1 **Abstract.** Microwave observations are sensitive to plant water content and could therefore provide essential information on
2 biomass and plant water status in ecological and agricultural applications. The combined data record of the C-band scatterom-
3 eters on ERS 1/2, the Metop series and the planned Metop Second Generation satellites will span over 40 years, which would
4 provide a long-term perspective on the role of vegetation in the climate system. Recent research has indicated that the unique
5 viewing geometry of ASCAT could be exploited to observe vegetation water dynamics. The incidence angle dependence of
6 backscatter can be described with a second order polynomial, the slope and curvature of which are related to vegetation. In a
7 study limited to grasslands, seasonal cycles, spatial patterns and interannual variability in the slope and curvature were found
8 to vary among grassland types and were attributed to differences in moisture availability, growing season length and pheno-
9 logical changes. To exploit ASCAT slope and curvature for global vegetation monitoring, their dynamics over a wider range
10 of vegetation types needs to be quantified and explained in terms of vegetation water dynamics. Here, we compare ASCAT
11 data with meteorological data and GRACE Equivalent Water Thickness (EWT) to explain the dynamics of ASCAT backscat-
12 ter, slope and curvature in terms of moisture availability and demand. We consider differences in the seasonal cycle, diurnal
13 differences, and the response to the 2010 and 2015 droughts across ecoregions in the Amazon basin and surroundings. Results
14 show that spatial and temporal patterns in backscatter reflect moisture availability indicated by GRACE EWT. Slope and cur-
15 vature dynamics vary considerably among the ecoregions. The evergreen forests, often used as a calibration target, exhibit very
16 stable behaviour even under drought conditions. The limited seasonal variation follows changes in the radiation cycle, and may
17 indicate phenological changes such as litterfall. In contrast, the diversity of land cover types within the Cerrado region results
18 in considerable heterogeneity in terms of the seasonal cycle and the influence of drought on both slope and curvature. Seasonal
19 flooding in forest and savanna areas also produced a distinctive signature in terms of the backscatter as a function of incidence
20 angle. This improved understanding of the incidence angle behaviour of backscatter increases our ability to interpret and make
21 optimal use of the ASCAT data record and VOD products for vegetation monitoring.

22 1 Introduction

23 Microwave remote sensing observations are sensitive to plant water content, which depends on above ground biomass and
24 plant water status (Konings et al., 2019). Data from active and passive microwave sensors can provide valuable information
25 about vegetation in a range of applications in ecological and agricultural monitoring (Konings et al., 2019; Steele-Dunne et al.,
26 2017). In particular, Vegetation Optical Depth (VOD) products derived from various passive and active microwave sensors are
27 increasingly used for biomass monitoring (Liu et al., 2015), drought monitoring (Liu et al., 2018), wildfire risk assessment
28 (Forkel et al., 2019) and have been related to Gross Primary Production (Teubner et al., 2018, 2019), carbon stocks (Chaparro
29 et al., 2019) and drought-driven tree mortality (Rao et al., 2019). Currently VOD datasets are available from single sensor
30 passive microwave observations, such as SMAP (Konings et al., 2016), SMOS (Fernandez-Moran et al., 2017) and AMSR2
31 (Owe et al., 2001; De Jeu, 2003). Furthermore, long-term data records are available that combine VOD from different sensors
32 (Moesinger et al., 2020; Liu et al., 2011).

33 The current study is motivated by the availability of consistent C-band data from 1991 to at least 2030, and its potential
34 value as a long-term data record for vegetation monitoring. The Advanced Scatterometer (ASCAT) is a real aperture radar
35 operating at 5.255 GHz with VV polarization. There are currently three ASCAT instruments in orbit on Metop-A, Metop-B
36 and Metop-C, launched in October 2006, September 2012 and November 2018 respectively. ASCAT builds on the success
37 of the European Scatterometer (ESCAT) which flew on the ERS-1/2 satellites from 1991-2011 (Attema, 1991; Figa-Saldaña
38 et al., 2002; Wagner et al., 2013)). Continuation of the ESCAT/ASCAT record is ensured by the plans to launch SCA on
39 Metop-SG in 2024 (Stoffelen et al., 2017). Using data from a single series of satellites with identical and inter-calibrated
40 instruments circumvents many of the challenges of reconciling data using different frequencies, viewing geometries and orbit
41 characteristics. The continuity from ERS to Metop and Metop-SG ensures an internally consistent data product for at least 40
42 years, rendering it ideal to study the role of vegetation in the climate system.

43 Many early studies demonstrated the sensitivity of ESCAT and ASCAT backscatter to vegetation, and explored the potential
44 value of these data for vegetation monitoring (Wismann et al., 1995; Frison et al., 1998; Woodhouse et al., 1999; Jarlan et al.,
45 2002; Steele-Dunne et al., 2012; Schroeder et al., 2016). These studies focused on spatial and temporal variations in backscatter
46 normalized to some reference angle. Here, the focus is on the potential information content of the incidence angle behaviour
47 of backscatter, and particularly the so-called "Dynamic Vegetation Parameters" describing the incidence angle behaviour of
48 backscatter as calculated in the TUW Wien Soil Moisture Retrieval (TUW SMR) algorithm (Hahn et al., 2017).

49 The ASCAT Dynamic Vegetation Parameters refer to the parameters of the second order Taylor polynomial used to describe
50 the incidence angle (θ) dependence of backscatter σ° . This is described as follows:

$$51 \sigma^\circ(\theta) = \sigma^\circ(\theta_r) + \sigma'(\theta_r) \cdot (\theta - \theta_r) + \frac{1}{2} \cdot \sigma''(\theta_r) \cdot (\theta - \theta_r)^2 \quad [dB] \quad (1)$$

52 where $\sigma^\circ(\theta_r)$, $\sigma'(\theta_r)$ and $\sigma''(\theta_r)$ are the normalized backscatter, slope and curvature at some reference angle θ_r . In the
53 TUW SMR, this expression is used to normalize backscatter values from different incidence angles to a reference angle θ_r . It is
54 also used to account for the influence of vegetation on backscatter as the incidence angle behaviour of σ° depends on whether

55 total backscatter is dominated by surface scattering from the soil, volume scattering from the vegetation, or multiple scattering
56 (Wagner et al., 1999; Naeimi et al., 2009; Hahn et al., 2017).

57 Results from Steele-Dunne et al. (2019) suggest that considering the slope ($\sigma'(\theta)$) and curvature ($\sigma''(\theta)$) dynamics in combi-
58 nation with the backscatter could yield valuable insights into vegetation water dynamics. Seasonal cycles, spatial patterns and
59 interannual variability in the slope varied between grassland cover type reflecting variations in soil moisture availability and
60 growing season length. Results also suggested that curvature variations were influenced by the total water content, but also its
61 vertical distribution within the vegetation and the geometry of constituents. Contiguous anomalies were observed in both slope
62 and curvature during drought periods, suggesting that the slope and curvature provide insight into when the severity of a soil
63 moisture anomaly is enough to impact vegetation. Diurnal variations were also observed and attributed to sub-daily variations
64 in the dominant scattering mechanism due to changes in the vertical moisture distribution of the grasses. More recently, Pfeil
65 et al. (2020) observed a “spring peak” in slope values around April in broadleaf deciduous forest in Europe. Using LAI and
66 data from the Pan European Phenological database (PEP725) (Templ et al., 2018) they argued that this spring peak in ASCAT
67 slope coincides with spring activation, particularly the increase in water content of bare twigs and branches prior to leaf out in
68 broadleaf deciduous forests. ASCAT slope and curvature therefore seem to be sensitive to changes in vegetation water content
69 and structure of vegetation.

70 The goal of this study is to improve our understanding of the ASCAT backscatter-incidence angle relationship and how
71 they might be used to monitor vegetation water dynamics. The Amazon basin and its surroundings has been chosen as a study
72 area as it provides a wide range in terms of expected variability in ASCAT backscatter, slope and curvature. Backscatter in
73 the evergreen forest was considered so stable that this region has been used for satellite radar calibration (Birrer et al., 1982).
74 In contrast, seasonal changes in the Cerrado are expected to yield strong annual cycles in backscatter, slope and curvature.
75 Seasonal cycles and diurnal differences in ASCAT backscatter, slope and curvature will be determined for several ecoregions
76 of interest. These will be compared to meteorological data and GRACE terrestrial water storage variations to relate the ASCAT
77 backscatter, slope and curvature to moisture availability and demand. Finally, we will investigate whether there are anomalies
78 in the ASCAT backscatter, slope and curvature as a result of the 2010 and 2015 droughts.

79 2 Data and Methods

80 2.1 Study Area

81 Figure 1 shows the extent of the study domain, highlights the biomes (by color) and outlines the ecoregions of interest identified
82 in the WWF Terrestrial Ecoregions dataset (WWF, 2019) and described by Olson et al. (2001). The study domain extends from
83 9°N to 19°S, and 44°W to 80°W. Most of the study region is covered by the Amazon rain forest, which extends over 5.3
84 million km² (Soares et al., 2006). Six forest ecoregions are investigated here:

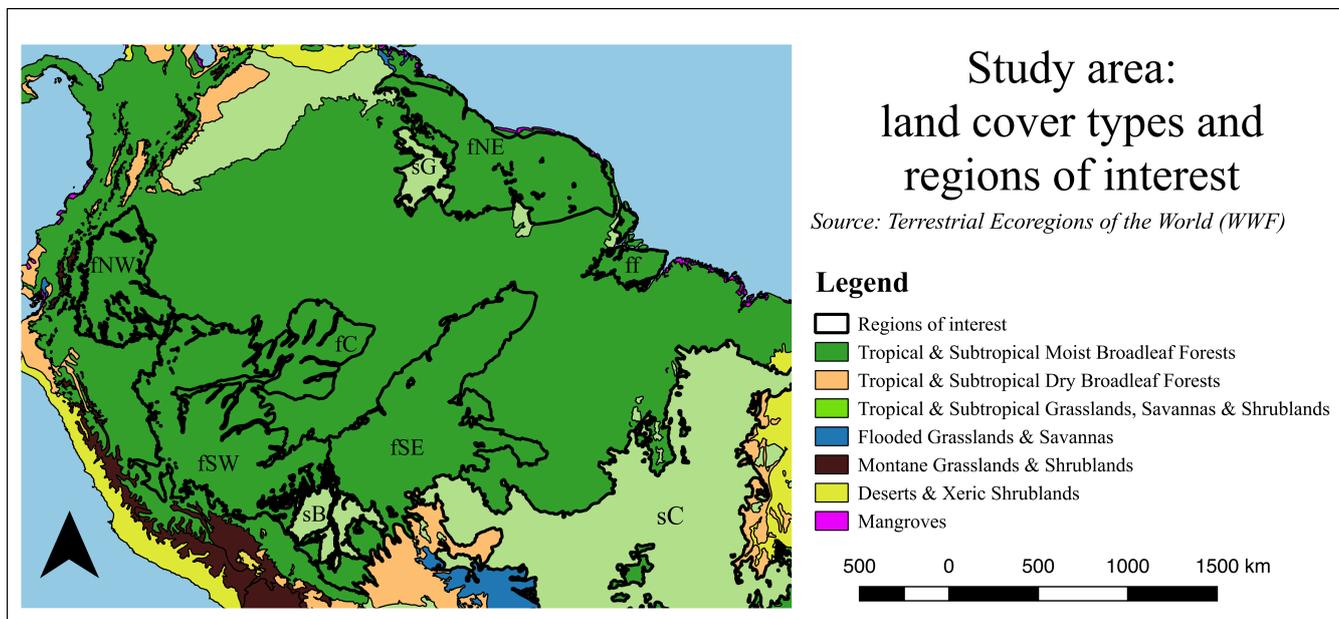

Figure 1. Study Area. The map is colored by biome, and nine ecoregions of interest are highlighted based on the dataset of Olson et al. (2001). The six forest ecoregions of interest are Napo moist forest (fNW), Guianan moist forests (fNE), Southwest Amazon moist forests (fSW), Madeira-Tapajós moist forest (fSE), Jurua-Perez moist forests (fC) and the Marajo Varzea flooded forests (ff). The three savanna ecoregions of interest are the Cerrado (sC), Guianan Savanna (sG) and Beni Savanna (sB).

