**Abstract.** Climate change impact studies on hydrological extremes often rely on the use of hydrological models with parameters inferred by using observational data of daily streamflow. In this work we show that this is an error prone procedure when the interest is to develop reliable Empirical Cumulative Distribution Function curves of annual streamflow maximum. As an alternative approach we introduce a methodology, coined Hydrological Calibration of eXtremes (HyCoX), in which the calibration of the hydrological model is carried out by directly targeting the probability distribution of high flow extremes. In particular, hydrological simulations conducted during a reference period, as driven by climate models' outputs, are constrained to maximize the probability that the modeled and observed high flow extremes belong to the same population. The application to the Adige river catchment (southeastern Alps, Italy) by means of HYPERstreamHS, a distributed hydrological model, showed that this procedure preserves statistical coherence and produce reliable quantiles of the annual maximum streamflow to be used in assessment studies.

10  
15

## Key Points/Highlights:

- A methodology for devising reliable extreme high streamflow scenarios from climate change model simulations
  - Accurate reproduction of observed ECDF of annual streamflow maximum
  - Preservation of statistical coherence between observed and simulated ECDFs of annual streamflow maximum
- 20

**Keywords:** Goal-oriented calibration; high streamflow extremes, Climate change; statistical coherence; hydrological modeling

## 1 Introduction

25 The recognition that an altered climate may affect severely water availability, floods and droughts, or other water-related resources and sectors, led in the past decades to a wealth of climate change impact assessment studies in hydrological

literature. A number of studies investigated the likely impact of climate change on hydrology by combining ensemble of projections from multiple climate models under different greenhouse gas emissions scenarios and hydrological modeling [e.g., Kundzewicz et al., 2007; Todd et al., 2010 and Wilby and Harris, 2006 for a comprehensive review]. A wealth of studies focus on long-term annual and/or seasonal changes in hydrological variables such as runoff, streamflow, snow melt and soil moisture [e.g., Chiew et al. 2009; Majone et al., 2012; Buytaert and De Bièvre, 2012]. Much less address projected changes in hydrological extremes, i.e. floods and droughts, though they are expected to exert profound and dramatic impacts on agriculture, economy, human health, energy and many other water-related sectors [e.g., Arnell 2011; Taye et al. 2011; Bouwer, 2013; Thornton et al., 2014].

35 The peculiarity of hydrological calibration in climate change impact studies has been highly debated in the hydrological modelling community [e.g. Peel and Blöschl, 2011; Muñoz et al., 2013; Montanari et al., 2013; Thirel et al., 2014]. The standard approach is to calibrate the selected hydrological model using a chronological time series of streamflow observations and then feed the model with future climate projections to evaluate changes of hydrological indicators [see e.g. Hattermann et al. 2018]. However, several studies showed that model parameters are dependent on the climatic characteristics of the input forcing used during the calibration of the hydrological model [e.g., Vaze et al., 2010; Laiti et al., 2018]. Although recognized, this additional source of uncertainty is mostly ignored in climate change impact studies.

40 Indeed, a number of studies suggest that observed streamflow extremes provide valuable information about the hydrological behavior of investigated catchments [Grubbs, 1969; Laio et al., 2010]. Similarly, Perrin et al. [2007] and Seibert and Beven [2009] concluded that a limited number of streamflow extremes encapsulate a significant amount of information that may be useful in the context of hydrological model calibration. Beven and Westerberg [2011] suggested also that, when dealing with extremes, including the entire time series might not be informative. This occurs, for instance, when streamflow extremes belong to a different population than ordinary flows [e.g., Calenda et al, 2009], such that the latter do not provide useful information for inferring the former. Hence, quantifying the influence of such extreme events on model calibration is still a challenge in hydrological studies [Brigode et al., 2015], such as quantifying the uncertainty associated to these estimates

50 [Honti et al., 2014].

Despite the above evidences, the typical approach adopted in impact assessments of hydrological extremes is to estimate the projected changes of selected indicators (e.g. flow quantiles) using a hydrological model calibrated against chronological time series of streamflow observations during a reference period [e.g., Wilby and Harris, 2006; Hattermann et al. 2018]. The drawbacks of such approach are however threefold: i) a model correctly reproducing the time series of observed streamflow does not guarantee the correct reproduction of the desired statistics for extremes, as discussed above; ii) due to epistemic uncertainty, a model calibrated with a given set of observed ground data may respond in a different way when fed with projections obtained from climate change scenarios; and iii) due to the impossibility of obtaining totally unbiased climate simulations there is no a-priori guarantee that simulations fed by climate models produce samples (e.g. time series of simulated annual streamflow maximum) that are statistically coherent with observations.

60 To overcome the aforementioned limitations, we propose an innovative methodology in which the calibration of a  
physically-based hydrological model is conducted by directly targeting the probability distribution of high streamflow  
extremes (i.e., the Empirical Cumulative Distribution Function, ECDF, of annual maxima). While the approach is  
exemplified in this work for high streamflows (also because of the broad interest in the topic), it can be applied to low flows  
as well (e.g., for droughts assessment). The methodology, coined here as Hydrological Calibration of eXtremes (HyCoX),  
65 targets specifically climate change impact assessment studies. In particular, hydrological simulations conducted during a  
reference period, as driven by climate models, are constrained to maximize the chances that the simulated and observed high  
flow extremes belong to the same population. Statistical coherence is obtained by using the two-sample Kolmogorov-  
Smirnov statistic [Smirnov, 1939] as the efficiency metric during the calibration procedure. The parameterization of the  
hydrological model obtained following this approach is then used in future climate change scenario runs to project changes  
70 in the distribution of high flows. The strengths of the methodology are highlighted by performing a comparison with  
experiments in which model parameterizations are obtained by calibrating the hydrological model, fed by observed ground  
data, with a suite of efficiency metrics customarily used in hydrological applications, i.e., Nash-Sutcliffe efficiency, [Nash  
and Sutcliffe, 1970] and flow duration curve-related metric [Westerberg et al., 2011].

We emphasize that the suggested approach is by definition “goal-oriented”, according to the definition discussed in Fiori et  
75 al. [2016], Savoy et al. [2017], Guthke [2017], Laiti et al., [2018] and Li et al. [2018]. In other words, the selection of the  
hydrological model, its level of complexity and the metric to be employed for the evaluation of the statistical coherence of  
simulated and observed extremes depend on modeler’s choice and the particular goal at hand. In the present work the main  
focus is on high streamflow extremes, and along the goal-oriented approach the proposed calibration procedure is tailored  
around it.

80 The paper is organized as follows: Section 2 presents the hydrological calibration framework, the adopted statistical  
coherence test and the calibration metrics; a description of the study area, the climate change projections available and the  
observational hydro-meteorological datasets used are summarized in Section 3. The main findings are presented and  
discussed in Section 4, whereas conclusions are finally drawn in Section 5.

## 2 Methods

### 85 2.1 Hydrological modelling

Hydrological simulations were performed at the daily time scale with the HYPERstreamHS model [Avesani et al., 2021;  
Laiti et al., 2018; Larsen et al., 2021] which couples the HYPERstream routing scheme, recently proposed by Piccolroaz et  
al., [2016], with a continuous SCS-CN module for surface and subsurface flow generation [Michel et al., 2005].  
HYPERstream routing scheme is specifically designed for being easily coupled with climate models and, in general, with  
90 gridded climate datasets. HYPERstream can share the same computational grid as that of any overlaying product providing  
the meteorological forcing, still preserving geomorphological dispersion of the river network [Rinaldo et al., 1991]

irrespective of the grid resolution. This “perfect upscaling” [cf. Piccolroaz et al., 2016] can be achieved by application of suitable transfer functions derived from a high-resolution Digital Elevation Model of the study area. The continuous soil-moisture accounting model for surface and subsurface flow generation, based on the SCS-CN methodology, is coupled with a non-linear bucket model for soil moisture dynamics [Majone et al., 2010], a degree-day model for snow melting and accumulation [Rango and Martinec, 1995] and the Hargreaves and Samani [1982] model for evapotranspiration. Furthermore, deep infiltration enters a linear bucket used to represent return flow. Notice that the surface and subsurface flow generation module was already successfully applied in two previous studies conducted in Alpine catchments [Piccolroaz et al., 2015; Bellin et al., 2016]. The model requires a total of 12 parameters, which are assumed as spatially uniform but uncertain and all subject to calibration. A detailed description of the hydrological modeling can be found in Laiti et al. [2018] and Avesani et al. [2021].

## 2.2 Evaluation of statistical coherence

Statistical coherence between the observed and simulated populations of extremes was evaluated by means of the two-sample Kolmogorov-Smirnov test [Smirnov, 1939], applied under the null hypothesis that the two samples are drawn from the same underlying distribution. In the two-tail application of interest here the test’s statistic is defined as the maximum absolute distance,  $D_n$ , between the simulated ( $F_s$ ) and observed ( $F_o$ ) ECDFs of annual daily streamflow maximum ( $Q^M$ ):

$$D_n = \max_{i \in [1, n]} |F_s(Q_{s,(i)}^M) - F_o(Q_{o,(i)}^M)|, \quad (1)$$

where  $i$  is the position of  $Q_{s,(i)}^M$  and  $Q_{o,(i)}^M$  in the ranked samples of the simulated ( $s$ ) and observed ( $o$ ) annual streamflow maxima, respectively, and  $n$  is the number of years considered in the simulation (29 values in this work, one for each year of the investigated period excluding the first two, see Sect. 2.4). As customary in statistics  $Q_{s,(i)}^M, i = 1, \dots, n$  indicates the ranked time series of the annual maxima  $Q_{s,i}^M$  of simulated streamflow. A similar definition has been introduced for observed streamflow. The closer  $D_n$  is to 0 the more likely it is that the two samples are drawn from the same population. In addition, the two-sample Kolmogorov-Smirnov test returns a p-value ( $p$ ) corresponding to the computed  $D_n$  statistic. The p-value is the probability of rejecting the null hypothesis when it is true. It can also be defined as the smallest significance level  $\alpha_s$  at which the null hypothesis would be rejected [Conover, 1999]. In simpler terms, the larger the p-value the stronger is the evidence in favor of the null hypothesis, i.e., in our work that the samples are drawn from the same distribution.

