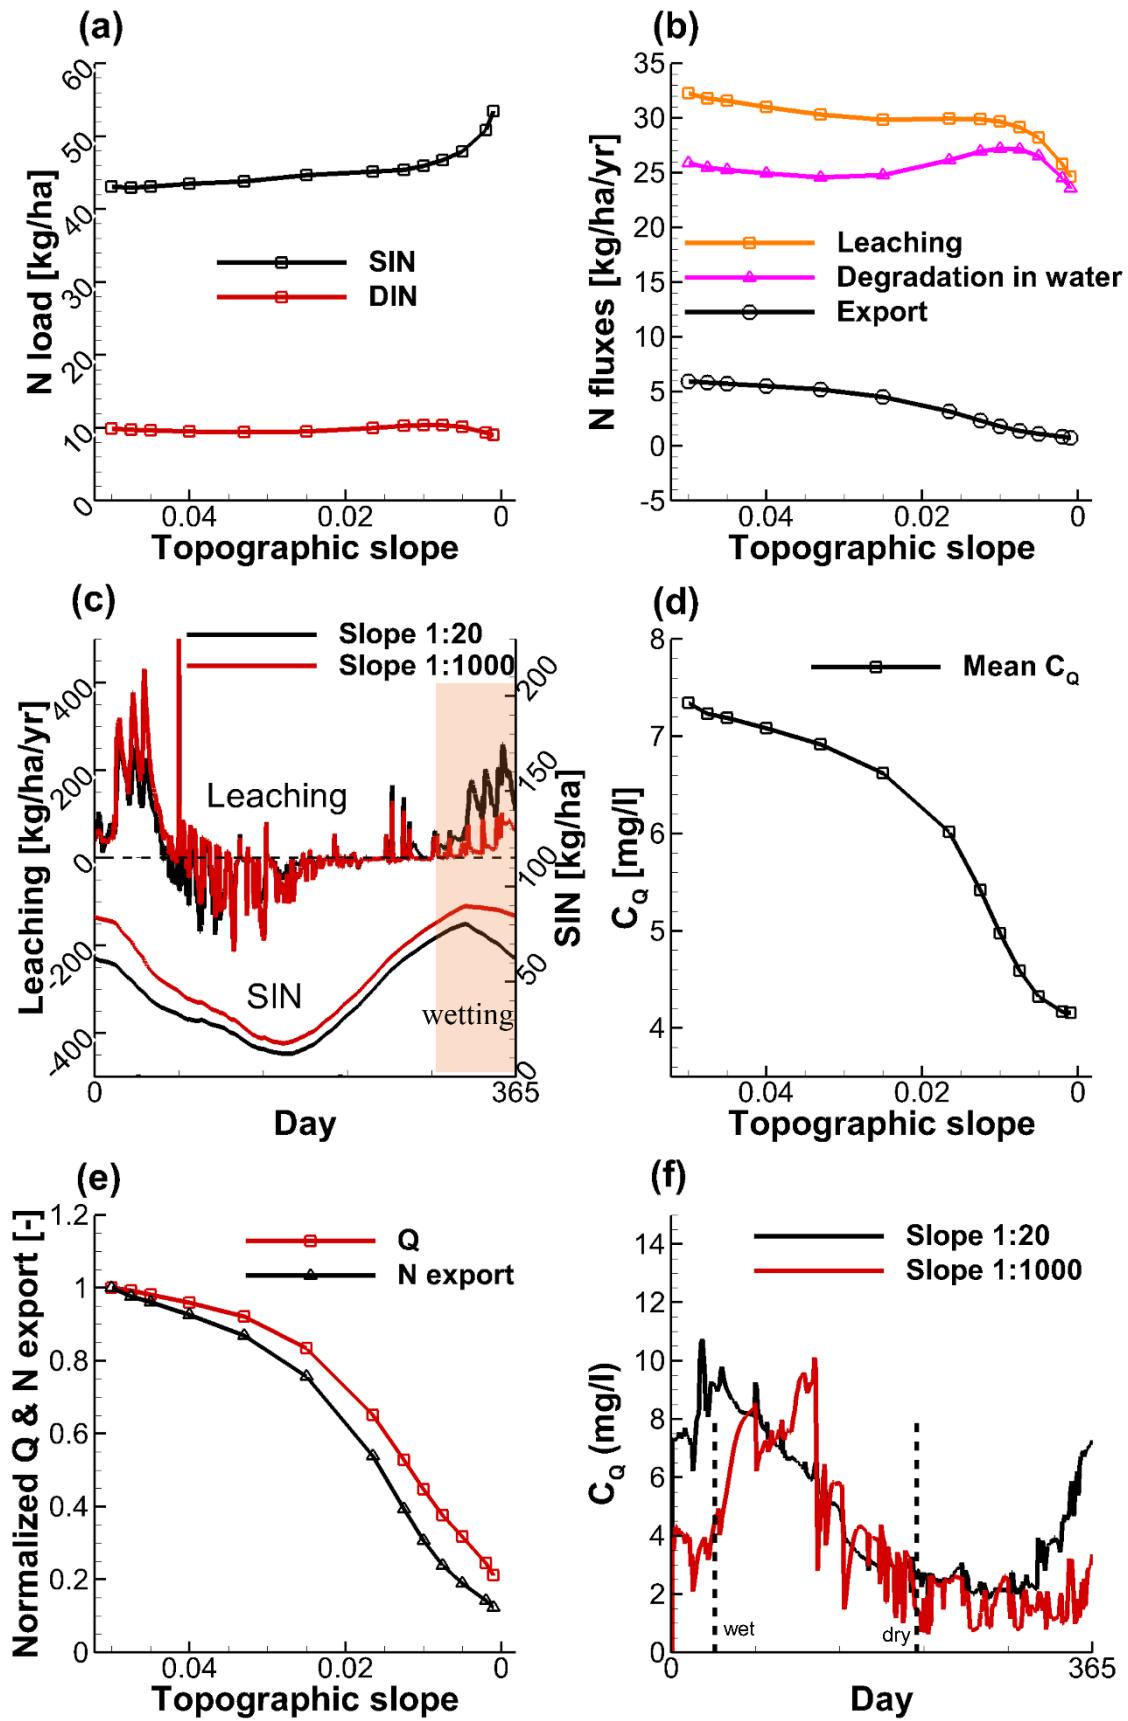

516
517 **4.3 Effect of topographic slope on N export**

518 Simulated results show that the topographic slope can influence the N loads and fluxes in catchments. Figure 8a
519 demonstrates that SIN tends to be higher in flatter and lower in steeper landscapes. This generally indicates that a flat

520 landscape has a higher potential to retain N in the soil. However, the DIN is not significantly influenced by the
521 topographic slope. N fluxes of leaching and export to the stream exhibit the opposite pattern. For the N fluxes, the
522 leaching into groundwater decreases with the decrease of topographic slope (Figure 8b). This is mainly because the
523 flow velocity (influencing the leaching rate according to equation 6) in flatter landscape is lower due to the reduced
524 hydraulic head gradient. Comparing the time-variable leaching between the steepest and flattest catchments (slope
525 1:20 and 1:1000, Figure 8c), it can be observed that the leaching reduction in the flatter landscape mainly occurs in
526 the wetting period (Nov to Dec). This may be because the response of flow velocity in the flatter catchment is not as
527 large as that in the steeper catchment when the system transitions from dry to wet conditions. A large portion of the
528 leached N mass has been degraded during transport in the groundwater, with the fraction rising from 80% in the
529 steepest landscape to 95% in the flattest landscape (Figure 8b). Mechanically, the reduced connectivity between the
530 stream and more distant hillslopes in flatter landscapes inhibits the N export to the stream promoting the degradation
531 by increasing the N residence time in the catchment. Subsequently, the N export shows a decreasing pattern with the
532 decrease of topographic slope (Figure 8b).