- 85 1. The Napo moist forests (fNW), located in northwest Amazonia, receive some of the highest amounts of annual pre-
86 cipitation in the biome, reaching up to 4000 mm in some parts. This highly biodiverse region has canopies reaching
87 40 m.
- 88 2. The Guianan moist forests (fNE) are one of the largest continuous stretches of relatively pristine lowland tropical rain-
89 forest in the world. There are two distinct wet seasons: from December to January and from May to August. The floral
90 diversity is rich, with multi-tiered vegetation of 40 m tall trees with herbaceous plants below. The dry season (September-
91 November) can see a substantial reduction in leaves, although the forest is evergreen.
- 92 3. The Southwest Amazon moist forests (fSW) have significant variations in topography and soil characteristics, leading
93 to extremely high biodiversity. The size and orientation of the ecoregion means that climatic conditions vary markedly
94 – the north being wetter and having less seasonal variability compared to the south. The inaccessibility of the region has
95 aided in its conservation.
- 96 4. The Madeira-Tapajós moist forests (fSE) are transected by the Transamazon Highway, and have high levels of urbaniza-
97 tion and deforestation. There are characteristic liana (woody vine) forests with a lower (< 25 m) and more open canopy
98 than the typical humid terra firme forests.

99 5. The Juruá-Perez moist forests (fC) are largely intact forests in the low Amazon Basin. The canopy can reach up to 30 m,
100 with some patches of open canopy.

101 6. The seasonally flooded forest, Marajó várzea (ff), is located at the mouth of the Amazon River. The vegetation is dom-
102 inated by palms, and shorter than surrounding forests. It has areas with tidal flows from the Atlantic Ocean, as well as
103 seasonally and permanently inundated forests. The annual seasonal flooding occurs during the peak precipitation period
104 between January-May (Camarão et al., 2002).

105 Three savanna ecoregions are also considered in this study:

106 1. The Cerrado (sC) borders the Amazon biome to the southeast. It occupies an area of 2 million km² in the Brazilian
107 Central Plateau and is the second most extensive biome in South America (Oliveira et al., 2005). The vegetation cover
108 varies from closed tree canopy to grasslands with low shrubs only (Eiten, 1972).

109 2. The Guianan savanna (sG) consists of forest patches encircled by extensive grasslands and shrub formations. The area
110 is more susceptible to vegetation fires than typical humid moist forest environments and the dry season lasts from
111 December-March.

112 3. The Beni savanna (sB) is a wetland region with riverine gallery forests and small forest islands. The landscape is domi-
113 nated by the palm species *Attalea princeps* (Hordijk et al., 2019). Seasonal flooding occurs in up to half the region for 4
114 to 9 months, peaking in March-April (Hamilton et al., 2004).

115 Three Köppen-Geiger Climate Classes (KGCC) cover most of the study region (Fig. 2). The evergreen forest regions are
116 classified as Af (tropical fully humid) or Am (tropical monsoonal), and the savanna regions have Aw (tropical winter dry)
117 climate (Bradley et al., 2011). The annual precipitation in the forests can exceed 2000-3000 mm, with less than 100 mm
118 rainfall for up to three months in the year. The savannas have a wet season extending for 5-8 months, with an annual total of
119 1000-2000 mm (Bradley et al., 2011). Net radiation peaks in the winter months, due to the absence of cloud cover in the dry
120 season (Liu et al., 2018). Two major droughts occurred in the region during the study period, in 2010 and 2015 (Jiménez-Muñoz
121 et al., 2016; Marengo et al., 2011) and are of particular interest in this study.

122 2.2 ASCAT data

123 The Advanced Scatterometer (ASCAT) data were processed using the same procedure as Steele-Dunne et al. (2019). Metop-A
124 ASCAT SZR Level 1b Fundamental Climate Data Record, resampled at a 12.5 km swath grid, were obtained from the EU-
125 METSAT Data Centre for the period 2007 to 2016. Following the procedure described by Naeimi et al. (2009), the backscatter
126 observations were resampled to a fixed Earth grid using a Hamming window function. The slope and curvature were calculated
127 from the ASCAT backscatter observations using the method introduced by Metzler (2013) and described by Hahn et al. (2017).
128 The ASCAT instrument on-board the Metop satellites has three antennas on either side, oriented at 45° (fore), 90° (mid) and
129 135° (aft) to the satellite track. As a result, three independent measurements of each location on the surface are obtained almost

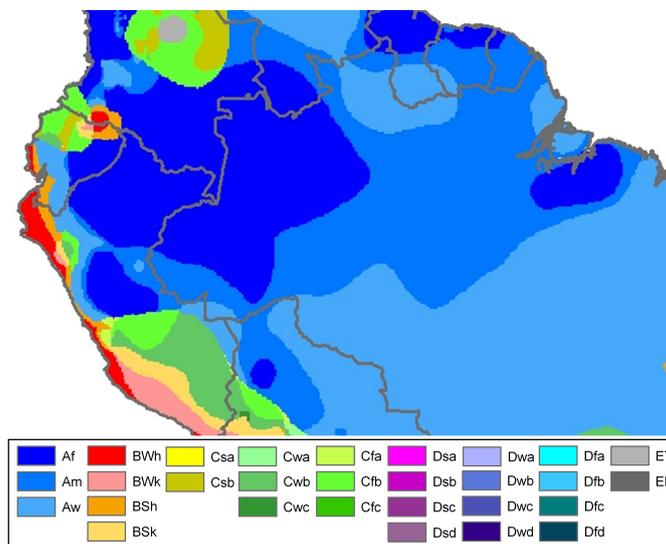

Figure 2. Köppen-Geiger climate zones in the study area (Source: (Peel et al., 2007)).

130 instantaneously. These so-called “backscatter triplets” (Hahn et al., 2017) are used to calculate an instantaneous backscatter
 131 slope, also known as the “local slope”:

$$132 \quad \sigma' \left(\frac{\theta_{mid} - \theta_{a/f}}{2} \right) = \frac{\sigma_{mid}^{\circ}(\theta_{mid}) - \sigma_{a/f}^{\circ}(\theta_{a/f})}{\theta_{mid} - (\theta_{a/f})} \quad [dB/deg] \quad (2)$$

133 where *mid*, *a* and *f* indicate the backscatter measurements from the mid-, aft- and fore-beams respectively. Following the
 134 approach of Metzler (2013), an Epanechnikov kernel (with width $\lambda=21$) is used to weight the local slope values by their
 135 temporal distance from a given day of interest. This yields an estimate of slope and curvature for a given day, based on all local
 136 slope values within a 42-day window. For a more detailed description of their derivation, the reader is referred to Steele-Dunne
 137 et al. (2019).

138 Observations from the descending and ascending overpasses are unlikely to occur on the same day. Hence, the σ_{40}° data were
 139 aggregated into 10-day intervals (dekads). Unless otherwise indicated, the analysis uses data from the descending pass only (~
 140 10 am). Diurnal differences refers to the values from the descending overpass (~ 10 am) minus the values from the ascending
 141 overpass (~ 10 pm).

142 2.3 Water Dynamics data

143 Downwelling shortwave radiation at the surface and specific humidity were obtained from the Princeton meteorological dataset
 144 (Sheffield et al., 2006). These data have a $0.5^{\circ} \times 0.5^{\circ}$ daily resolution. Precipitation data were obtained from the Global
 145 Precipitation Climatology Product (GPCP) Precipitation Level 3 Monthly 0.5-Degree V3.0 beta dataset (Huffman et al., 2009).
 146 Data from the Gravity Recovery and Climate Experiment (GRACE) mission were used to provide insight into terrestrial water

147 storage variations (Landerer and Swenson, 2012; Swenson and Wahr, 2006). Here, we used the equivalent water thickness
148 (EWT) from the GRACE Tellus dataset which is available at $1^\circ \times 1^\circ$, monthly resolution from the NASA JPL Physical
149 Oceanography Distributed Active Archive Center (PO DAAC). These data give the relative change in EWT with respect to a
150 baseline, the method of calculation for which is explained by Wahr et al. (1998). These data provide information on fluctuations
151 in EWT on monthly to inter-annual timescales.

152 Seasonal cycles were determined for precipitation, radiation, humidity, and EWT by averaging data from the entire study
153 duration. Anomalies in precipitation during the drought years were also calculated (as drought year values minus climatology)
154 to provide an indicator of the water stress against which to compare the backscatter, slope and curvature anomalies.

155 3 Results and Discussion

156 3.1 Seasonal Climatology

157 Figure 3 shows the mean and range of normalized backscatter (σ_{40}°), slope and curvature for the study period (2007-16). In
158 general, the spatial patterns in the mean and range of all three quantities reflect the spatial patterns in land cover expected
159 from Fig. 1. It is striking that even the influence of the riverine network on the vegetation cover is discernible in the maps,
160 particularly that of the mean backscatter (Fig. 3(a)). Striping effects are visible in several of the maps, particularly that of the
161 range in curvature (Fig. 3(f)). This is due to the backscatter observations at the swath edges being available only at very high
162 or very low incidence angles, which skews the calculation of the slope and curvature. This effect is particularly noticeable in
163 forest regions where the natural dynamic range in both quantities is limited.

164 Mean backscatter is highest, with the least variability, in the evergreen forest regions. Mean backscatter is 2-2.5 dB lower
165 in the savanna areas, but the range is up to 3 dB, compared to just 0.5 to 1 dB in the forest. The stability of the forest is also
166 apparent in the maps of slope and curvature. Though there is some variability among the forest ecoregions, the most striking
167 differences in slope and curvature are between the forest and savanna areas. Limited structural and water content changes in
168 the forest canopy result in a limited range of slope and curvature values in the forest ecoregions. The range of both slope and
169 curvature are highest in the Cerrado areas. One interesting feature is the difference in mean slope between the Guianan savanna
170 (sG) in the north and the Cerrado (sC) region in the south. The Guianan savanna, with sparse vegetation, has low mean slope
171 values. The Cerrado, on the other hand, shows mean values higher than the evergreen forests. This is unexpected since slope
172 is generally considered a measure of “vegetation density”, and the evergreen forests are much denser than savannas. This will
173 be discussed in detail in Sect. 3.1.1. Seasonal flooding of the Marajó várzea (the seasonally flooded forest) and Beni savannas
174 ensure that both ecoregions have strong seasonal cycles in all three quantities. These will be discussed separately in Sect. 3.1.2.