In our framework the evaluation of statistical coherence of observed and simulated populations of extremes is performed a-posteriori for each simulation experiment described in Section 2.4. In particular, the p-value will be used as a measure of the statistical coherence between simulated and observed high streamflow extremes.

## 120 2.3 ECDF computation

The daily average annual streamflow maxima are extracted from the chronological daily time series of observed (o) and simulated (s) streamflow and their empirical probability,  $F$ , is computed separately according to the classic Weibull formulation [Weibull, 1939]:

$$F_j(Q_{j,(i)}^M) = \frac{i}{n+1}, \quad j = o, s, \quad i \in [1, n]. \quad (2)$$

125 Empirical probabilities provided by Eq. (2) are used in Eq. (1) to compute the Kolmogorov-Smirnov statistic  $D_n$ .

## 2.4 Hydrological model calibration

The HYPERstreamHS hydrological model was calibrated against streamflow observations using as meteorological forcing both an observational dataset (i.e. ADIGE, see Sect. 3.2) and three climate models each under two emission scenarios. A short description of these datasets is provided in Sect. 3.3. Calibrations were performed during the period 1980-2010, assumed as reference, with the first two years used as spin-up and therefore excluded from the computation of model performances. Parameters were inferred by optimizing three efficiency metrics by means of the Particle Swarming Optimization algorithm [Kennedy and Eberhart, 1995].

130 The first efficiency metric is the classic Nash-Sutcliffe index [Nash and Sutcliffe, 1970], which is widely used in hydrological applications:

$$135 \quad NSE = \max_{\theta \in P^q} \left( 1 - \frac{\sum_{i=1}^m (Q_{s,i}(\theta) - Q_{o,i})^2}{\sum_{i=1}^m (Q_{o,i} - \bar{Q}_o)^2} \right), \quad (3)$$

where  $m$  is the total number of daily time steps,  $Q_{s,i}(\theta)$  and  $Q_{o,i}$  are the simulated and observed streamflow value at time step  $i$ , respectively,  $\bar{Q}_o$  is the mean of the observed values and  $\theta = [\theta_1, \dots, \theta_q]$  are the  $q$  model parameters forming the parameter space  $P^q$ . A daily time step is used here. Since this metric is sensitive to the chronological time series of simulated and observed daily streamflow, it was applied only in the simulations calibrated by using the observational dataset ADIGE as meteorological input.

140 The second efficiency metric ( $R_{FDC}$ ) is an adaptation of the objective function proposed in Westerberg et al. [2011] with the aim to obtain a good match between simulated,  $\hat{Q}_{s,(i)}(\theta)$ , and observed,  $\hat{Q}_{o,(i)}$ , flow duration curves (i.e., the ranked streamflow values this time in descending order):

$$R_{FDC} = \max_{\theta \in P^q} \left( 1 - \frac{\sum_{i=1}^{n_{EP}} |\hat{Q}_{s,(i)}^{EP}(\theta) - \hat{Q}_{o,(i)}^{EP}|}{\sum_{i=1}^{n_{EP}} |\hat{Q}_{o,(i)}^{EP} - \bar{Q}_o|} \right), \quad (4)$$

145 where  $\hat{Q}_{s,(i)}^{EP}(\theta)$  and  $\hat{Q}_{o,(i)}^{EP}$  are the simulated and observed streamflow values at the  $n_{EP}$  evaluation points (EPs) in which the flow duration curves are partitioned (ranked from the larger to the smaller value) and  $\bar{Q}_o$  is the mean of the observed time series. According to this metric,  $R_{FDC} = 1$  when the two flow duration curves coincide (i.e., they are the same at all the EPs). Given that the flow duration curve is insensitive to chronologic sequence,  $R_{FDC}$  has been used as objective function for

streamflow maxima obtained with both climate models and the observational dataset ADIGE. Furthermore, following  
150 Westerberg et al. [2011], we employed the so-called volume method in which EPs are identified as the upper boundary of the  
elements obtained by partitioning the area below the curve in  $n_{EP}$  elements such that each of them is characterized by the  
same water volume. Given the same number of EPs, we remark that the procedure is performed independently for observed  
and simulated FDCs and it is indeed possible that the total volume under the curves and the water volume of each interval  
differ between observations and simulations. The water volume pertaining to each interval as well the total water volume of  
155 the flow duration curve are computed by using the right Riemann sum procedure [Protter and Morrey, 1977]. In the  
computations we used  $n_{EP} = 50$ , which has been shown sufficient to obtain convergence of the statistic (4) irrespective of  
the integration scheme [Vogel and Fennessey, 1994].

The third efficiency metric is the minimum of the two-sample Kolmogorov-Smirnov ( $D_n$ ) statistic defined in Eq. (1):

$$KS = \min_{\theta \in P^q} (D_n) = \min_{\theta \in P^q} \left( \max_{i \in [1, n]} |F_s(Q_{s,(i)}^M(\theta)) - F_o(Q_{o,(i)}^M)| \right), \quad (5)$$

160 where  $F_s$  and  $F_o$  are the simulated and observed ECDF as introduced in Eq. (2), and  $Q_{s,(i)}^M(\theta) = \max(Q_{s,k}(\theta), k \in i -$   
 $th \text{ year})$  and  $Q_{o,(i)}^M = \max(Q_{o,k}, k \in i - th \text{ year})$  are the simulated and observed annual streamflow maxima of the  $i$ -th  
year, respectively. This metric, which is at the core of the proposed approach, aims to maximize the chances that the  
modeled and observed samples of extreme high flows belong to the same population. In other words, among all possible sets  
of model parameters we consider the one leading to the sample of simulated annual maxima with the smallest  $D_n$  (i.e., KS  
165 metric). Since KS is not sensitive to the temporal sequence of observed and simulated streamflows, similar to the  $R_{FDC}$  case,  
it has been applied to climate projections in addition to the simulations with the observational dataset ADIGE.

## 2.5 Probability distribution computation and confidence intervals

The probability distributions of simulated and observed annual streamflow maxima were obtained by fitting the Extreme  
Value Type I (Gumbel) [Gumbel, 1941] distribution,  $P(Q \leq q) = \exp[-\exp[-\beta(q - u)]]$ , with the Maximum Likelihood  
170 Method (MLE) [Hosking, 1985] to the respective samples. The Pearson's chi-squared test [Pearson, 1990] with a confidence  
level  $\alpha_s = 0.05$  was applied to validate the parameters  $\beta$  and  $u$  provided by the MLE. The adaptation of the Gumbel  
distribution to the annual maxima of the observed and simulated daily streamflow was performed a-posteriori for comparison  
purposes in order to extrapolate high flow quantiles (i.e., high return periods) for all the simulation experiments presented in  
Sect. 4.

175 Confidence intervals of observed streamflow ECDF were computed by means of parametric bootstrap [Efron, 1982] under  
the assumption that the quantity of interest was distributed according to the above parametric Gumbel probability  
distribution. In particular, 90% confidence band was estimated by using 10000 uniform random samplings from the  
underlying inferred distribution.

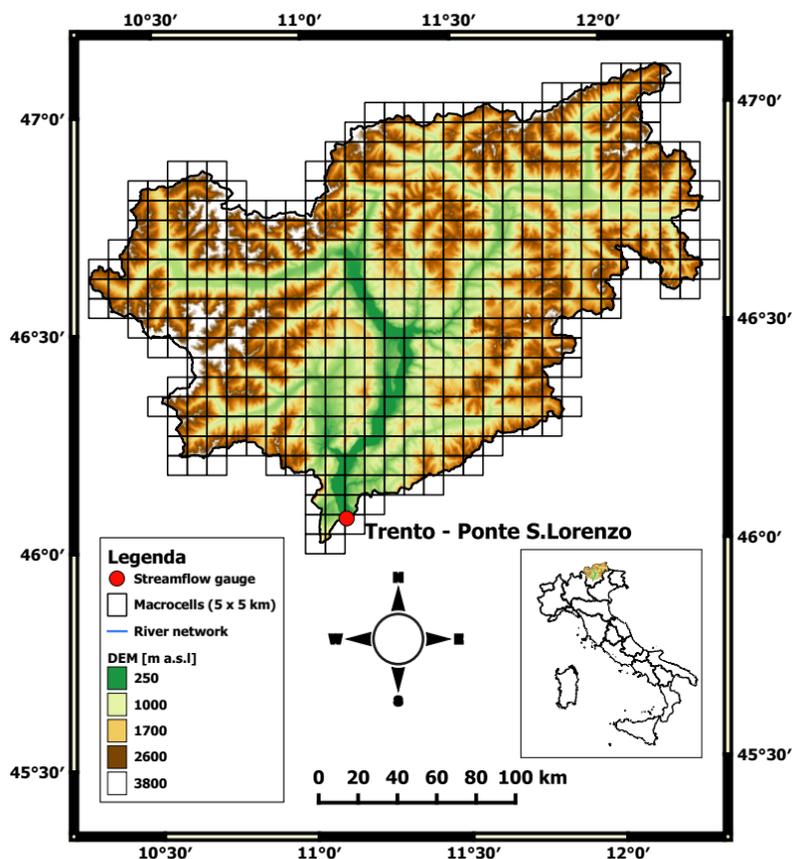

### 3 Study area and hydro-climatic datasets

#### 180 3.1 Study area

To exemplify the application of the methodology we selected as a case study the upper portion of the Adige river basin (Italy), located in the south-eastern Alpine region (see Figure 1), at the gauging station of Trento (11° 06' 54.8" E, 46° 04' 13" N, drainage area of about 9850 km<sup>2</sup>). The Adige river originates at the Resia Pass (close to the Alpine divide) and ends its course after 410 km in the northern Adriatic Sea. It is a typical Alpine watershed, with terrain elevations ranging from 185 m a.s.l. at Trento to 3500 m a.s.l. at the Italian-Austrian border. The morphology is characterized by deep valleys and high mountain crests.