533 The calculated flow-weighted mean C_Q shows a decreasing trend in response to the decreasing topographic slope
534 (Figure 8d), from 7.3 mg l⁻¹ in the steepest catchment to 4.2 mg l⁻¹ in the flattest catchment. Even though both Q and
535 N export show decreasing patterns with the decrease of topographic slope, the N export decreases to a higher degree
536 than Q, indicated by the normalized values (Figure 8e). Comparing the time-variable C_Q between the steepest and
537 flattest catchments (slope 1:20 and 1:1000, Figure 8f), it can be observed that the topographic slope influences the C_Q
538 in two ways: (i) The C_Q is generally lower (but not always) in the flatter landscape over most of the time in a year, and
539 (ii) the high peaks of C_Q in flatter landscapes are delayed in time. However, the high concentrations always occur in
540 the wet periods (Jan – Apr) and low concentrations always occur in the dry periods (Jul – Oct).

541

543 **Figure 8.** The simulated (a) N loads, (b) N fluxes in relation to the topographic slope for the simulated catchments.
544 (c) Comparison of the time variable N loads and fluxes between a steep (slope 1:20) and a flat land scape (slope
545 1:1000). The simulated (d) flow-weighted mean C_Q , and (e) the normalized Q and N export (normalized to their values
546 of the base scenario) in relation to the topographic slope. (f) Comparison of the time variable C_Q between a steep
547 (slope 1:20) and a flat land scape (slope 1:1000). Note that for the leaching fluxes in (c), positive values are referred
548 to as the N leaching from the soil to the groundwater, negative values are referred to as the precipitation of N from
549 groundwater to the soil by the evapoconcentration effect. The vertical dashed lines indicate the time when the
550 catchment reaches the wettest (left) and the driest (right) conditions.

551

552 4.4 Discussion

553 *Jasechko et al.*, [2016] reported that (the logarithm of) catchment topographic slope was significantly negatively
554 correlated with young streamflow fractions with a spearman rank correlation of -0.36. This conclusion was made
555 statistically based on their observed 254 sites. Our numerical study based on the eleven catchments with different
556 slopes but identical climate conditions resulted in more physically-based information that goes beyond such statistical
557 correlations. Our results confirm that young streamflow fraction and slope generally exhibit a negative correlation.
558 Additionally, our results show that the young water fraction in ET is positively correlated with the slope.

559 From the steepest landscape to the flattest landscape, catchments are likely to transition from a partially topography-
560 limited flow system to a recharged limited system, due to the reduction of hydraulic gradient. The groundwater table
561 is closer to the land surface when the landscape becomes flatter. The larger young streamflow fraction in flatter
562 landscapes is consistent with the statement made by *Jasechko et al.* [2016] that the young streamflow fraction is more
563 prevalent in flatter catchments which are characterized by more shallow lateral flow and less vertical infiltration. This
564 phenomenon is also consistent with a negative correlation between groundwater table depth and young streamflow
565 fraction, which has been frequently reported [Bishop et al., 2004; Seibert et al., 2009; Frei et al., 2010; *Jasechko et*
566 *al.*, 2016]. Using the insight into the flow processes of the catchment, we found that the connectivity between the
567 stream and the more distant hillslopes is reduced in flatter landscape, due to the reduced seepage flow, the weakened
568 infiltration and the formation of local flow cells that do not deliver flow to the stream. Our study points out that the
569 reduction of this connectivity, which results in the reduction of the longer flow paths and the persistence of shorter
570 flow paths, causes the increase of the young streamflow fraction.

571 Basically, the position of the groundwater table, flow path lengths and flow velocities, which are all different for
572 different topographic slopes, jointly affect the young streamflow fractions. Besides that, temporal variability of these
573 three factors drives the distinct responses of the young streamflow fraction to topographic slope between seasons. In
574 our simulated catchments, the negative correlation between young streamflow fraction and topographic slope is more
575 pronounced in the flat landscapes with slopes $< 1:60$. This demonstrates that the system is complex and apparently
576 contains various threshold effects disturbing a straightforward monotonous relationship between catchment
577 characteristics (e.g. slope) and young water fraction (or streamflow concentration). In this sense, systematically

578 investigating the reaction of the flow dynamics to catchment characteristic is necessary, rather than assuming a
579 straightforward cause-effect relationship that can be misleading.