175 The mean seasonal cycles in backscatter for the ecoregions of interest are compared in Fig. 4 (a). This highlights the contrast
176 between the very stable evergreen forest regions and the flooded forest and savanna areas. The mean backscatter value is high,
177 with limited seasonal amplitude in the evergreen forest regions. In contrast, backscatter is generally low, but also exhibits
178 strong seasonal variations in the flooded forest and savanna areas. Figures 4 (b-f) show the seasonal variation in backscatter
179 for five ecoregions of interest, against the corresponding climatologies of precipitation and EWT. In all of the ecoregions, the

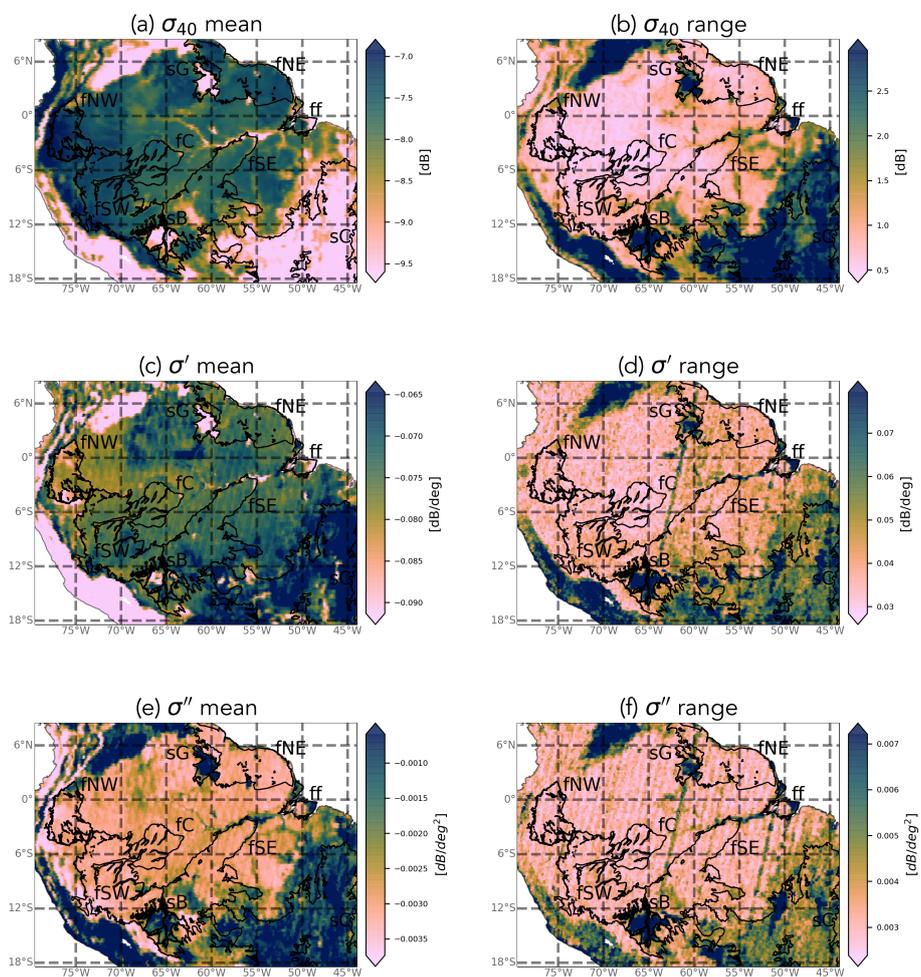

Figure 3. Mean and range of ASCAT normalized backscatter, slope and curvature in the study period (2007-16). Note that there are no data gaps, so white indicates that the quantity has a value equal to or less than the minimum value indicated on the colorbar.

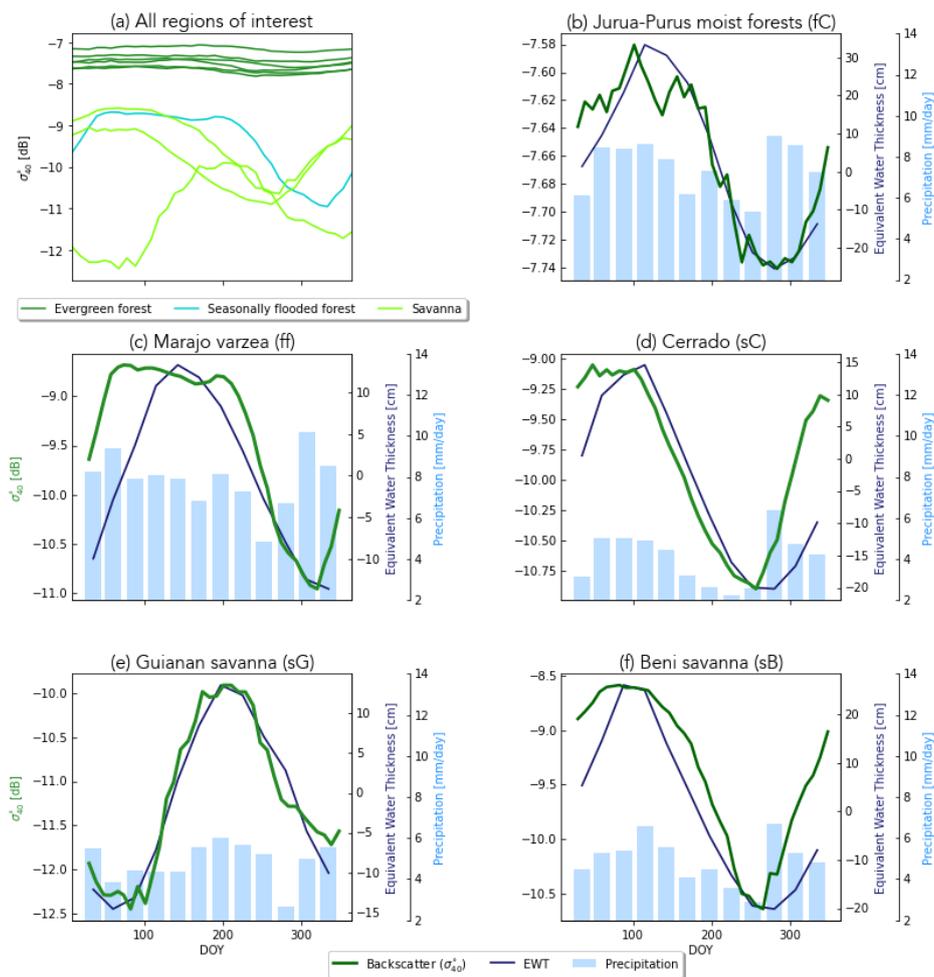

Figure 4. Climatology of backscatter (green line), precipitation (bars), and EWT (blue line) for different cover types.

180 maximum backscatter occurs during the wet season, and a decrease in backscatter is observed during the dry season, though
 181 the amplitude of the variations is obviously much smaller in the forest ecoregions. In each ecoregion, there is clear agreement
 182 between the seasonality of EWT and backscatter. This indicates that backscatter is influenced by moisture availability in terms
 183 of total terrestrial water storage, which includes groundwater storage. It is noteworthy that this temporal consistency between
 184 backscatter and EWT is apparent for both forest (fC in Fig. 4 (b)) and the Guianan Savanna (sG in 4 (e)) despite the contrast
 185 between almost zero (0.25 dB) variability in backscatter in fC and the 2.5 dB seasonal cycle in sG.

186 Figure 5 (a) summarizes the mean seasonal cycle in the slope for the ecoregions of interest. The difference between ecore-
 187 gions is more pronounced than for backscatter. The seasonal cycle for the evergreen forest ecoregions are similar in magnitude
 188 but there are minor differences in the timing of the peak. The differences between the savanna regions are more pronounced

189 than for backscatter. Significant differences can be seen in the mean slope value, as well as the amplitude and timing of the
190 seasonal cycle of slope values for each ecoregion of interest.

191 In Fig. 5(b-e), the seasonal cycle of slope in each ecoregion is compared to the corresponding cycles of radiation, specific
192 humidity and precipitation which drive photosynthetic activity in the region. In the Jurua-Purus moist forests (Fig. 5(b)), the
193 change in slope is one-tenth that observed in the other ecoregions. The variations in radiation and specific humidity are also
194 very limited. Nonetheless, the seasonal cycle of the slope follows that of the radiation with a lag of about 30 days. This can
195 be explained by the fact that the vegetation phenology in this tropical evergreen forest is driven by radiation (Romatschke and
196 Houze Jr, 2013). The photosynthetic capacity depends on the available solar energy (Borchert et al., 2015). Energy availability
197 drives transpiration and the accumulation of leafy biomass. This increases volume scattering from the canopy and therefore
198 leads to an increase in the slope. Similar results were observed for the other forest ecoregions. In the Marajo varzea flooded
199 forest (Fig. 5(c)), the variation in slope is much larger, and the seasonal cycle is clearly out of phase with that of the radiation.
200 The seasonal variations in slope in this ecoregion are dominated by the influence of surface flooding rather than vegetation
201 water content variations (Sect. 3.1.2).

202 In the Cerrado (Fig. 5(d)), there is a significant variation in specific humidity, and radiation as well as a strong seasonal
203 cycle in precipitation. The peak in slope occurs during the driest time of year, when radiation is at a maximum and specific
204 humidity and precipitation are at a minimum. Recall from Fig. 4, that this is also during the minimum EWT and backscatter
205 period. Section 3.1.1 provides a detailed analysis of the vegetation types within the Cerrado ecoregion to better understand
206 these variations. The slope values in the Guianan Savanna (Fig. 5(e)) are the lowest observed in all ecoregions, and also have
207 the smallest variations among the non-forest cover types. This is consistent with the relatively low, but stable vegetation density
208 associated with grasslands (Steele-Dunne et al., 2019). In the Beni Savanna (Fig. 5(f)), on the other hand, slope varies as much
209 as in the Cerrado, and there is a very clear relationship between the slope and the atmospheric forcing data (Fig. 5 (f)). The
210 maximum slope occurs at the peak of precipitation, EWT (from Fig. 4) and humidity. The minimum slope occurs during the dry
211 season at the minimum in precipitation, humidity and EWT. This is consistent with the interpretation of slope as an indicator
212 of vegetation density as the vegetation cover in this savanna changes dramatically in response to atmospheric forcing. The
213 contrast in the seasonal cycles in slope in Fig. 5 reflect the diversity of the vegetation cover types in the ecoregions and their
214 varied response to moisture supply and demand.