The climate of the watershed is characterized by relatively dry and cold winters followed by humid summers and autumns. Streamflow is minimum in winter, when precipitation falls as snow over most of the river basin, and shows two maxima: one occurring early in summer, due to snowmelt, and the other in autumn, triggered by intense cyclonic storms. The annual average precipitation ranges from 500 mm in the North-West to 1600 mm in the southern part of the basin [Lutz et al., 2016; Diamantini et al., 2018; Laiti et al., 2018]. Projected decrease of snowfall in winter and anticipation of earlier snow-melting, essentially due to rising temperatures associated with global warming [Gobiet et al., 2014; Gampe et al., 2016], will likely affect Adige streamflow regime by the second half of 21<sup>st</sup> century [Bard et al., 2015; Majone et al., 2016]. This may have relevant consequences on water resources and hydropower production, which is particularly relevant in this region of the Alps [Zolezzi et al., 2009; Bellin et al., 2016; Majone et al., 2016]. See also Chiogna et al. [2016] for a comprehensive review of the hydrological stressors acting in the Adige basin, as well as of its ecological status.

200 **Figure 1: Map of the Adige river basin, with the computational grid cells (“macrocells”) superimposed to the Digital Elevation Model (DEM) and the river network. The streamflow gauging station used in the study is marked with a red dot. The inset shows the location of the Adige river basin within the Italian territory.**

### 3.2 Observational datasets

The regional dataset ADIGE developed by Mallucci et al., [2019] by using the meteorological stations within the catchment and in the nearby Austrian territory bounding the catchment from the north, was used as an observational precipitation and temperature dataset. ADIGE was selected since it is the most accurate gridded meteorological dataset of the investigated river basin (as shown in the recent paper by Laiti et al., 2018). Meteorological data at the selected stations were provided by the Austrian Zentralanstalt für Meteorologie und Geodynamik ([www.zamg.ac.at](http://www.zamg.ac.at)) and the meteorological offices of the Autonomous Provinces of Trento ([www.meteotrentino.it](http://www.meteotrentino.it)) and Bolzano ([www.provincia.bz.it/meteo](http://www.provincia.bz.it/meteo)). The time series were interpolated over a 1-km grid at a daily time step by means of the kriging with external drift algorithm [Goovaerts, 1997; Journal and Rossi, 1989], with an exponential semivariogram and by using the 16 closest neighbouring stations to generate the estimates. The spatial distribution model was selected by Mallucci et al. [2019] according to the leave-one-out cross-validation procedure, applied to ordinary kriging and kriging with external drift algorithms, in association with multiple semi-variogram models (i.e., Gaussian, spherical and exponential models) and different numbers of neighbouring stations

205  
210

(namely 8, 16 and 32 stations). An average absolute error of the daily estimates of about 1.32 mm for precipitation and  
215 0.02°C for temperature is reported in Mallucci et al. [2019], comparable with the error estimates provided by other ground  
data-based datasets available in the Alpine region such as APGD [Isotta et al., 2014]. To comply with the computational grid  
adopted by HYPERstreamHS model, ADIGE was aggregated by areal averaging to the 5 km grid depicted in Figure 1.  
Daily streamflow data collected at the Trento Ponte san Lorenzo gauging station (see Figure 1) during the period 1980-2010  
were provided by the Hydrological Office of the Autonomous Province of Trento ([www.floods.it](http://www.floods.it)).

### 220 3.3 Climate change projections

Climate projections applied in this study were derived from the combination of General Circulation Models (GCMs) and  
Regional Climate Models (RCMs) available from EURO-CORDEX initiative under 4.5 and 8.5 Representative  
Concentration Pathways (RCP4.5 and RCP8.5), at a spatial resolution of about 12 km [EUR-11, <http://www.eurocordex.net/>,  
Jacob et al., 2014]. To reduce the computational burden in the hydrological modeling experiments, we adopted the model  
225 sub-selection proposed by Vrzal et al. [2019] whom applied a hierarchical clustering approach [Wilcke and Barring, 2016] in  
selected European river basins (including the Adige) in order to reduce the number of available Climate Model (CM)  
simulations (i.e., GCM-RCM combinations) while preserving the variability of the overall ensemble of climate change  
signals. In particular, model reduction involved 5 steps: 1) identification of meteorological variables; 2) transformation of  
variables into orthogonal and therewith uncorrelated variables by means of singular vector decomposition; 3) identification  
230 of the optimum number of clusters; 4) hierarchical clustering to group the simulations; and finally 5) selection of the  
simulation closest to the group's mean as representative. This procedure led to the selection of the three GCM-RCM  
combinations (out of the 12 available), here referred to as CLMcom, KNMI and SMHI (see Table 1).

These three Climate Models (CMs) provide an assessment of likely future climate changes for the mid-term horizon 2040-  
2070, with the time window 1980-2010 selected as a period of reference. The projected climate change meteorological  
235 signals in the Adige are discussed in Gampe et al. [2016]. Both RCP4.5 and RCP8.5 emission scenarios are available for all  
the three adopted CMs, thereby leading to a total of six CMs which are investigated in the present study (see Table 1). Since  
GCMs/RCMs combinations are prone to model biases especially in complex terrain [Kotlarski et al., 2014], bias-correction  
is needed to accurately reproduce historical meteorological forcing during the reference period. As customarily done in most  
of the climate change impacts studies, we rely on bias-corrected products retrieved from EURO-CORDEX initiative. For the  
240 reference period 1989-2010 EURO-CORDEX products are available bias corrected by the distribution-based scaling  
approach [DBS, Yang et al., 2010] using as a reference the MESAN gridded reanalysis datasets of daily precipitation and  
temperature [Landelius et al., 2016]. CMs forcing in the reference period 1980-2010 slightly differ between the two RCPs as  
a consequence of: i) the bias correction method adopted, which matches observed and simulated frequency distributions  
rather than the observed values; and ii) the correction used in the reference period 1989-2010 is extended to the period 1980-  
245 2010. Finally, before using them as input in hydrological calibration experiments, the gridded CMs outputs were resampled

by means of the nearest neighbour method to the computational 5 km spacing grid used in the discretization of the Adige river basin (see the grid shown in Figure 1).