580 Our results demonstrate that stream water quality is potentially less vulnerable in flatter landscapes. The flatter
581 landscapes tend to retain more N mass in the soil and export less N mass to the stream. This behavior can be attributed
582 to (i) the reduced leaching in flat landscapes since the decreased flow velocity physically reduces the potential of water
583 to solve and transport the solute, and (ii) the increased potential of degradation because the connectivity between the
584 stream and hillslope is blocked (i.e. there is more time for decay). Our results also show that higher C_Q is more
585 prevalent in steeper landscapes. Note that this is concluded for average concentrations. Observations from the Selke
586 catchment, central Germany show that the C_Q is not always lower in flatter regions [Dupas *et al.*, 2017; Nguyen *et al.*,
587 2022]. In the future more attention should be paid to the temporal variation and the time-scale concerning the effect
588 of topographic slope on C_Q . Additionally, our results show that we can expect lower C_Q and higher young streamflow
589 fractions in flatter landscapes. This suggests that, with regard to the N transport in catchments, a large young
590 streamflow fraction is not sufficient for high levels of C_Q . This phenomenon has not yet been reported to the best of
591 our knowledge.

592 Concerning the seasonal variations of C_Q , our results showed that significant seasonal variation can be expected under
593 temperate humid climates regardless of topographic slope. The high peak concentrations occurred in the wet and the
594 low in the dry seasons, being consistent with the findings of previous studies [Benettin *et al.* 2015; Harman, 2015;
595 Kim *et al.*, 2016; Yang *et al.*, 2018]. However, the topographic slope can slightly shift the high peak concentrations in
596 time.

597

598 **4.5 Limitations and outlook**

599 The cross-comparison between catchments with differing topographic slopes provides physically-based insights into
600 the effects of topographic slope on nitrate export responses in terms of N fluxes and mean concentrations. However,
601 this study is limited in scope in that it neglects other factors that may also have important impacts on the young
602 streamflow and nitrate export processes:

603 First, our study only considered the aquifers that is unconfined with an impermeable base and prescribed heterogeneity.
604 Other catchment characteristics such as landscape aspect, catchment area, aquifer permeability or drainage ability,
605 aquifer depth, stream bed elevation, fractured bedrock permeability, bedrock slope and shape of basin can potentially
606 change the flow patterns and age composition in streamflow [McGlynn *et al.*, 2003; Broxton *et al.*, 2009; Sayama and
607 McDonnell, 2009; Stewart *et al.*, 2010; Jasechko *et al.*, 2016; Heidbüchel *et al.*, 2013, 2020; Zarlenga and Fiori,
608 2020]. For example, aquifers with high permeability or highly fractured bed rock are more likely to use deep rather
609 than shallow flow paths and preferential discharge routes that lead to rapid drainage. Apart from that, it was reported
610 that hydrological features such as precipitation variability, ET, antecedent soil moisture are also significantly linked
611 to transit times [Sprenger *et al.*, 2016; Wilusz *et al.* 2017; Evaristo *et al.*, 2019; Heidbüchel *et al.*, 2013, 2020]. For
612 example, compared to uniform precipitation, event-scale precipitation is more likely to trigger rapid surface runoff

613 and intermediate flow, such that the contribution of young water from storage to streamflow can be increased.
614 Therefore, further research should consider a more complex model structure involving various heterogeneity and
615 climate types.

616 Second, several main simplifications were used in the formulation of the nitrate transport processes. (i) Transport
617 modelling employed a constant degradation rate coefficient assuming that transit time was the only factor to determine
618 degradation. This assumption neglected other factors that can spatially and temporally affect denitrification rates, such
619 as temperature, redox boundaries (e.g., high oxygen concentration in shallow flow paths), the amount of other nutrients
620 (e.g. carbon), which also contribute to the seasonality in nitrate concentrations [Böhlke *et al.*, 2007]. Apart from that,
621 we did not account for the long-term (decades [Van Meter *et al.*, 2017]) nitrate legacy effect as the dissolved nitrate
622 in groundwater reservoirs degraded continuously in our model, which would not occur in older reservoirs where the
623 denitrification is very slow or deactivated (e.g. due to the lack of a carbon source). (ii) The N external input source
624 was uniformly applied across the land surface in our modelling. However, strong source heterogeneity may exist in
625 catchments. For example, the N external input varies between land uses or along the soil profile [Zhi *et al.*, 2019].
626 This spatial source heterogeneity could affect the seasonal variations of C_Q [Musolff *et al.*, 2017; Zhi *et al.*, 2019] and
627 should be considered in further research.