215 Figure 6 (a) shows the mean seasonal cycles in curvature for the regions of interest. The differences in the amplitudes of the
216 seasonal cycles vary considerably among the regions. While the evergreen forests vary less than 0.0005 dB/deg^2 , variations
217 in the wetland regions (Beni savanna and Marajó várzea) are an order of magnitude larger. Aside from the Guianan savanna,
218 the timing of the seasonal cycle is similar across all ecoregions. Previous research has suggested that curvature is related to
219 vegetation phenology and structure (Steele-Dunne et al., 2019). Since the vegetation phenology in much of the forested region is
220 radiation-driven, we hypothesize that the curvature seasonality is related to the radiation and evaporative demand. Wagner et al.
221 (2016) observed that litterfall coincides with maximum evaporative demand, which would coincide with lower humidity and
222 higher solar radiation. Leaf flushing is induced by an increase in radiation (Borchert et al., 2015). Figures 6 (b-f) demonstrate
223 that higher values of curvature generally correspond to lower humidity, higher solar radiation and lower precipitation. It is also

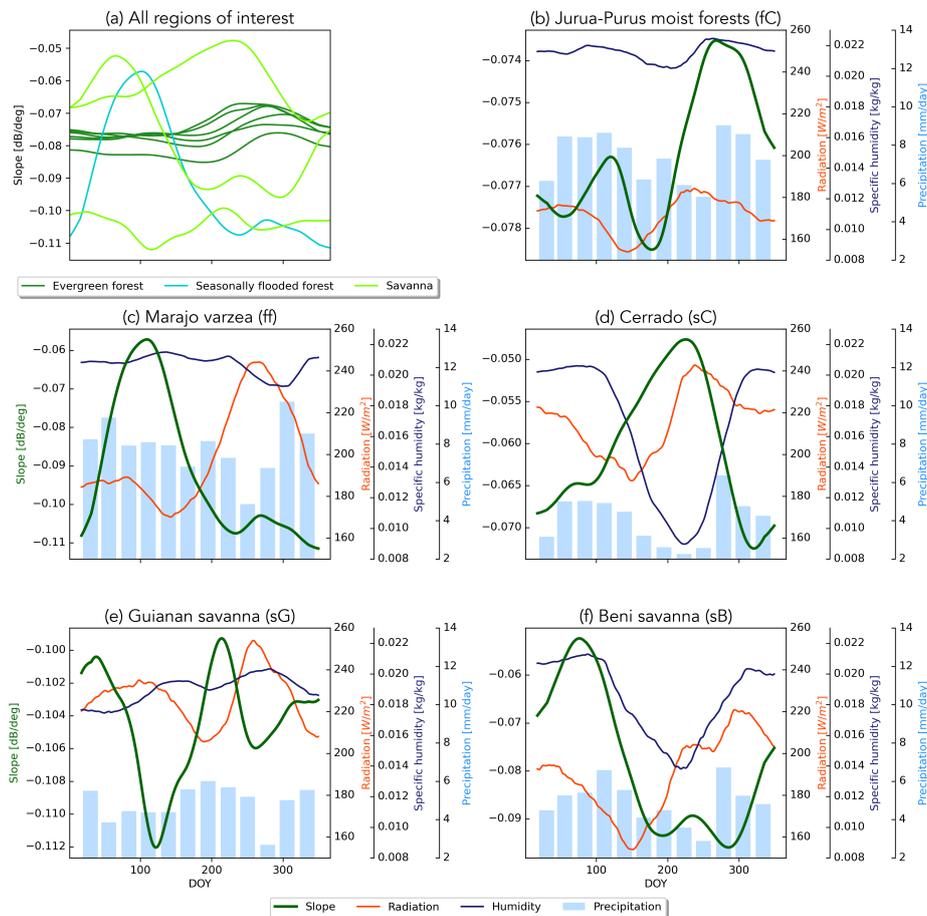

Figure 5. Climatology of slope (green line), radiation (red line), humidity (blue line) and precipitation (bars) for different cover types.

224 noteworthy that the curvature values in the Guianan savanna (Fig. 6 (e)) are positive for much of the year, consistent with the
 225 dominance of grass cover in this region.

226 3.1.1 Cerrado

227 Figure 7 provides a detailed map of the Copernicus Global Land Service Land Cover within the Cerrado region Buchhorn
 228 et al. (2020). The dominant cover types are herbaceous cover and shrubland, with patches of cropland and forest. Figures 8 and
 229 9 show the spatial patterns and boxplot per land cover type of mean, maximum and the DOY of the maximum for backscatter,
 230 slope and curvature. The mean backscatter varies between -13 and -7 dB and is highest for forest regions and lowest for
 231 croplands. The DOY for the maximum backscatter varies with latitude, from December to January in the southern region
 232 to April in the northern region. The highest backscatter corresponds with the months of highest precipitation and EWT, the
 233 minimum in backscatter corresponds with the months of lowest moisture availability (Fig. 4). The slope mean and maximum

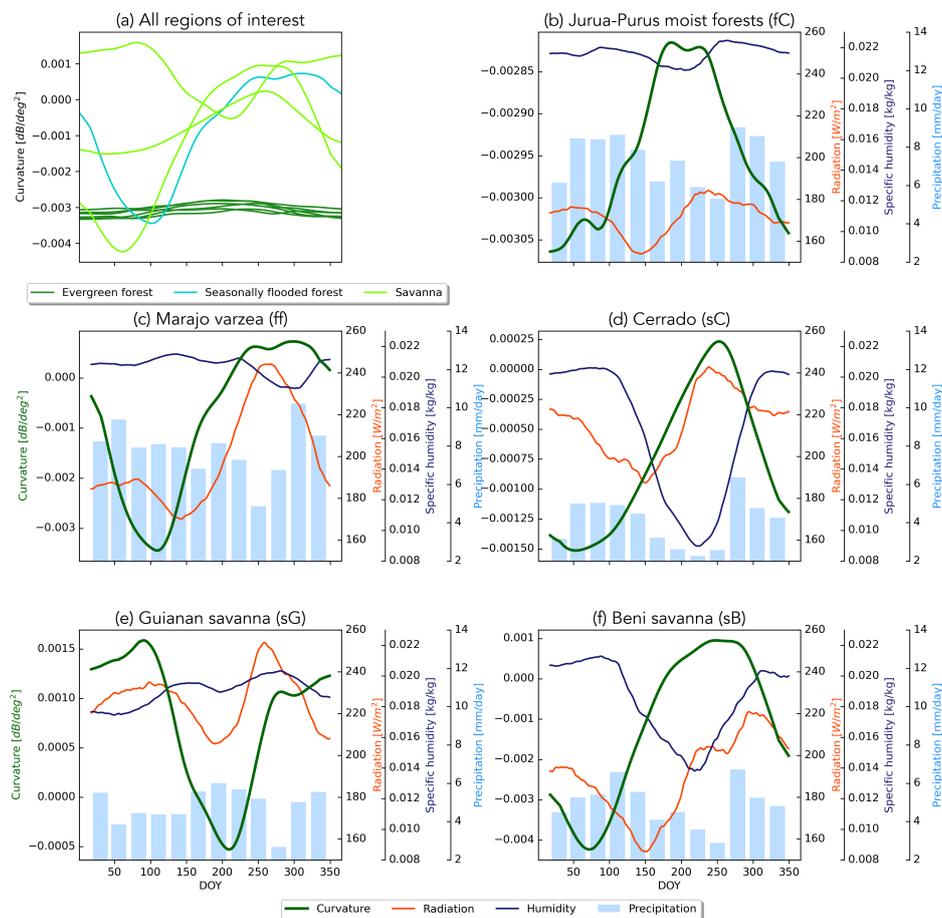

Figure 6. Climatology of curvature (green line), radiation (red line), humidity (blue line) and precipitation (bars) for evergreen forests.

234 values show a decrease from shrubs to herbaceous to cropland, decreasing with vegetation density. Forests are characterised by
 235 high mean and maximum slope values. The seasonal dynamics and DOY of the maximum slope vary strongly with land cover
 236 type. In croplands, the maximum of slope occurs between DOY 340-150, corresponding to the highest precipitation and EWT.
 237 In natural vegetation, such as herbaceous cover, shrubs and forests, the highest slope occurs between day 200 and 300 and
 238 coincides with the minimum in precipitation and EWT and maximum radiation (Fig. 5). Within the Cerrado region, vegetation
 239 can be moisture limited or energy limited (Nemani et al., 2003), depending on location and land cover type. Figure 10 shows the
 240 slope and radiation dynamics for different land cover classes. To exclude confounding effects due to heterogeneous land cover
 241 within ASCAT pixels, we used only pixels with a dominant land cover fraction of $> 80\%$. The slope dynamics in cropland
 242 are following the precipitation dynamics and have their peak during the wet season. Herbaceous cover shows two peaks in
 243 slope, one coinciding with the wet season at the beginning of the year, and a higher peak coinciding with the dry season and
 244 maximum in radiation. The increase in slope coincides with the onset of the increase in radiation. In shrubs and forests, slope

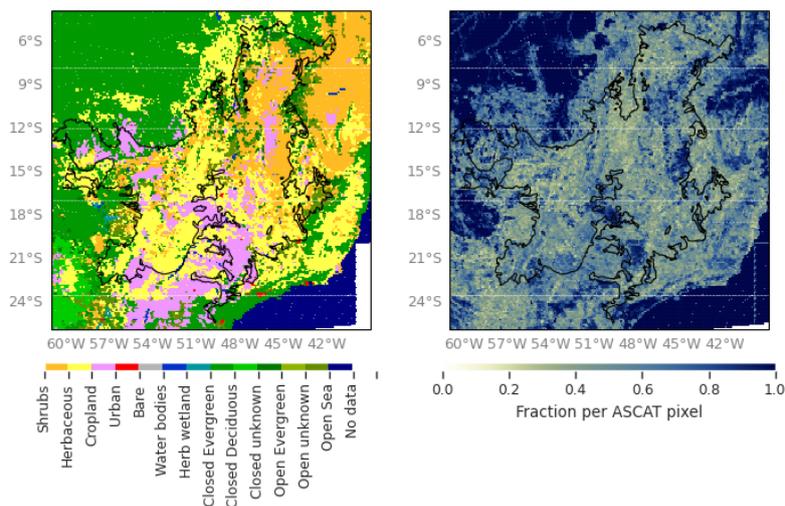

Figure 7. Dominant land cover type (left) and fraction (right) derived from the Copernicus Global Land Service Land Cover (2015) for the Cerrado region Buchhorn et al. (2020)

245 starts to increase after the wet season, but before the increase in radiation (Fig. 10). Shrubs and forests have deeper root systems
246 they can tap into deeper water reservoirs. This enables them to increase photosynthesis and leaf development slightly before
247 or at the onset of increasing radiation even though precipitation is at its minimum. Chave et al. (2010) found that, among the
248 tropical forest types in South America, the highest seasonality in litterfall was observed in "low" stature forests, such as those
249 found in the Cerrado. They also cite Wright and Van Schaik (1994) to argue that seasonality of solar radiation rather than
250 precipitation may be the most important trigger for leaf flushing and leaf abscission. Croplands and herbaceous vegetation show
251 positive curvatures, whereas forests are characterised by negative curvatures with the maximum values occurring between DOY
252 200 and 300 across the Cerrado. The positive curvature for crops and herbaceous vegetation can be explained by the vertical
253 structure of the vegetation.