**Table 1: List of the EURO-CORDEX CMs used in this study. Acronyms adopted are listed in the last column.**

## 4 Results and discussion

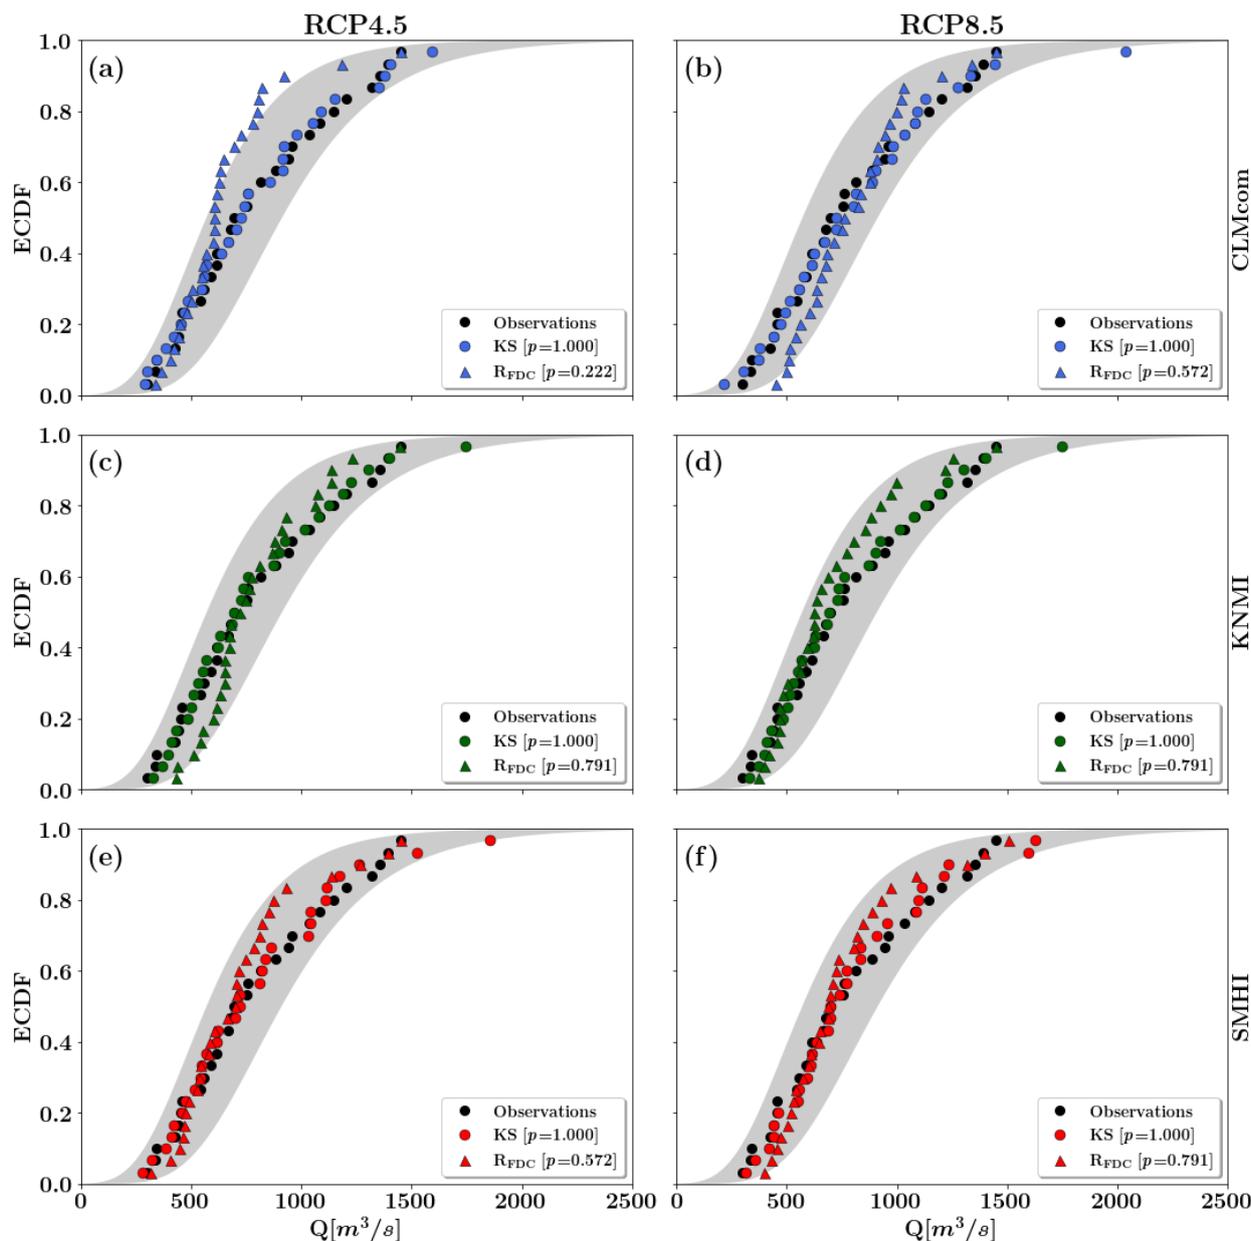

### 250 4.1 Direct calibrations forced by CMs

Here we consider the results of hydrological simulations performed by using precipitations and temperature from the three GCM-RCM combinations selected as described in Section 3.3 each one with both RCP4.5 and RCP8.5 pathways, for a total of six combinations, as shown in Table 1. The parameters of the hydrological model are obtained by optimizing KS and  $R_{FDC}$  in the period 1982-2010. The ECDFs of the daily average annual streamflow maximum are extracted a-posteriori from the  
 255 six optimized models and then compared with that of the historical observations in the same period. The comparison is performed by applying the Kolmogorov-Smirnov two-sample test between simulated and observed ECDFs (see Sect. 2.2), with the former obtained by optimizing the two metrics  $KS$  (Eq. (5)) and  $R_{FDC}$  (Eq. (4)), respectively.

Results presented in Table 2 show that for both RCP4.5 and RCP8.5 emission scenarios simulations performed by optimizing  $KS$  (Eq., (5)) provided samples that with high probability (i.e.  $p = 1.000$ ) belong to the same population of the  
 260 observed values for all the 3 CMs used. On the other hand, the optimization of  $R_{FDC}$  leads to samples belonging to the same population with probability larger than  $p=0.05$  (i.e. the level of significance customarily adopted in the statistical literature to reject the null hypothesis), though significantly lower than for  $KS$  (fourth column in Table 2). The lowest  $p$  value is obtained when the calibration is performed by using the climate model CLMcom with RCP4.5 ( $p = 0.222$ , see Figure 2a and Table 2). Consistently, the absolute maximum distance between the ECDF of observed and simulated sample distributions (i.e.,  $D_n$ )  
 265 obtained by using  $R_{FDC}$  as calibration metric are always larger than those obtained by using  $KS$  (see third column in Table 2). The consequence in terms of correspondence between observed and simulated ECDFs is indeed appreciable. The ECDFs obtained from simulations performed by adopting  $KS$  as optimization criteria are in a better agreement with the observed ECDF than the ECDFs obtained from simulations that use  $R_{FDC}$  as optimization criterion (see all subplots in Figure 2). These results highlight that adopting the  $KS$  metric is preferable than using  $R_{FDC}$  when dealing with high flow extremes, thus

270 strengthening the idea of targeting directly the desired statistics for extremes in calibration instead of calibrating the hydrological model on the entire streamflow record.

275 **Figure 2:** ECDFs of annual maximum daily streamflow at Trento gauging station during the period 1982-2010 using CLMcom (first row), KNMI (second row), and SMHI (third row) climate models as input forcing under the RCP4.5 (left) and RCP8.5 (right) emission scenarios. Calibrations have been performed using both KS and RFDC metrics. The ECDF of observations is also shown with black dots together with the associated 90% confidence interval obtained by bootstrapping as described in Section 2.5 (grey shaded area). p-values of the Kolmogorov-Smirnov two-sample test are also reported within brackets in the legend.

The above findings can be cast and discussed in the context of the hydrological literature of hydrological extremes, and in the following we further expand the discussion presented in the Introduction in light of the results obtained so far. Climate change effects on extremes are typically assessed by using a hydrological-climatological modeling chain [Wilby and Harris, 2006] in which the adopted hydrological model is calibrated against chronological time series of observed streamflows during a reference period, and then used with GCM-RCM future projections as meteorological input to assess projected changes of the extremes [see e.g. Ngongondo et al., 2013; Aich et al., 2016; Pechlivanidis et al., 2017; Vetter et al., 2017; Hattermann et al. 2018]. Calibration of the hydrological model by targeting directly the statistics of extremes (e.g. high flow quantiles or KS metric as in our case) are indeed much less common in hydrological applications [see e.g. Honti et al., 2014]. This distinction may appear unnecessary since it seems reasonable to assume that a model correctly reproducing the chronological time series of streamflow will also reproduce the statistics of interest (or distribution). However, unavoidable epistemic and parametric errors, impairs this implicit assumption. A possible alternative, we explore here, is to calibrate on the distribution of the considered extremes, i.e. the annual streamflow maxima in our case.

Examples of hydrological models calibrated by using tailored information instead of the entire observed streamflow series are present in the hydrological literature. Montanari and Toth [2007] used the spectral properties of the streamflow time series as a goodness of fit metric. Blazkova and Beven [2009] used certain flow quantiles as acceptability criteria within a GLUE framework. Westerberg et al. [2011] used an informal triangular likelihood function for calibrating a hydrological model on the basis of observed flow duration curves. Furthermore, Lindenschmidt (2017) used water stage frequency curves as objective functions for reproducing ice jam formation in northern rivers. However, these approaches are typically adopted for reproducing watershed response to meteorological forcing under observed conditions, and have not been applied (to our best knowledge) using directly the GCM-RCMs simulations as input forcing in the calibration procedure. The only example somewhat similar to our approach we found in literature is that of Honti et al. [2014], which however used a stochastic weather generator trained by observed weather time series coupled with observed discharge data to sample the posterior distribution of model parameters. The adoption of a time-independent calibration (i.e., timing errors do not influence the model performance) has the intrinsic advantage of allowing the use of GCM-RCM runs conducted without the assimilation of observational data, as in our case. In fact, these runs provide time-slice experiments representing a stationary climate for both reference and future periods [see e.g., Majone et al., 2012] and by definition cannot be used in the context of a classical day-by-day hydrological comparison experiment with observed historical data [see e.g., Eden et al., 2014].

Studies adopting the two-sample Kolmogorov-Smirnov test to evaluate if simulated hydrological variables are distributed according to a given probability distribution [e.g., Kleinen and Petschel-Held, 2007], to detect changes in hydrological variables [e.g., Wang et al., 2008], or to understand if calibrated parameters of hydrological models belong to a given probability distribution [e.g., Wu et al., 2017; Wang and Solomatine, 2019] are relatively common in the literature. This notwithstanding, we are not aware of any study adopting directly the KS metric in the context of hydrological model calibration on extremes.

The proposed method, coined here as Hydrological Calibration on Extremes (HyCoX), hence consists in the calibration of a physically-based hydrological model on the probability distribution of extremes (in our case the ECDF of the annual maximum of daily streamflow), i.e. the possibility to constrain simulated (driven by GCM-RCM runs during the reference period) and observed data samples to belong to the same population. In this respect, HyCoX also provides a framework for excluding CMs forcing datasets not coherent with hydrological observations of high flow extremes (i.e., cases with  $p < 0.05$  in the Kolmogorov-Smirnov two-sample test). Finally, the parameterization obtained for the hydrological model guaranties statistical coherence between scenarios and observations during the reference period, and can then be used in future climate change scenario runs to project changes in extremes.

