12 **Abstract.**

13
14 Extensive efforts over decades have focused on quantifying chemical transport in subsurface
15 geological formations, from microfluidic laboratory cells to aquifer field scales. Outcomes of
16 ~~resulting models~~ ~~these efforts~~ have remained largely unsatisfactory, however, largely because
17 domain heterogeneity – ~~(characterized for example by~~ ~~in terms of, e.g.~~ porosity, hydraulic
18 conductivity, ~~and~~ geochemical properties ~~)~~ is present over multiple length scales, and
19 “unresolved”, practically unmeasurable heterogeneities and preferential pathways arise at virtually
20 every scale. While *spatial* averaging approaches are effective when considering overall fluid flow,
21 ~~—wherein pressure propagation is essentially instantaneous,~~ ~~and the system is “well-mixed”~~
22 purely *spatial* averaging approaches are far less effective for chemical transport, essentially
23 because well-mixed conditions do not prevail. We assert here that an explicit accounting of
24 *temporal* information, under uncertainty, is an additional, but *fundamental*, component in an
25 effective modeling formulation. As an outcome, we further assert that “upscaling” of chemical
26 transport equations – in the sense of attempting to develop and apply chemical transport equations
27 at large ~~(length)~~ scales, based on measurements and model parameter values obtained at
28 significantly smaller length scales – ~~can be considered~~ ~~is very much an~~ ~~unattainable~~ “holy grail”.
29 Rather, we maintain that it is necessary to formulate, calibrate and apply models using
30 measurements at similar scales of interest, ~~in both space and time.~~

33 1 Introduction

34

35 1.1 Background

36

37 There have been extensive efforts over the last ~60 years to model and otherwise quantify fluid
38 flow and chemical (contaminant) transport in soils ~~layers~~ and subsurface geological formations,
39 from millimeter-size, laboratory microfluidics cells to aquifer field scales extending to hundreds
40 of meters and even tens of kilometers.

41 Soils ~~layers~~ and subsurface formations ~~can~~ typically exhibit significant heterogeneity, in terms
42 of domain characteristics such as porosity, hydraulic conductivity, structure, and biogeochemical
43 properties (mineral and organic matter content). However, only more recently has it become
44 broadly accepted ~~recognition~~ that effects of heterogeneity over multiple length scales, with
45 “unresolved”, practically unmeasurable heterogeneities arising at every length scale (from pore to
46 field), cannot be simply “averaged out”, ~~has become broadly accepted only more recently~~. Indeed,
47 much research on flow and transport in porous media, dating since ~~particularly from~~ ~1950–1990,
48 ~~but also essentially to date~~, has been based on the search for length scales at which one can define
49 a “representative elementary volume”, or otherwise-named “averaging volume”, above which
50 variability in fluid and chemical properties become constant. In this context, too, many varieties
51 of homogenization, volume averaging, effective medium, and stochastic continuum theories have
52 been developed in an extensive literature. These methods allowed formulation of continuum-scale,
53 generally Eulerian, partial differential equations to quantify (“model”) fluid flow and chemical
54 transport, which were then applied in the soil and groundwater literature at length scales ranging
55 from millimeters to full aquifers. While originally deterministic in character, a variety of stochastic
56 formulations, and ~~use of~~ Monte Carlo numerical simulation techniques, introduced from the 1980s,
57 enabled analysis of uncertainties in input parameters such as hydraulic conductivity.

58 However, while analysis of fluid flow using these methods has proven relatively effective,
59 ~~modeling quantification~~ of chemical transport, and an accounting of associated (biogeo)chemical
60 reactions in cases of reactive chemical species and/or host porous media, has revealed serious
61 limitations ~~remained largely unsatisfactory~~. We discuss the reasons for this, ~~in detail~~, in the sections
62 below. Briefly, the overarching reason for these successes and failures is that *spatial* averaging
63 approaches are effective when considering overall fluid flow rates and quantities; ~~—wherein~~
64 pressure propagation is essentially instantaneous and the system is “well mixed” (because mixing
65 of water “parcels” is functionally irrelevant). However, purely *spatial* averaging approaches are
66 far less effective for chemical transport, essentially because well-mixed conditions do not prevail,
67 and spatial averaging is inadequate; here, an explicit, additional accounting of *temporal* effects is
68 required.