254 3.1.2 Seasonal Flooding

255 Fig. 11 shows the striking effect of seasonal flooding on the incidence angle dependence of backscatter. This relationship was
256 obtained using Equation 1 for a reference angle of 40° with the climatological mean values of σ_{40}° , slope and curvature for
257 several days during the year. The flooded period is indicated in shades of blue. First, note that σ_{40}° is around 2 dB higher during
258 the seasonal flooding. This is due to multiple scattering between the water surface and the vegetation. Recall from Fig. 5 that
259 the slope is slightly higher during this period as this multiple scattering is apparently slightly less sensitive to incidence angle
260 than scattering from the vegetation during non-flooded period. However, the most noteworthy difference is in the curvature. In

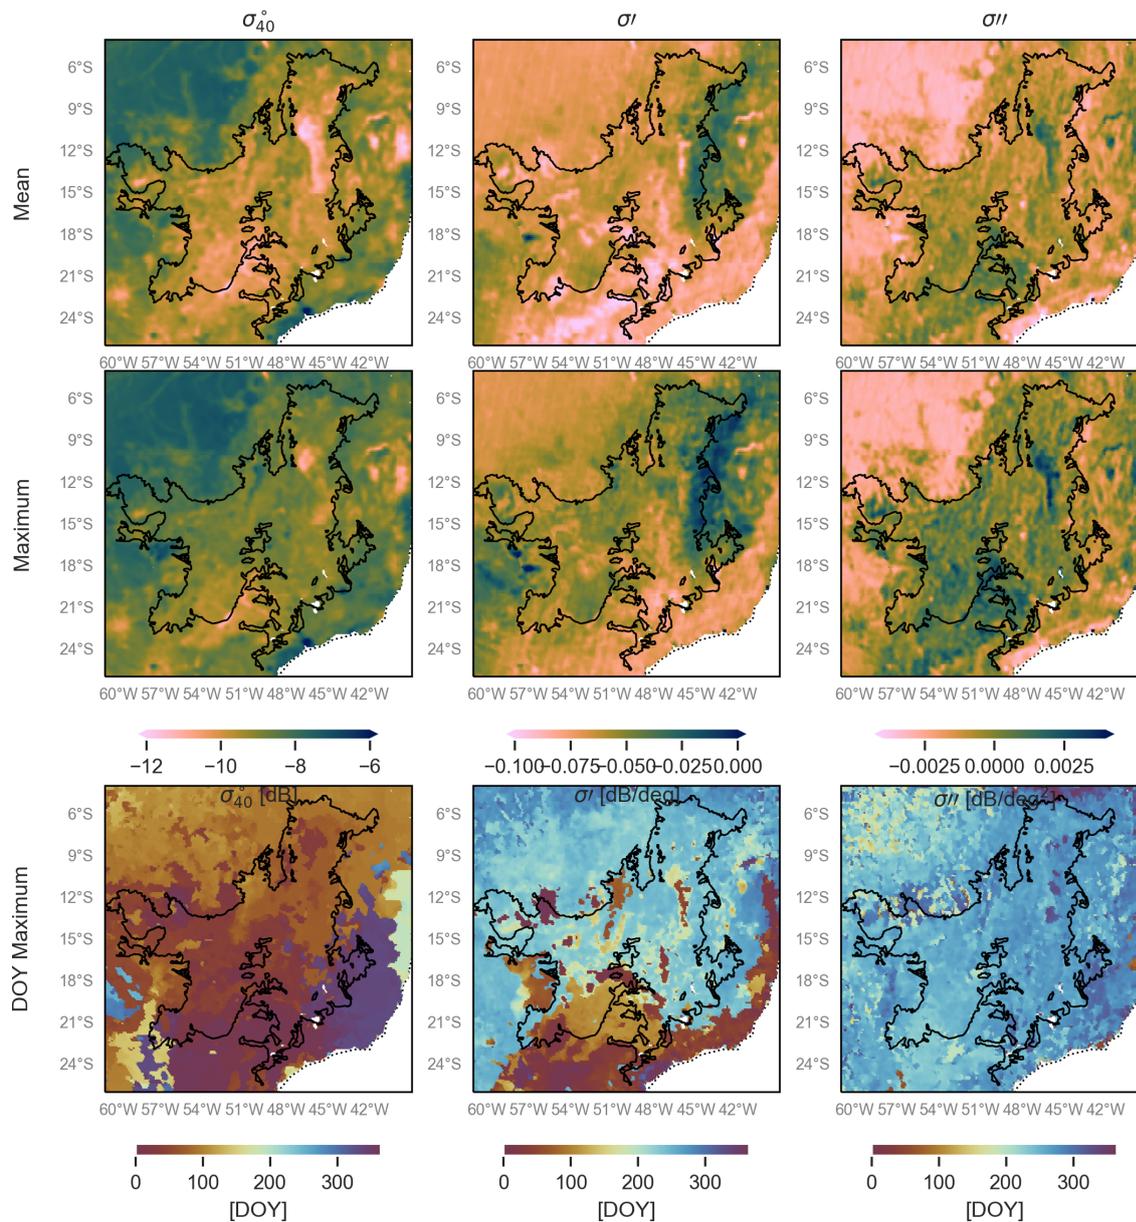

Figure 8. Mean, maximum and day of year of maximum for backscatter, slope and curvature over the Cerrado.

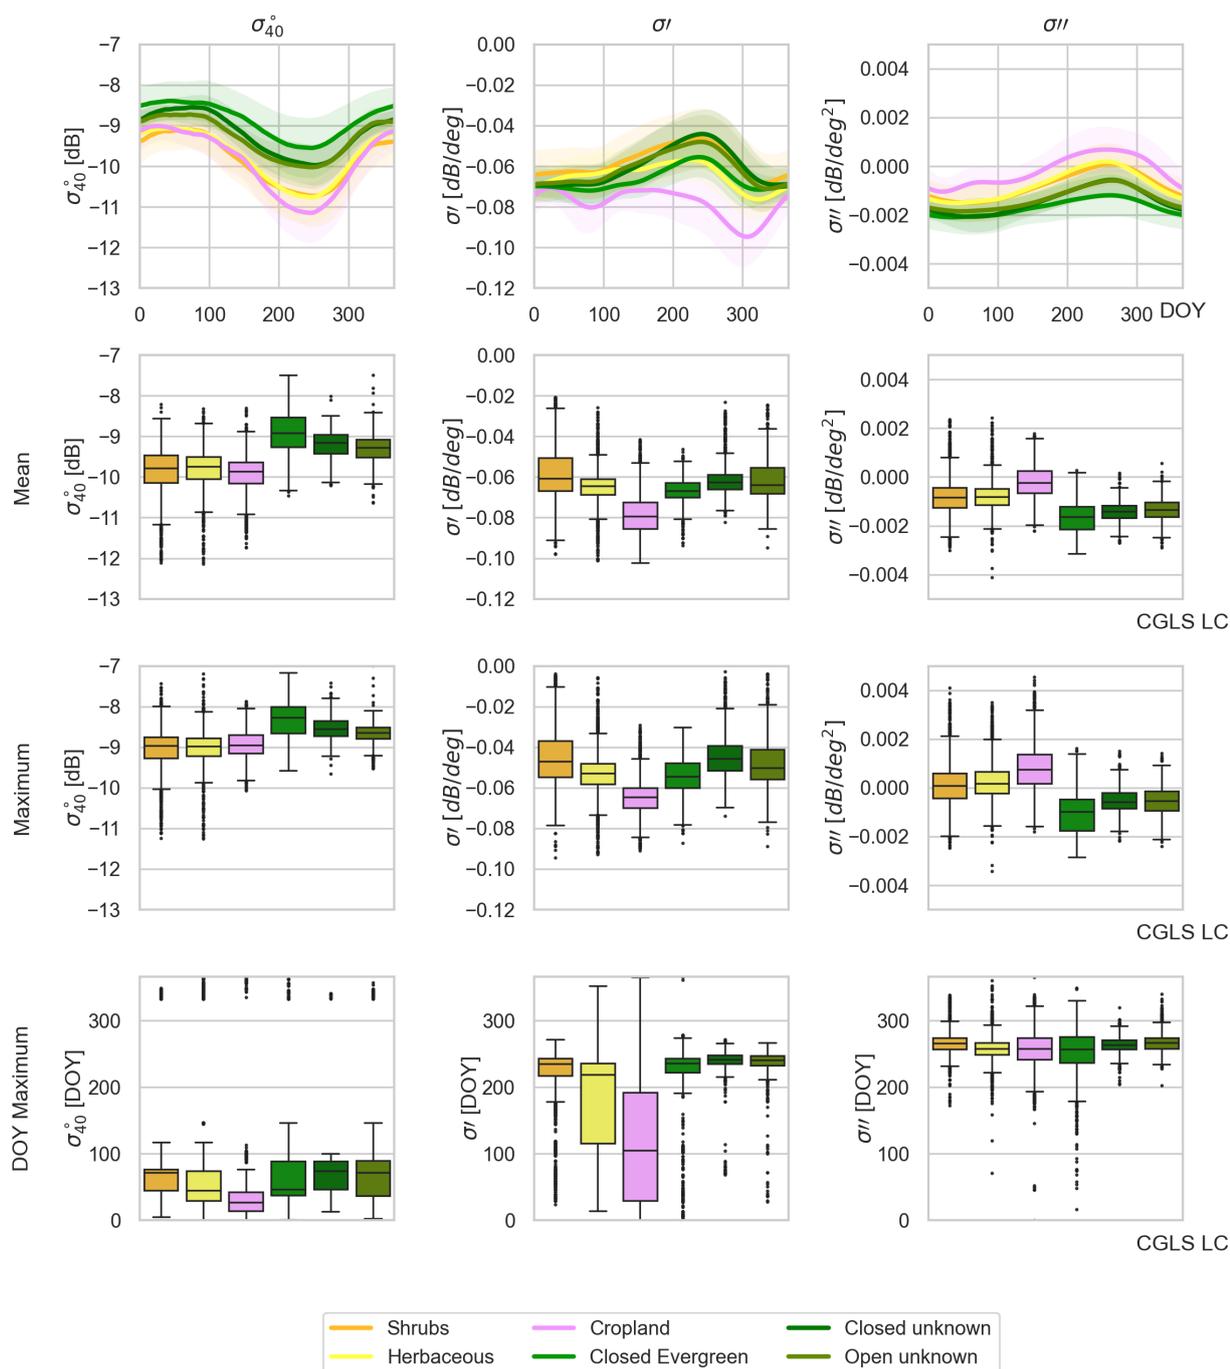

Figure 9. Time series averaged per land cover class and boxplots of mean, maximum and day of year of maximum for backscatter, slope and curvature over the Cerrado.