#### 325 4.2 Forward simulations using parameterizations derived from calibrations with observed ground data

The typical way to assess the impact of climate change on hydrology is to run a model, calibrated with observed meteorological and hydrological data, with the meteorological forcing provided by climate models. This approach is pursued here by using HYPERstreamHS calibrated against daily streamflow in the period 1982-2010, with precipitation and temperature extracted from the ADIGE dataset [Mallucci et al., 2019], and meteorological input provided by the six

330 aforementioned CM simulations. The main objective is to assess if a model well calibrated with observational data responds  
coherently when applied with precipitation and temperature obtained from climate models. Again, the comparison is  
performed by applying the Kolmogorov-Smirnov two-sample test between simulated and observed ECDFs.  
HYPERstreamHS was calibrated at the Trento gauging station by using NSE, KS and  $R_{FDC}$  metrics. In order to ease the  
ensuing discussions, these three parameterizations are hereafter termed as NSE-ADIGE, KS-ADIGE and  $R_{FDC}$ -ADIGE,  
335 respectively (see also Table 2).

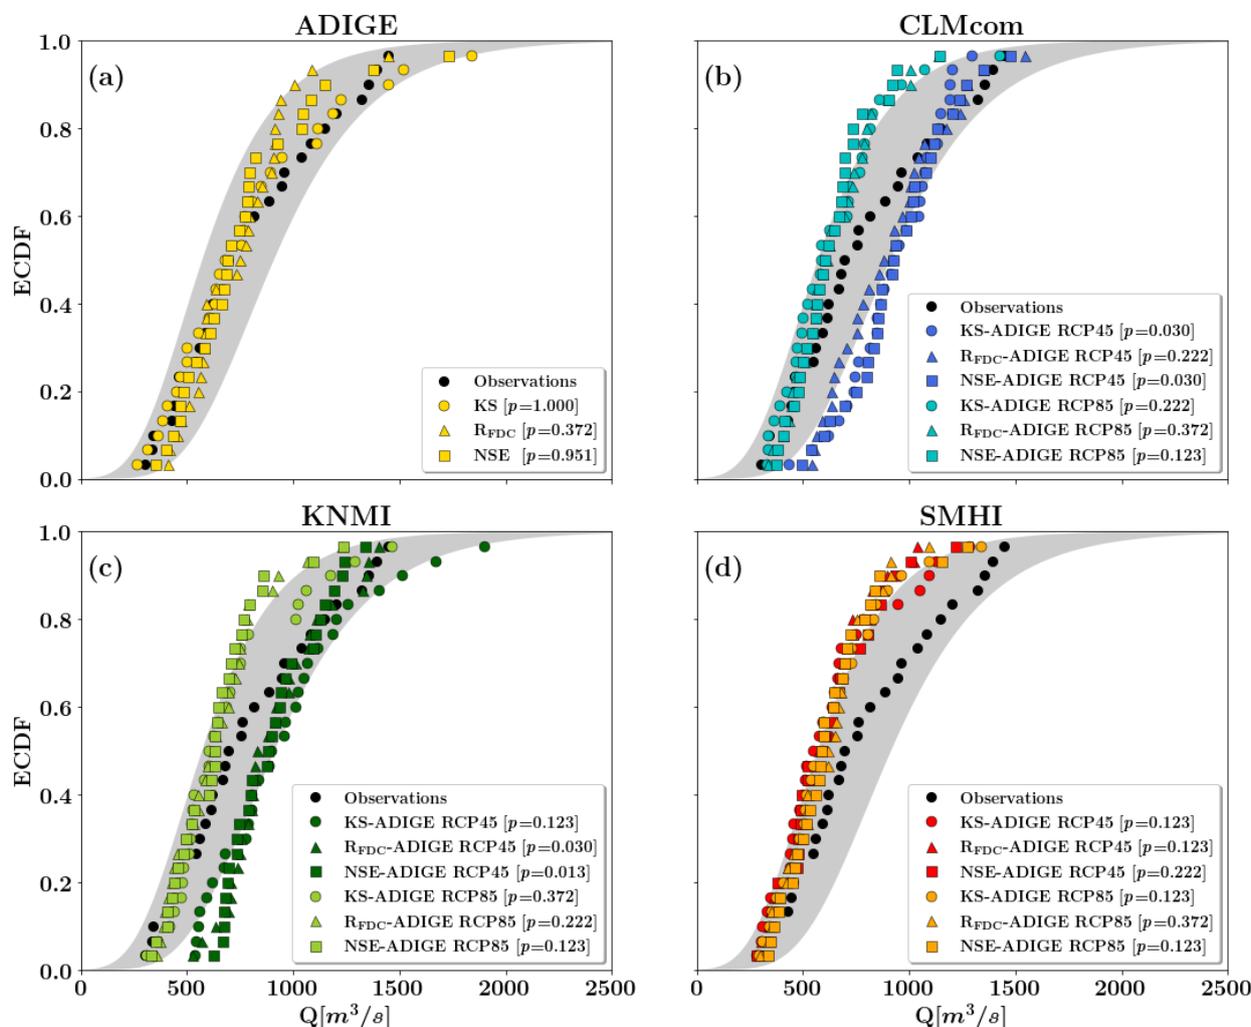

Figure 3a shows the simulated ECDFs and the associated  $p$ -values of the Kolmogorov-Smirnov test for calibrations  
conducted with the ADIGE dataset as input and the three aforementioned metrics (NSE, KS and  $R_{FDC}$ ). In a strict statistical  
sense all the three metrics provide simulated samples of annual streamflow maxima belonging to the same population of the  
observed ones, given that in all cases  $p > 0.05$ , but with an evidence in favor of this conclusion that is maximum for KSE ( $p =$   
340 1.000) and minimum for  $R_{FDC}$  ( $p = 0.372$ ). At the same time, calibration conducted by using KS as efficiency metric leads to  
NSE and  $R_{FDC}$  values (0.4 and 0.564, respectively, see Table 2) which are lower than those obtained optimizing the two  
metrics in the calibration (NSE = 0.822 and  $R_{FDC} = 0.975$ , see Table 2). This is in accordance with several studies showing  
that the adoption of a given metric in calibration may lead to suboptimal results for other metrics since each one of them is  
more sensitive to specific aspects of the time series with its own limitations and trade-offs [see e.g., Schaeffli and Gupta,  
345 2007; Gupta et al., 2009; Mcmillan et al., 2017; Fenicia et al., 2018]. This latter limitation is, in our opinion, outweighed by  
the improvements in representing the ECDF of observed high flow extremes during the calibration of the hydrological  
model. Accordingly, in our analyses the use of different efficiency metrics leads to different simulated ECDFs and hence to  
different  $p$ -values in the application of the statistical coherence test (see Table 2).

When the 3 aforementioned parameterizations (i.e., NSE-ADIGE,  $R_{FDC}$ -ADIGE, KS-ADIGE) are used in the forward  
350 simulations of the reference period 1982-2010 using as input the meteorological variables produced by the climate models,  
the conclusions are significantly different (see Figures 3b, 3c, 3d). In particular, the adopted parameterizations lead to  
simulations that show low  $p$ -values (always lower than  $p = 0.372$ ) for all the considered CMs and pathways. In particular,  
NSE-ADIGE and  $R_{FDC}$ -ADIGE show on average the lowest  $p$ -values, with KS-ADIGE showing a slightly better  
performance:  $p = 0.372$  for KNMI and SMHI under the RCP8.5 scenario (see Figures 3c and 3d).

355 The above results highlight how the classical approaches based on feeding the hydrological model calibrated to observed  
streamflow data (i.e., by using the NSE metric) or to flow duration curve (i.e., by using the  $R_{FDC}$  metric), with meteorological  
forcing provided by Climate Models produce results characterized by low statistical coherence with the observational data.  
Furthermore, our results indicate that the same drawback arises when employing parameterizations obtained with a  
calibration approach optimizing the desired statistic of extremes, but still using observational data as input, i.e., KS-ADIGE  
360 in Figures 3b, 3c and 3d. These results are in agreement with previous studies evidencing that the use of parameterizations of  
hydrological models (obtained with observational input forcing) providing a good reproduction during a baseline period is  
questionable for simulating streamflow under future climate conditions [Brigode et al., 2013; Lespinas et al., 2014]. Indeed,  
it is well recognized that the use of different datasets can lead to different optimized parameter sets that will partially account

for their specific climate characteristics [Yapo et al. 1996; Vaze et al., 2010; Laiti et al., 2018]. Furthermore, it is  
 365 acknowledged that climate change impact simulations are certainly affected by uncertainties in climate modeling, but also  
 the calibration strategy adopted during the reference period plays a, often dominant, role [Lepinas et al., 2014; Mizukami et  
 al., 2019]. In this respect, we believe that the preservation of statistical coherence between climate scenarios and  
 observations (i.e., high flow extremes in our case) should be taken into account directly during hydrological calibration, at  
 least in the reference period.

370 Figure 3: a) ECDFs of annual maximum daily streamflow at Trento gauging station in the period 1982-2010 obtained by using as  
 input the observational dataset ADIGE. Calibrations have been performed using NSE, RFDC and KS metrics, respectively.  
 Forward simulations using CLMcom, KNMI, and SMHI climate models as input are presented in panel b), c) and d), respectively,  
 375 for both RCP4.5 and RCP8.5 emission scenarios. The ECDF of observations is also shown with black dots together with the  
 associated 90% confidence interval (grey shaded area). p-values of the Kolmogorov-Smirnov two-sample test are also reported  
 within parenthesis for each simulation run.