628 While the numerical model provided general insights, there was potential uncertainty in the simulated results. Firstly,
629 the aforementioned simplifications may introduce model structural errors. Secondly, the model calibration was only
630 constrained by limited data sets, which may lead to the non-uniqueness in the model parameters. Both of the aspects
631 may introduce uncertainty in the simulated N loads and fluxes. Future work should be devoted to better constrain the
632 model parameters, either by enhancing the concentration data quality through more frequent measurements or by
633 providing additional data sets related to the N pool.

634 Despite these limitations, the numerical experiments in this study could clearly identify the response of young
635 streamflow and nitrate export to topographic slope under a humid seasonal climate, and show that hydraulic gradient
636 is an important factor causing flow field differences between the catchments. This was achieved by using the
637 advantages of a physically-based flow simulation that allows for a more mechanistic evaluation of flow processes,
638 which would be impossible with a purely data driven analysis based on, e.g., isotopic tracers only.

639

640 **5 Conclusions**

641 Previous data driven studies suggested that catchment topographic slope impacts the age composition of streamflow
642 and consequently the in-stream concentrations of certain solutes [Jasechko *et al.*, 2016]. We attempted to find more
643 mechanistic explanations for these effects. We chose the small agricultural catchment ‘Schäfertal’ in Central Germany
644 and, based on it, generated eleven synthetic catchments of varying topographic slope. The groundwater and overland
645 flow, and the N transport in these catchments were simulated using a coupled surface-subsurface model. Water age
646 compositions for Q and ET were determined using numerical tracer experiments. Based on the calculated flow patterns,
647 young water fractions in streamflow YF_Q , N mass fluxes and in-stream nitrate concentration C_Q , we systematically

648 assessed the effects of varying catchment topographic slopes on the nitrate export dynamics in terms of the mass fluxes
649 and annual mean concentration levels. The main conclusions of this study are:

- 650 • Under the considered humid climate, YF_Q is generally negatively correlated to topographic slope. When the
651 landscape becomes flatter, the hydraulic head gradient is the main driving force to change the aquifer from a
652 partially topography-limited system to a recharge-limited system, reducing the connectivity between the
653 stream and the more distant hillslopes. This change results in the reduction of longer flow paths and the
654 persistence of shorter flow paths, subsequently causing the flatter landscapes to generate younger streamflow.
- 655 • The flatter landscapes tend to retain more N mass in soil and export less N mass to the stream. These patterns
656 are attributed to (i) the reduced leaching in flat landscape as the decreased flow velocity physically reduces
657 the potential of water to transport the solute towards the stream, and (ii) the increased potential of degradation
658 as the connectivity between the stream and hillslope is blocked and the solute stays inside the aquifer longer.
- 659 • For the considered catchment, the annual mean C_Q shows a decreasing trend in response to the decreasing
660 topographic slope, because the N export decreases to a higher degree than Q. Flatter landscapes tend to
661 generate larger young streamflow fractions (but lower C_Q), suggesting that a large young streamflow fraction
662 is not sufficient for a high level of C_Q .

663 Overall, this study provided a mechanistic perspective on how catchment topographic slope affects young streamflow
664 fraction and nitrate export patterns. The use of a fully-coupled flow and transport model extended the approach to
665 investigate the effects of catchment characteristics beyond the frequently used tracer data-driven analysis. It can be
666 used for similar studies of other catchment characteristics and for other solutes. The results of this study improved the
667 understanding of the effects of certain catchment characteristics on nitrate export dynamics with potential implications
668 for the management of stream water quality and agricultural activity, in particular for catchments in temperate humid
669 climate with pronounced seasonality. Given the limitations of this study, future work should be devoted to improve
670 the degradation formulation, to investigate further catchment characteristics, as well as to consider various climate
671 types.