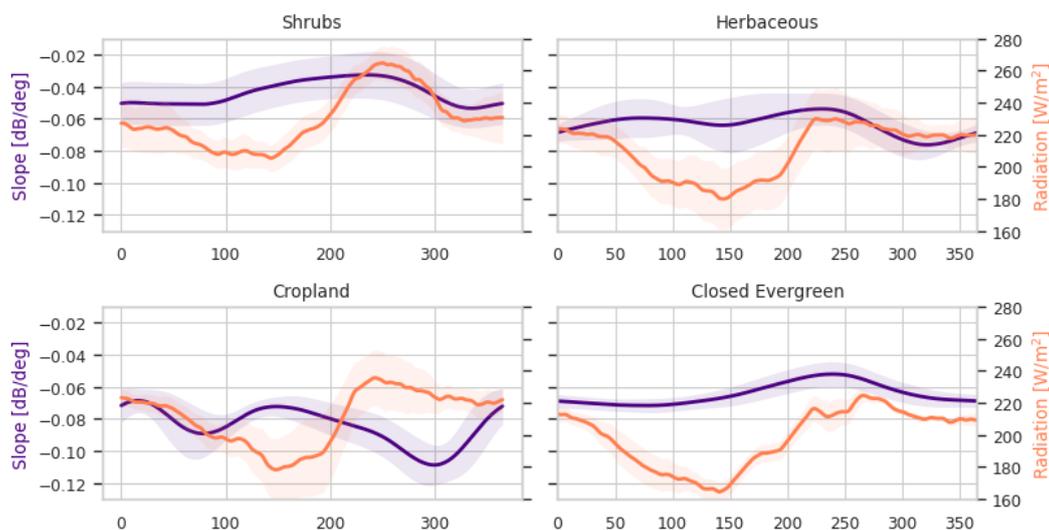

Figure 10. Seasonal cycle of slope and radiation per land cover class in the Cerrado region. Only ASCAT pixels in which the fraction of the dominant land cover type exceeds 80% are included.

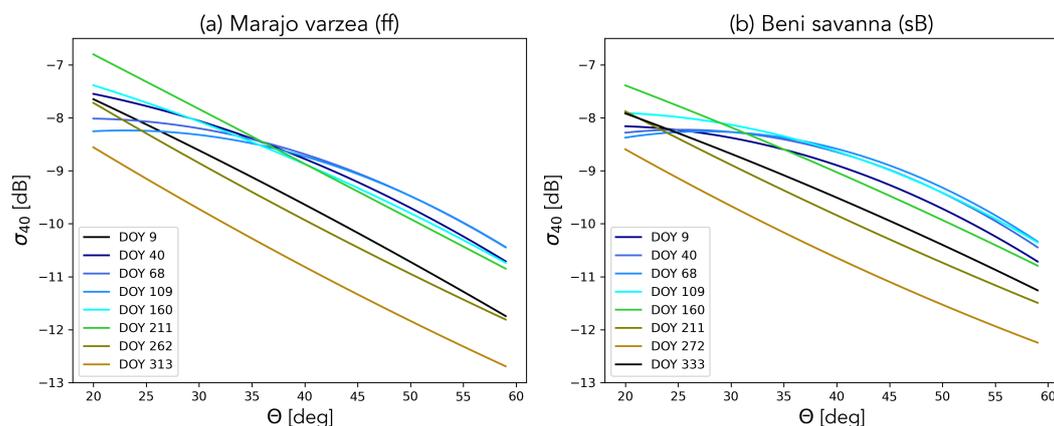

Figure 11. Averaged backscatter as a function of incidence angle for several dates in the Marajo varzea (a) and Beni Savanna (b) ecoregions.

261 both ecoregions, the curvature changes considerably and even changes sign during the flooded period. This illustrates that the
 262 curvature includes useful information on changes in the scattering mechanisms, which are related to physical changes at the
 263 land surface.

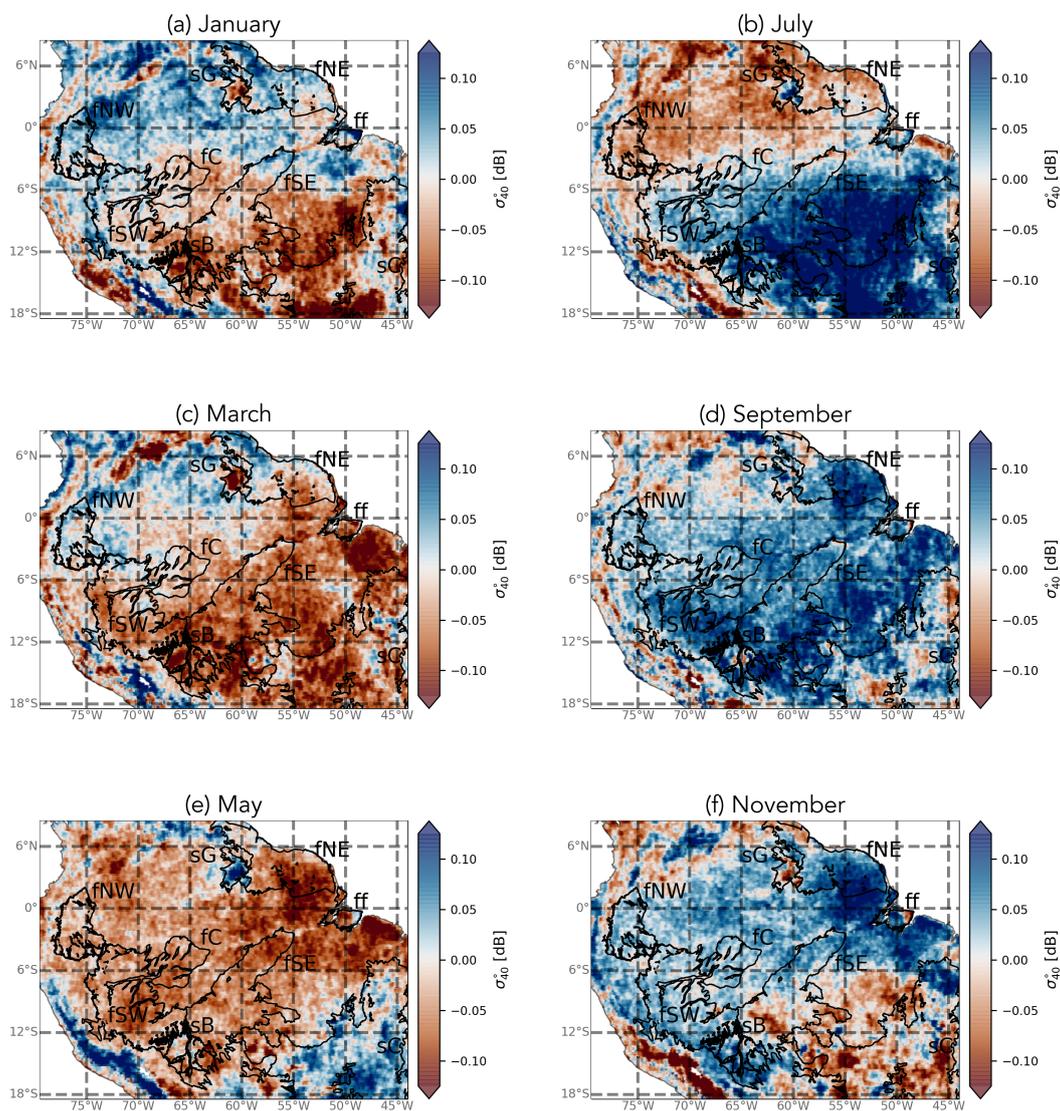

Figure 12. Map of monthly mean diurnal differences in sig_{40} (morning minus evening passes) for different months in the year.

264 3.2 Diurnal Differences

265 Figure 12 shows the mean diurnal differences for backscatter in the study area for alternate months in the year, where positive
266 values indicate that values are higher during the descending (10 am) overpass than those from the ascending (10 pm) overpass.
267 The diurnal differences in backscatter are generally very small, with maximum values less than 0.15 dB. Nonetheless, there is
268 a clear seasonal variation, broadly following that of EWT (shown in Fig. 13).

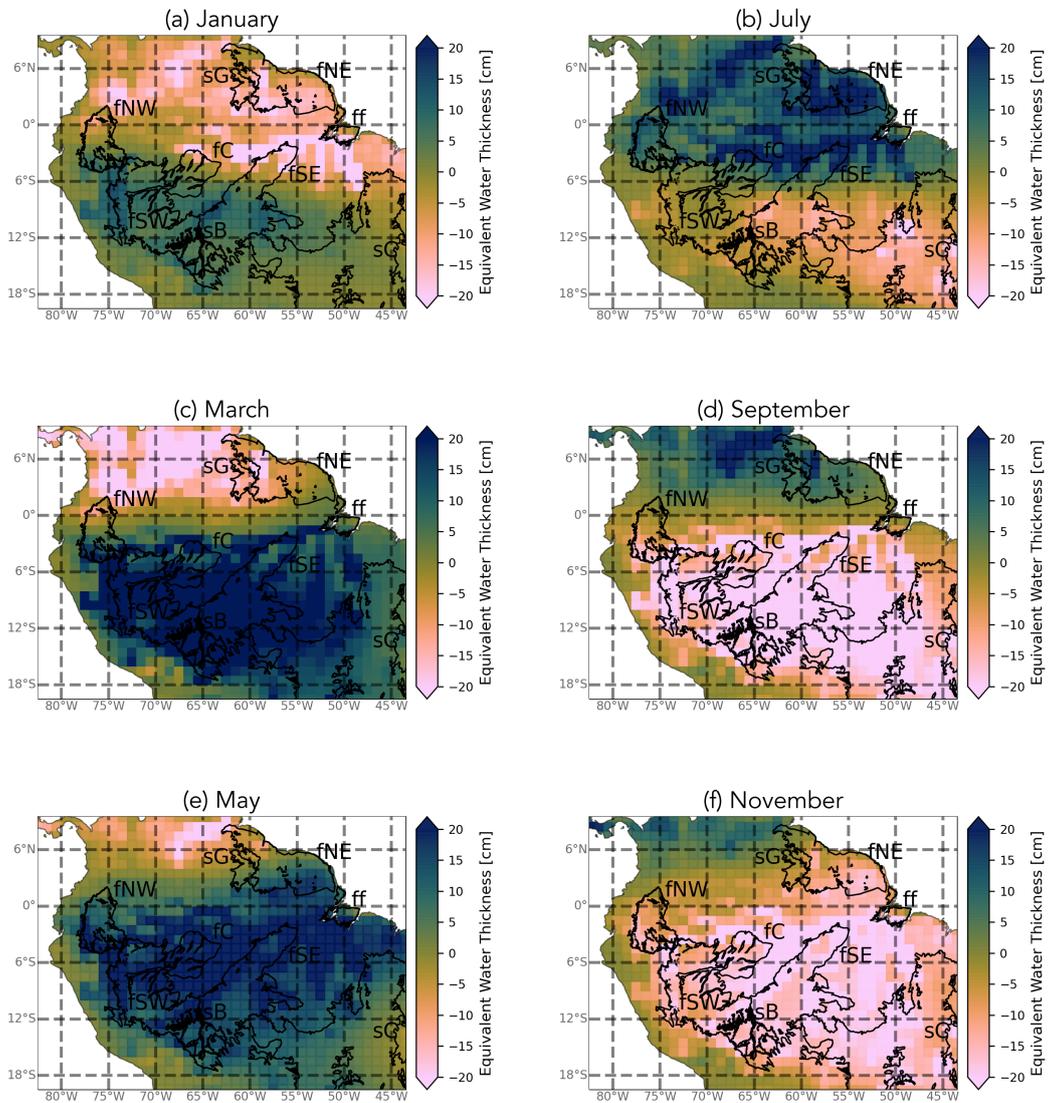

Figure 13. Map of monthly mean Equivalent Water Thickness from GRACE

269 For most of the domain, especially the evergreen forests, high values in EWT coincide with negative diurnal differences in
270 backscatter and vice versa. During periods of maximum EWT, the backscatter is higher in the evening than in the morning.
271 This is consistent with the finding that precipitation in tropical South America (since it is generally produced by convective
272 systems) predominantly occurs in the late afternoons and evenings (Romatschke and Houze Jr, 2013). Hence, these higher
273 backscatter values are due to the canopy being wetter in the evening.