Figures 3b), 3c) and 3d) evidence that for high quantiles the simulated ECDFs are often outside the 90% confidence interval of the observed ECDF for all the considered forward simulations. This is further highlighted in Figure 4, which shows the quantiles of annual maximum daily streamflow as a function of return period at the Trento gauging station. Following the procedure described in Section 2.5 extrapolations are performed under the assumption that the simulated ECDFs are distributed according to the parametric Gumbel probability distribution. All the adaptations to the simulated ECDFs passed the Pearson's chi-squared test. Confidence intervals of observed streamflow are derived from the parametric bootstrap procedure outlined in Sect. 2.5. Visual inspection of Figure 4 shows that for all investigated return periods parameterizations obtained by fitting the model to observed streamflow with meteorological data provided by the ADIGE dataset (i.e., NSE-ADIGE,  $R_{FDC}$ -ADIGE, KS-ADIGE) significantly underestimate the ECDF of annual maximum and fall outside the confidence interval of observations (i.e., outside the grey area). The only exceptions are curves derived from simulations conducted with KNMI (KS-ADIGE, dotted line in Figure 4c) and CLMcom (all the 3 metrics, Figure 4a) climate models under RCP4.5 pathway. We note however how these curves are obtained with forward simulations providing low p-values of the Kolmogorov-Smirnov test with respect to the other cases (always lower than  $p = 0.222$ ).

Quantiles obtained by calibrating the hydrological model with the meteorological input provided by the Climate Models and KS as metric are in a very good agreement with the experimental data, while those obtained by using  $R_{FDC}$  are outside or at the lower bound of the interval of confidence, though they generally are in a better agreement with the quantiles of the experimental data than those obtained with the aforementioned NSE-ADIGE,  $R_{FDC}$ -ADIGE, and KS-ADIGE parametrizations. Exceptions are represented by CLMcom and KNMI under RCP4.5 and  $R_{FDC}$  as metric that present the largest deviations from observations (see Figures 4a and 4c, respectively). We attribute this occurrence to the additional source of uncertainty arising from the extrapolation procedure (i.e., the selection of the probability distribution and of the statistical inference method for the parameters, MLE in our case). The interval of confidence (gray area) widens as the return period increases and this is line with the recent findings of Meresa and Romanowicz [2017], which showed that errors in fitting theoretical distribution models to annual extreme streamflow series might contribute significantly to the overall uncertainty associated to projections of future hydrological extremes.

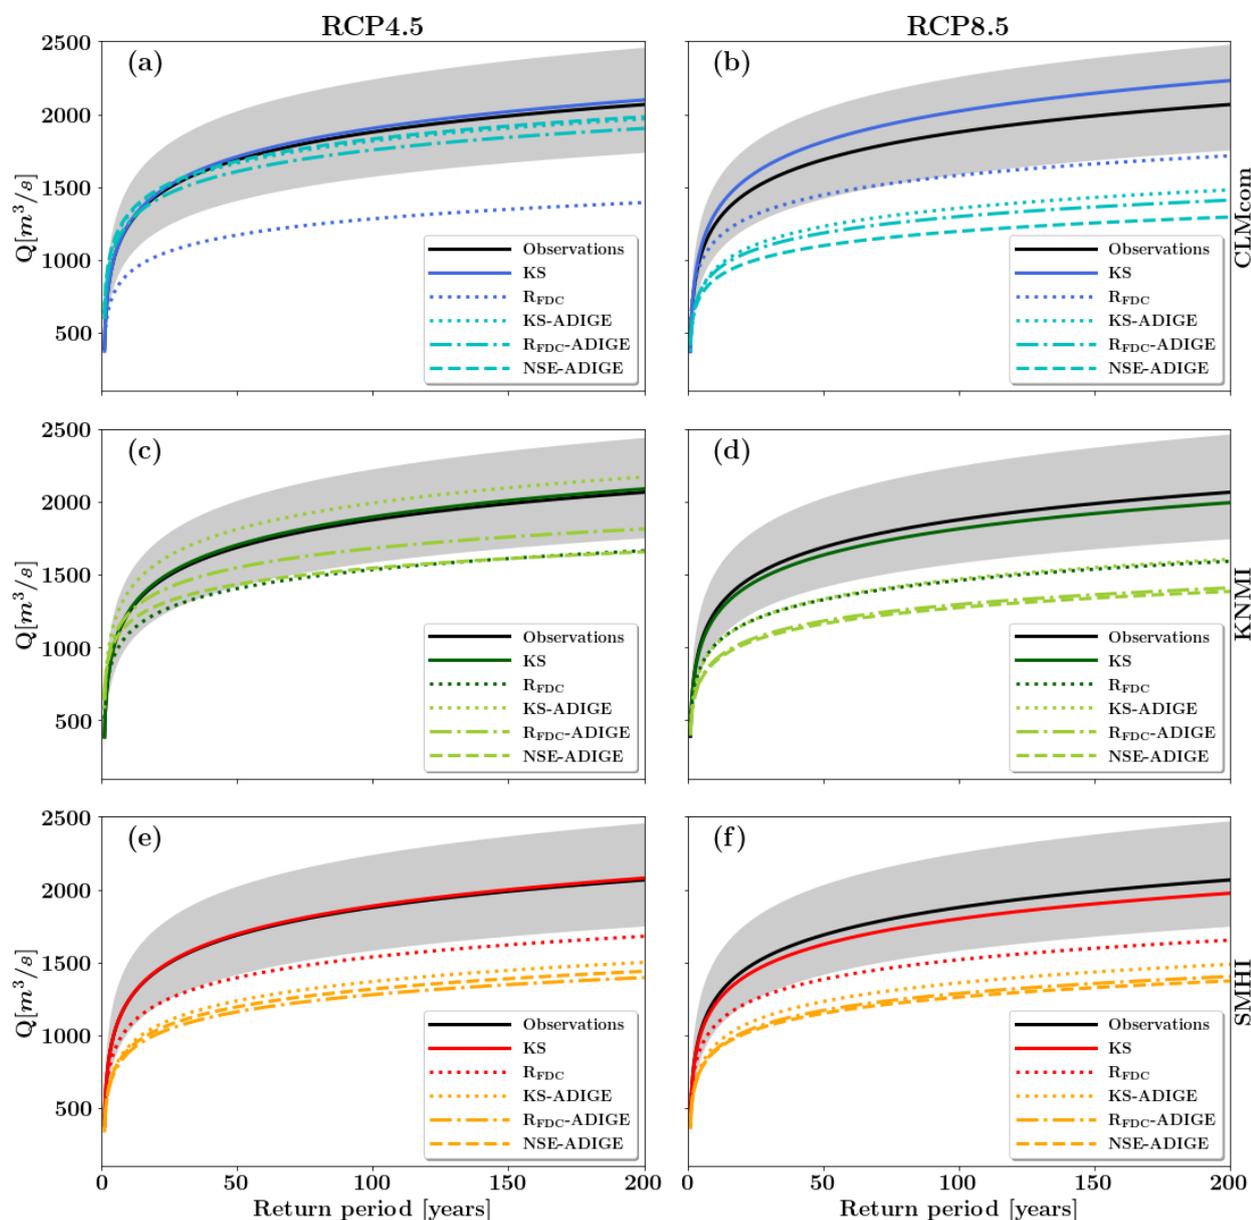

Figure 4: Quantiles of annual maximum daily streamflow as a function of return period at the Trento gauging station. Extrapolations are based on simulations conducted during the period 1982-2010 using as input forcing the CLMcom (first row), KNMI (second row), and SMHI (third row) climate models under the RCP4.5 (left) and RCP8.5 (right) emission scenarios, respectively. Each curve represents a combination of CM, emission scenario and parameterization obtained during the calibration. Forward simulations are labelled as NSE-ADIGE, RFDC-ADIGE and KS-ADIGE depending on the metric adopted during calibrations conducted using the observational dataset ADIGE as input forcing. Extrapolation from observed streamflow data is also shown (continuous black line) together with the associated 90% confidence interval (grey shaded area).