274 During the drier periods (e.g. September (e) and November (f) in the south of the study area), backscatter is higher at 10 am
275 than at 10 pm, consistent with the loss of moisture through transpiration during the day. In a light-limited evergreen forest
276 such as the Amazon (rather than a water-limited forest), the canopy photosynthetic capacity seasonality is driven by radiation
277 (Wagner et al., 2016). When the plants are phenologically active, they lose water during the daytime through transpiration
278 resulting in lower evening backscatter values. The results in Fig. 12 and 13 are consistent with the findings of previous studies
279 by Frohking et al. (2011) and Friesen et al. (2012) who also found the morning backscatter over Amazonia to be higher (on
280 average) than the evening values due to higher water content in the vegetation. In the areas surrounding the evergreen forests,
281 the patterns can be less straight-forward. Note, for example, that the diurnal difference in σ_{40}° in the Guianan savanna (sG)
282 consistently has the opposite sign to that of the surrounding forest.

283 In Fig. 14, the seasonal cycle of the diurnal difference in σ_{40}° is compared to those of the radiation, precipitation and EWT
284 for each of the ecoregions of interest. Figure 14(a) is indicative of the seasonal variations observed across the evergreen forest
285 ecoregions. Note that the diurnal differences are very small (< 0.06 dB). Recall from Fig. 4, 5 and 6 that the backscatter, slope
286 and curvature in these evergreen forests was essentially stable throughout the year, so even this small diurnal difference is
287 noteworthy given the limited seasonal variation. As mentioned in the discussion of Fig. 12, evening values are higher than
288 morning values during the EWT maximum and vice versa. Diurnal differences are larger in the Marajo varzea (Fig. 14(b)), but
289 interpreting their seasonal variation is complicated by the seasonal inundation. In the Cerrado and Beni Savanna ecoregions
290 (Fig. 14(c) and (e)), the diurnal differences in backscatter are almost twice as large as those observed in the evergreen forest
291 regions. Morning values are up to 0.1 dB higher than evening values during the dry season due to loss of plant moisture during
292 the day. Similar to the forest regions, evening backscatter values are higher during the rainy season. The Guianan savanna is
293 quite distinct in that morning backscatter is up to 0.15 dB higher than evening backscatter during the EWT and backscatter
294 peak. One possible explanation for this unusual seasonal cycle is that it is related to a change in the relative dominance of the
295 forests and grasslands in the backscatter signal. The transition from positive to negative curvature values during the EWT peak
296 indicate an increased contribution from tree patches and shrubs during the wetter period. The higher backscatter in the morning
297 may be due to water uptake in the trees during the night.

298 3.3 The 2010 and 2015 droughts

299 During the study period (2007-16), two major droughts occurred in Amazonia, in 2010 and 2015. Figure 15 shows the spatial
300 distribution of anomalies in σ_{40}° , slope and curvature during the peak of the droughts from June to September 2010 and October
301 to December 2015. Two regions of interest are indicated in the maps, the savanna Cerrado (sC) ecoregion and Southwest
302 Amazon moist forests (fsW). The 2010 drought was most severe over southern and western Amazonia (Panisset et al., 2018).

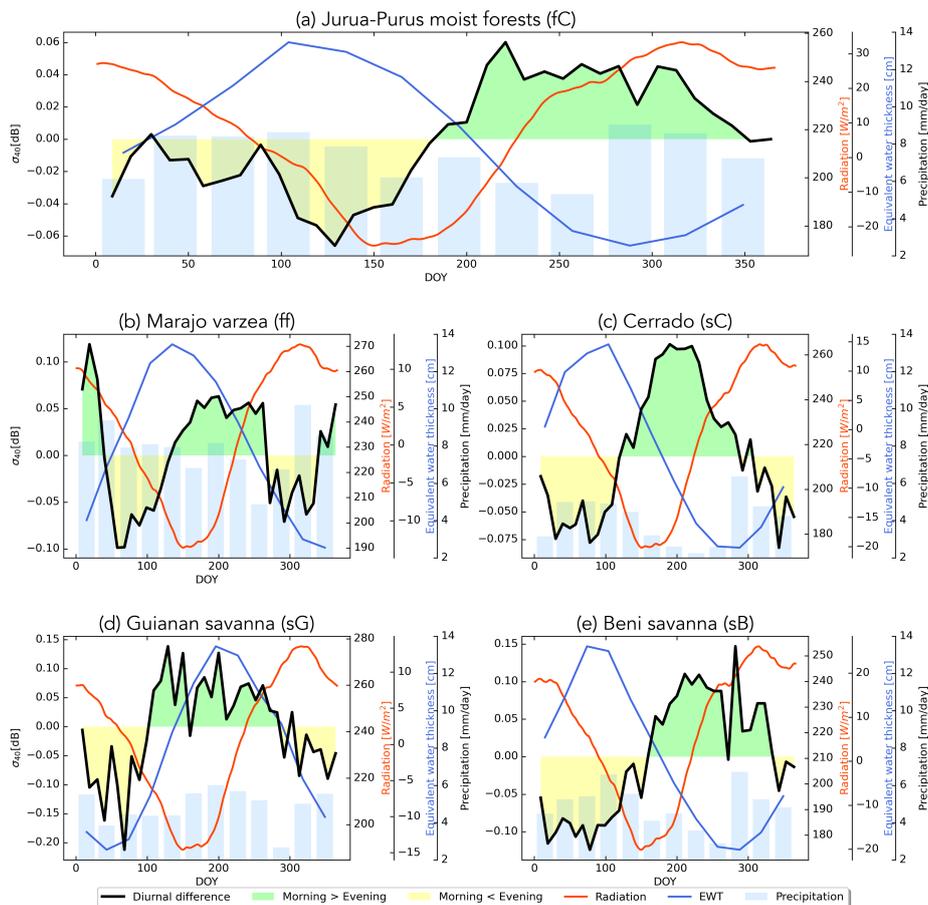

Figure 14. Seasonal cycle of diurnal difference in backscatter (black line), radiation (red line), EWT (blue line), and precipitation (bars) for different cover types. Green (yellow) fill indicates days in which backscatter is higher (lower) in the morning than in the evening.

303 The 2015 drought was considered a “record-breaking” event with stronger warming than that seen in previous events (Jiménez-
 304 Muñoz et al., 2016). According to Panisset et al. (2018), there was a “pronounced lack of rainfall availability during late spring
 305 and early summer”. The 2015 drought was more widespread than the event in 2010, and strongest in eastern Amazonia.

306 Negative anomalies are observed in σ_{40}^o , especially in the southern regions and in the Cerrado in 2010 and in eastern regions
 307 in 2015. Note that the most eastern part of the Cerrado shows positive anomalies in 2010. The forests in fsW show minor
 308 negative anomalies (<0.1 dB) in σ_{40}^o in 2010 and slightly stronger negative anomalies in 2015. Negative anomalies in backscat-
 309 ter from QSCAT were also observed during the 2005 drought (Saatchi et al. (2013); Frohling et al. (2017)). The slope and
 310 curvature do not show clear spatial patterns in anomalies during the 2010 drought, although the southern region shows slightly
 311 more positive anomalies. A clear positive anomaly can be observed in the slope in eastern Amazonia in the 2015 drought. The
 312 curvature shows less clear patterns, although a striping pattern can be seen, likely related to swaths.

313 Figure 16 shows the time series of anomalies in backscatter, slope and curvature for the moist forests in fsW and the Cerrado
314 region for the 2010 and 2015 drought. The backscatter, slope and curvature over the closed evergreen forest in fsW shows very
315 little variation (both in time and space) during both droughts. A slight increase up to 0.002 in slope can be observed during
316 the peak of the 2015 drought. This demonstrates that the fsW forests are stable for satellite calibration. The Cerrado shows
317 varying responses depending on land cover type and are therefore investigated further. Negative anomalies in σ_{40}° in cropland
318 and herbaceous land cover can be seen during both droughts. Especially during the 2010 drought the croplands in the Cerrado
319 are strongly affected, with a negative anomaly of $>-1\text{dB}$ for some pixels. During the more extensive drought in 2015, σ_{40}° in
320 forest is also affected and negative anomalies up to -1.5 dB are observed. The slope shows minor positive anomalies during
321 the peak of the drought in 2010. In an analysis of drought impact on VOD over the forests in southern Amazonia, Liu et al.
322 observed similar positive anomalies in VOD from May to August during the 2010 drought. Negative anomalies in VOD were
323 only observed during later stages of the drought, from August to October. In 2010, negative slope anomalies in the Cerrado
324 are observed from October on. During the 2015 drought strong positive anomalies in slope and curvature are present over the
325 Cerrado especially in forests. Contrary to the drought of 2010, the peak of the 2015 drought occurs during the precipitation
326 season in the Cerrado. Normally the precipitation season is characterised by lower radiation, and the positive anomalies in
327 radiation during the drought might enhance vegetation growth.

328 4 Conclusions

329 In this study, ASCAT backscatter, slope and curvature were analyzed in conjunction with meteorological data and terrestrial
330 water storage from GRACE in the Amazon region. Previous results, limited to grasslands, had suggested that the slope and
331 curvature contained useful information for monitoring vegetation water dynamics. However, the current study is the first to
332 relate the spatial and temporal variations in slope and curvature to moisture availability and demand. Furthermore, it confirms
333 that the conclusions of Steele-Dunne et al. (2019) can be extended to a wide range of cover types.