405

### 4.3 Model parameters

410 The results presented in the previous Sections highlight how the largest level of statistical coherence between observations and simulations (performed with CMs simulations as input) can be achieved only by optimizing the desired statistics of extremes (i.e., see the curves labeled KS in Figures 3 and 4) in the calibration of the hydrological model. Starting from this evidence, we investigated what is the effect on model parameters of performing the calibration by using different input data (observational data as well CMs simulations). The list of the 12 parameters of the model with their units together with a short description and range of variation is presented in Table 3. Notice that all the 12 parameters of HYPERStreamHS are calibrated. To simplify the comparison, we considered for the 3 CMs and for both emission scenarios only the calibrations performed by using the KS metric. In particular, for each calibration run we considered the 200 simulations (out of 40000 performed in total) presenting the highest efficiency. In addition, we considered the 100% confidence bands resulting from the retained solutions, and used the distance between the upper and lower limits of the confidence interval,  $\bar{d}$ , as a metric of uncertainty for the calibrated parameter [see Piccolroaz et al., 2015]. We remark that the procedure adopted here aims at

415

420

**Table 3: List of the calibration parameters with their units and ranges of variation.**

Model Component	Parameters	Description	Units	Range of variation
Snow model	$T_{snow}$	temperature threshold for snow precipitation	°C	-2 ÷ 6
	$T_{melt}$	temperature threshold for snow melting	°C	-2 ÷ 6
	$c_{melt}$	snow melting factor	$mm\ ^\circ C^{-1} d^{-1}$	0 ÷ 10
Continuous soil-moisture accounting SCS-CN based model	$c_s$	parameter of the rainfall excess model	-	0.1 ÷ 10
	$c_a$	parameter of the rainfall excess model	-	0.01 ÷ 1
	$q_{ref}$	parameter of the nonlinear bucket	$mm\ s^{-1}$	$10^{-7} \div 10^{-3}$
	$\mu$	parameter of the nonlinear bucket	$mm$	0.5 ÷ 300
	$c_{fc}$	coefficient for field capacity	-	0 ÷ 1
	$c_r$	coefficient for residual soil moisture	-	0 ÷ 0.25

<b>Base-flow model</b>	$k$	mean residence time for baseflow linear reservoir	$day$	$200 \div 1000$
	$\alpha$	partition coefficient for leakage flux	-	$0 \div 1$
<b>HYPERstream routing</b>	$v$	stream velocity	$m s^{-1}$	$0.2 \div 4.0$

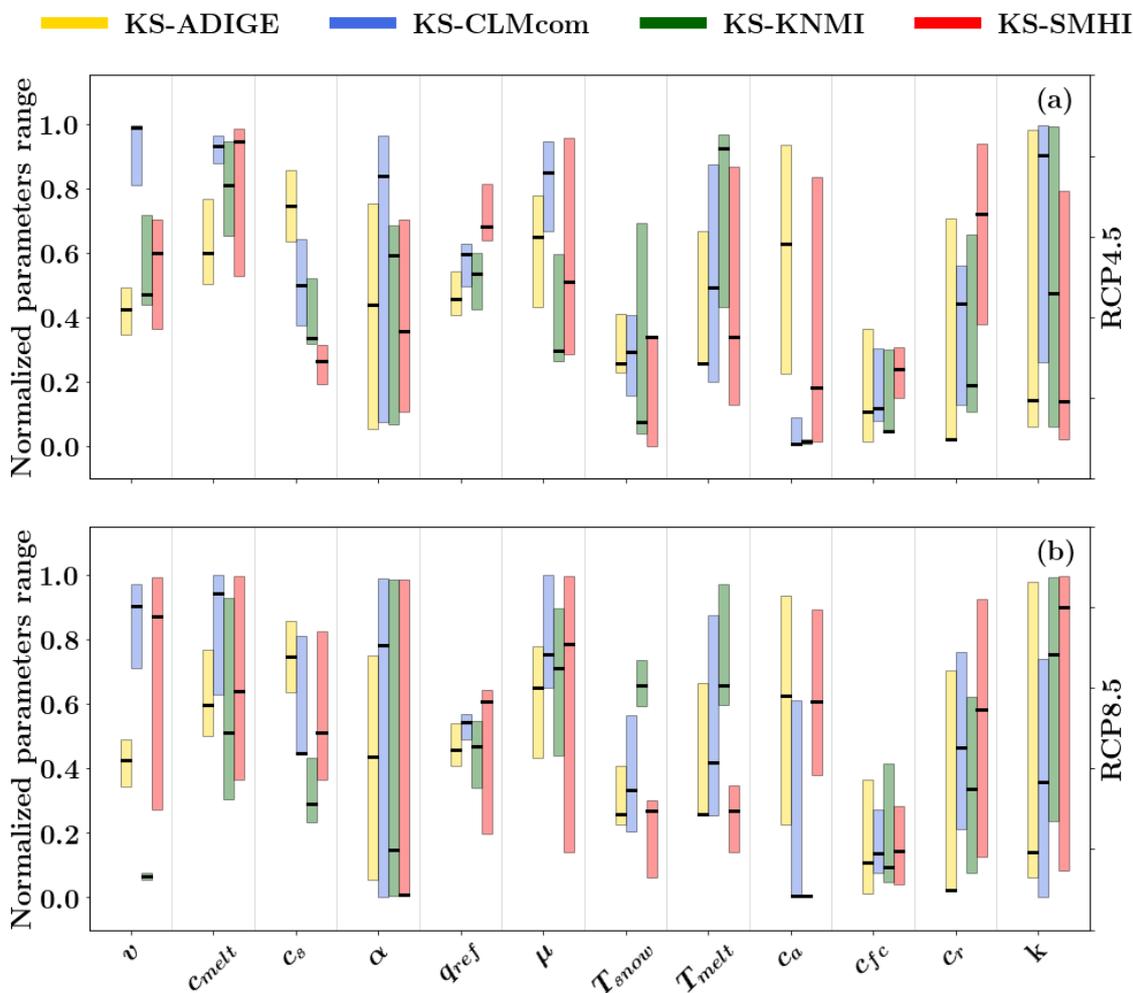

425 Figure 5 shows the range of variability of the parameters associated with the retained solutions together with the corresponding optimal parameter sets. The values of the parameters are normalized with respect to their range (see Table 3). The boundary of the parameters space has been set by means of preliminary simulations such as to minimize the probability of excluding from the search domain combinations of parameters leading to behavioral solutions [Beven and Binley, 1992]. Furthermore, we verified a-posteriori that the optimal parameters are inside the range of variation. In all cases, confidence

430 bands are generally well distributed between 0 and 1, indicating a proper choice of their range of variation, although for a few parameters optimality was located close to the boundary of the search domain. As shown in Figure 5 the majority of the parameters have a confidence band that is similar (or slightly larger) to that obtained in the case of KS-ADIGE, thus supporting the conclusion that calibration using CMs simulations does not lead, for both RCP, to anomalous identification of model parameters. Figure 5 also shows that for most of the parameters, simulations performed with CMs lead to generally

435 overlapping confidence bands with respect to the case in which the observational dataset ADIGE is used. The largest deviations in terms of confidence bands are observed for KS-KNMI, particularly under RCP8.5. Notably, the parameters shaping the continuous soil-moisture accounting module result in values of the optimum which are very similar (see  $q_{ref}$ ,  $\mu$ , and  $c_{fc}$  in Figures 5a and 5b). Notwithstanding, this analysis evidences the possibility to identify to what degree each parameter is sensitive to the adoption of a different input in the calibration procedure.

440 The differences observed in the optimal value of model parameters are due to structural errors in the GCMs and RCMs (i.e., their different capabilities to simulate the present climate), which are a substantial source of uncertainty in the impact assessment modeling chain [Honti et al., 2014; Tian et al, 2016]. Along the concepts brought forward here, this source of uncertainty can be addressed effectively by calibration of the hydrological model to the quantities of interest (i.e. the observed streamflow statistics of extremes) using as input the forcing provided by a specific GCM-RCM combination. This

445 approach can be seen as a “hydrologic-based bias-correction” and is rooted in the adoption of a “goal-oriented” calibration framework [see e.g., Laiti et al., 2018] along the lines stated in the Introduction. Furthermore, our approach provides an answer to the need of reducing uncertainty in climate change impact assessments recently highlighted in the review by Clark et al. [2016].

450 **Figure 5: Normalized parameters range obtained by retaining the 200 simulations presenting the highest efficiency. Calibrations are conducted for the 3 different CMs under (a) RCP4.5 and (b) RCP8.5 emission scenarios with reference to the KS metric. Marked dashes indicate the optimal parameter sets for all experiments. See Table 3 for the description of parameters and their ranges.**

#### 4.4 Projected changes of streamflow quantiles

455 Here we evaluate projected changes of high flow extremes in the future period 2040-2070. Notice that, similar to the reference period, the first two years of simulations (i.e., 2040 and 2041) have been used as a spin-up period. Figure 6 presents the annual maximum streamflow as a function of return period at Trento gauging station for the 3 considered CMs under both RCP4.5 and RCP8.5 emission scenarios. As customary, extrapolations are performed under the assumption that the simulated ECDFs are distributed according to a parametric Gumbel probability distribution and the comparison is presented only for the optimal solution obtained during calibration. For each CM we considered the following

460

parameterizations referred to the reference period: direct calibration with KS and  $R_{FDC}$  metrics, and NSE-ADIGE as representative of a standard calibration procedure.