334 Results show that the unique viewing geometry of ASCAT provides valuable insight into vegetation water dynamics across a
335 diverse range of ecoregions. Strong temporal consistency was found between ASCAT backscatter and GRACE EWT, with the
336 maximum backscatter coinciding with periods of maximum moisture availability. Spatial patterns in mean and range of slope
337 reflected spatial patterns in vegetation density. The seasonal cycle in slope was found to follow the moisture availability and
338 demand indicated by meteorological data and their influence on phenology. A detailed analysis per land cover type over the
339 Cerrado demonstrated this. Slope dynamics were concurrent with precipitation in croplands and herbaceous cover, although
340 herbaceous cover showed a second peak coinciding with the maximum in radiation. Slope dynamics in shrubs and forest
341 corresponded with radiation, although the onset in increasing slope preceded the onset of increasing radiation. This may be due
342 to leaf flushing, but it is difficult to draw a firmer conclusion given the limited availability of ground data Chave et al. (2010).
343 While the mechanism driving these variations in slope may not be immediately clear, it is important to note that there are open
344 questions around the process of litterfall and its relation to precipitation and radiation in general. A recent study from Hashimoto
345 et al. (2021) demonstrated that the temporal density of optical data from the Advanced Baseline Imager (ABI) onboard the

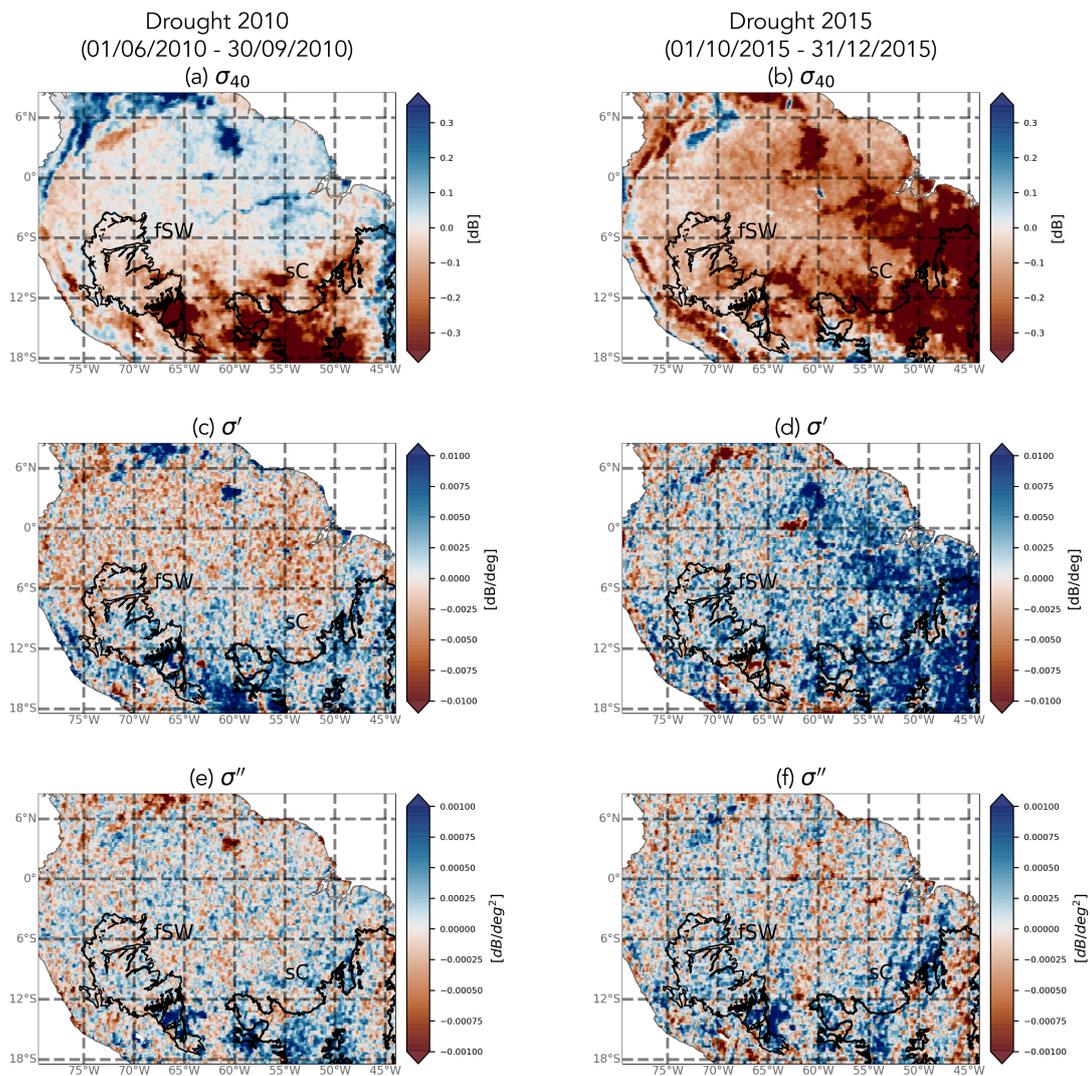

Figure 15. Spatial patterns in anomalies in backscatter, slope and curvature in response to the 2010 and 2015 droughts.

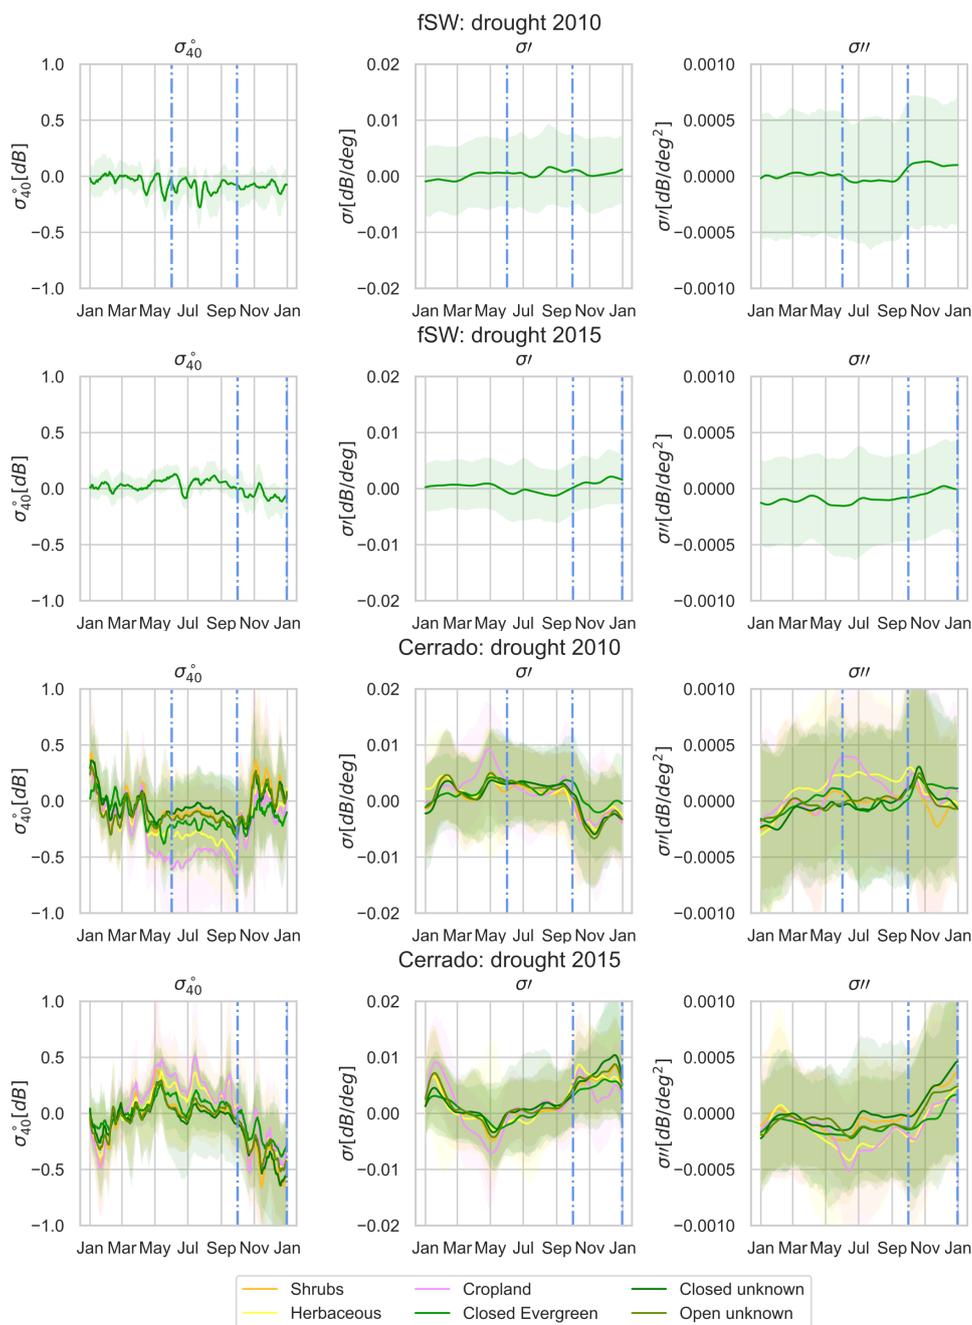

Figure 16. Time series of anomalies in backscatter, slope and curvature for moist forest (fsW) and Cerrado region. The shaded areas indicate the 5th and 95th percentile. The peak drought intervals (June-September 2010 and September-December 2015) are shown within dotted blue lines.

346 Geostationary Operational Environmental Satellite 16 (GOES-16) yields unprecedented detail on the seasonality of NDVI
347 and LAI in the evergreen Amazon forests. A comparison of ASCAT slope and curvature and ABI data may yield additional
348 insight into the connection between slope, curvature and litterfall in the various ecoregions of our study area. Consistent
349 with the findings of Steele-Dunne et al. (2019) in a study limited to grasslands, variations in curvature seem to be related to
350 phenological change. Temporal consistency between the curvature and meteorological data suggests sensitivity to events such
351 as litterfall and leaf flushing. Areas affected by seasonal flooding exhibited dramatic changes in both backscatter and curvature
352 due to a suspected increase in multiple scattering between water on the surface and the vegetation.

353 Diurnal variations (i.e. the difference between morning and evening overpasses) were generally small, particularly in the
354 evergreen forests. Nonetheless, their relation to the timing of precipitation highlights the importance of overpass time in using
355 microwave observations for vegetation monitoring. Diurnal differences in backscatter during the dry season are dominated by
356 transpiration losses. Long-term monitoring of these diurnal differences could provide insight into moisture availability and
357 its influence on transpiration and vegetation functioning. Consistent with previous studies on the effect of drought on the
358 backscatter signal over the Amazon forests (Frolking et al., 2011; Saatchi et al., 2013), a negative anomaly in backscatter was
359 observed during the 2010 and 2015 drought, although this was minor for the moist forests, strong anomalies were observed in
360 the Cerrado. The slope showed positive anomalies during the drought events in the Cerrado, similar to positive anomalies in
361 VOD over forests observed by Liu et al. who attributed this to enhanced canopy growth due to increased radiation. Persistent
362 positive anomalies in radiation were observed over the Cerrado, especially in 2015. The analysis confirms the confounding
363 effects of mechanisms driving variation in slope in these regions and further research is needed.

364 This improved understanding of slope and curvature is valuable in terms of our ability to use ASCAT for vegetation mon-
365 itoring, and specifically for vegetation water dynamics. The slope and curvature are used to produce the vegetation optical
366 depth from ASCAT (Vreugdenhil et al., 2016). Improved understanding of the slope and curvature and how they are affected
367 by vegetation structure and water content, and interactions between the soil and vegetation is essential to improve our ability
368 to interpret and optimally use VOD derived from ASCAT. Furthermore, the fact that the slope and curvature themselves reveal
369 different aspects of the vegetation response to the balance between moisture availability and demand means they are potentially
370 useful low-level observables, i.e. they are obtained with minimal processing, and avoid the assumptions and simplifications re-
371 quired to retrieve geophysical variables. The results of this study suggest that their information content can be directly exploited
372 to monitor vegetation water dynamics.