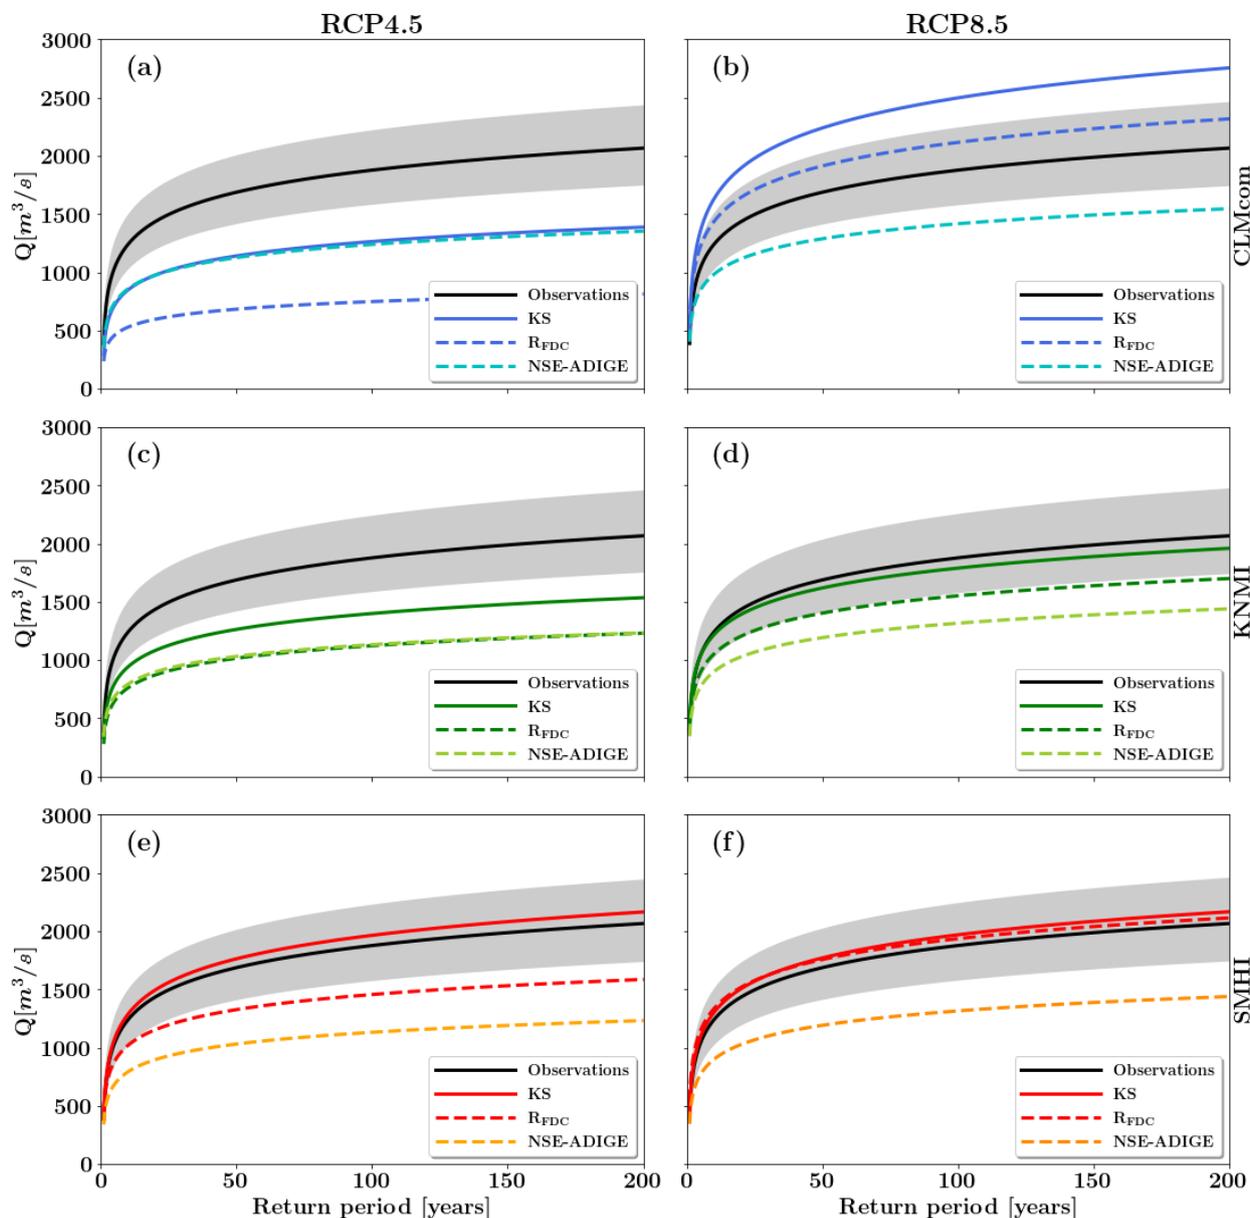

Visual inspection of Figure 6 confirms that using the standard calibration (i.e., NSE-ADIGE) of the hydrological model leads to a significant underestimation of all quantiles with respect to using KS and  $R_{FDC}$  for all the 3 considered CMs under both

465 RCPs. This is in agreement with the results obtained for the reference period (see Figure 4), where simulations using NSE-ADIGE parameterization provided streamflow quantiles systematically lower than with the CMs. In addition, KS-based calibrations always provide larger streamflow quantiles with respect to the cases in which the  $R_{FDC}$  metric is considered (considering the same RCP emission scenario). We remark how the adoption of the KS metric is preferable since it provided an almost perfect match with observed streamflow quantiles in the calibration period (see Figure 4).

470 Figure 6 shows that projected changes of high flows extremes depend on the selected CM and emission scenario. Projected streamflow quantiles under RCP8.5 emission scenario are larger than those under RCP4.5 for all the CMs. In general, the projected streamflow quantiles do not exceed the extrapolations from observations in the period 1982-2010 (black lines in Figure 6), with the exceptions of CLMcom and SMHI models under RCP8.5 and SMHI under RCP4.5 when KS metric is adopted. These results are in line with other recent contributions which concluded that the sign and magnitude of projected

475 changes of high flow extremes vary significantly with the location of the investigated river basin, the climate models used, emission scenario as well as the selection of the investigated time window [Ngongondo et al., 2013; Aich et al., 2016; Pechlivanidis et al., 2017; Vetter et al., 2017]. Similar results were also found by Brunner et al. [2019] who implemented a stochastic framework to simulate future streamflow time series in 19 regions of Switzerland, and concluded that future shifts in maximum streamflow will increase and decrease in rainfall-dominated and melt-dominated regions, respectively. In

480 agreement with our results, Di Sante et al. [2019] also showed that a moderate increase in high flow magnitude (return time of 100 years) is projected for large river basin (drained area  $>10.000 \text{ km}^2$ ) in the Central Europe region under RCP8.5 and considering a mid-century time slice.

485 **Figure 6: Quantiles of annual maximum daily streamflow as a function of return period at Trento gauging station. Projections are based on simulations conducted during the future time period 2042-2070 using as input the CLMcom (first row), KNMI (second row), and SMHI (third row) climate models under the RCP4.5 (left) and RCP8.5 (right) emission scenarios, respectively. Black line denotes the extrapolation of observational data in the period 1982-2010.**

## 5 Conclusions

490 We investigated different strategies for the calibration of hydrological models to be used in assessing projections of hydrological high flows in light of climate change. In particular, we proposed a methodological framework in which the calibration of the hydrological model is carried out by optimizing the reproduction of the probability distribution of high flows extremes. The methodology, coined here as Hydrological Calibration on eXtremes (HyCoX), is such that the hydrological simulations conducted during a reference period, as driven by climate model outputs, are constrained to  
495 maximize the probability that the modeled and observed extreme streamflows belong to the same population. The proposed framework is “goal-oriented” and aims at reducing the uncertainty associated to the estimation of extremes by directly calibrating the selected hydrological model to the quantities of interest (i.e. flow statistics instead of time series) using as input directly the meteorological data (precipitations and temperature in the case at hand) provided by the Climate Model (CM). This approach ensures statistical coherence between scenarios and observations during the reference period, and,  
500 likely, preserves it in the future climate change scenario runs performed with the aim of projecting changes in streamflow extremes.

The proposed procedure is exemplified through application of a few climate models and observational data to the analysis of annual maximum streamflow of the Adige river at the Ponte San Lorenzo gauging station in Trento (Italy). Though the nature of the present work is inherently methodological, it is worth mentioning that the application of the framework over a  
505 statistically-sized number of watersheds is currently ongoing in order to demonstrate method’s generality. The hydrological model employed is HYPERstreamHS, a continuous simulation distributed model. Three performance metrics were adopted, including the proposed one, for which the Kolmogorov-Smirnov two-sample statistical test was employed (KS for brevity). We remark that the HyCoX methodology is not metric dependent, and any type of metric assessing the statistical coherence between observed and simulated streamflow extremes could have been employed without any loss of generality.

510 The results highlight that adopting KS is preferable to other popular metrics (e.g. Nash-Sutcliffe or fit to Flow Duration Curve) when dealing with high flow extremes. This result validates our hypothesis that targeting directly the statistics of extreme values under consideration during the calibration exercise leads to coherent and consistent hydrological models for addressing the impact of climate change. We remark that such approach may lead to a suboptimal performance if the target is different from the one employed in this study, limitation that is outweighed by the improvements in representing high flow  
515 extremes in line with the goal-oriented framework pursued in this work.

In addition, our analysis revealed that using CMs simulations as input of the hydrological model, and adopting the parameterizations derived from calibration against historical time series, is an error prone procedure. Nowadays, it is generally acknowledged that the uncertainties arising at the different steps of the hydrological-climatological modeling chain can cause a significant divergence in the statistics of extremes. However, it appears crucial that the simulated effects on  
520 projected extremes in a climate change impact assessment can be safely attributed to the change in climate alone, and not to

uncertainties arising from the selection of the efficiency metric in the calibration process. Finally, investigation of optimal values highlighted that direct calibration using CMs outputs lead to unbiased identification of model parameters.

In climate change impact assessments on streamflow extremes the way the hydrological model is calibrated against observations assumes paramount importance. In the present work we showed that calibrating on daily streamflow observations by using observed meteorological data is an error prone procedure when the objective is to project the probability distribution of streamflow extremes by using climate models. Streamflow quantiles are dramatically underestimated and fall outside the confidence interval of the quantiles of observed annual maxima when applied to the observation period. Extrapolations performed by using the proposed calibration procedure, with input provided by CMs, are instead more consistent and provide a good match with observed quantiles.

The goal-oriented approach envisaged in this work can be applied to a variety of hydrological scenario and modeling approaches. While the approach is exemplified here for high flows, it can be applied to low flows as well (e.g. for drought assessment). In any case, it is advisable to calculate the uncertainty band for both the simulation model and the ECDF from observations.