69 The focus of the current contribution is on modeling conservative chemical transport in
70 geological media. In terms of modeling, one can delineate two main types of scenarios: (i) *pore-*
71 *scale modeling* in relatively small domains, with a detailed (and specified) pore structure, and (ii)
72 *continuum-scale modeling* in porous media domains, that average pore space and solid phases at

73 scales from laboratory flow cells to field-scale plots and aquifers. Case (i) requires, e.g., Navier-
74 Stokes or Stokes equations solutions for the underlying flow field, coupled with solution of a local
75 (e.g. advection-*diffusion*) equation for transport, while ~~c~~Case (ii) requires Darcy (or related)
76 equation solutions for the underlying flow field, coupled with solution of a governing transport
77 equation for chemical transport. *Note:* here and throughout, we shall use the terms “*continuum*
78 *level*” and “*continuum scale*” in reference to case (ii) scenarios, and “*pore-scale*” to refer to ~~c~~Case
79 (i) scenarios, although we recognize, ~~too~~, that pore-scale Navier-Stokes and advection-diffusion
80 equations, too, are continuum partial differential equations.

81
82 ***Disclaimer:*** Here and throughout this contribution, the overview comments and references to
83 existing philosophies, methodologies and interpretations are written, ~~largely, mostly~~ in broad
84 terms, without only (~~necessarily limited numbers of~~) citations selected from the vast literature.
85 This approach is taken with a clear recognition and respect for the extensive body of literature that
86 has driven our field forward over the last decades, but with the express desire to avoid any risk of
87 unintentionally alienating colleagues and/or misrepresenting aspects of relevant studies. *As an*
88 *Opinion contribution, and with length considerations in mind, there is no attempt to provide an*
89 *exhaustive listing and description of relevant literature.*

90 91 92 **1.2 Assertions**

93
94 The pioneering paper of Gelhar and Axness (1983) focused on quantifying conservative chemical
95 transport at the continuum level. They expressed heterogeneity-induced chemical spreading in
96 terms of the (longitudinal) macrodispersion coefficient – as it appears in the classical
97 (macroscopically 1d) advection-dispersion equation – with knowledge of the variance and
98 correlation length of the log-hydraulic conductivity field and the mean, ensemble-averaged fluid
99 velocity. The conceptual approach embodied in Gelhar and Axness (1983) – and by many
100 researchers since then (as well as previously) – was founded on delineation of the *spatial*
101 *distribution* of the hydraulic conductivity, and application of an averaging method to determine
102 the yield a governing transport equation with “effective parameters” ~~that~~ describes chemical
103 transport at a given length scale (e.g. Dagan, 1989; Gelhar, 1993; Dagan and Neuman, 1997).

104 In contrast, we assert here that *spatial* information, *alone*, is generally *insufficient* for
105 quantification of chemical transport phenomena. Rather, *temporal* information is an additional,
106 but *fundamental*, component in an effective modeling formulation. In the discussion below, we
107 shall justify this argument by a series of examples. We examine (i) *spatial* information on, e.g. the
108 hydraulic conductivity distribution at the continuum level, or distribution of the solid phase at the
109 pore-scale level; and (ii) *temporal* information on, e.g. contaminant (tracer, “particle”) transport
110 mobility and retention in different regions of a domain. We thus define a type of “information
111 hierarchy”, with different types of information required for different flow and chemical transport
112 problems of interest.

113 As an outcome of the above assertion and the discussion below, we further assert that

114 “upscaling” of chemical transport equations – development and application of chemical transport
115 equations at large (length) scales, with corresponding parameter values, based on measurements
116 and model parameter values obtained at significantly smaller length scales – ~~can be considered an~~
117 ~~unattainable~~ ~~is very much a~~ “holy grail”. Rather, we maintain that it is necessary to formulate ~~and,~~
118 calibrate ~~models,~~ and ~~then~~ apply ~~them~~ ~~models,~~ ~~using measurements over spatial scales with~~
119 ~~relatively similar orders of magnitude~~ ~~in both space and time.~~ This does not exclude use of similar
120 equation *formulations* at different spatial scales, but it does entail use of different parameter values,
121 at the relevant scale of interest, that cannot be determined *a priori* or from purely spatial or flow-
122 only measurements.

123
124

125 1.3 Approach – Outline

126

127 While our focus is on chemical transport, knowledge of fluid flow and delineation of the velocity
128 field throughout the domain is a prerequisite. We therefore first discuss fluid flow as an intrinsic
129 element *aspect* of the “information hierarchy”. Specifically, we address how:

130 (1) Basic structural information on “conducting elements” in a system representing a ~~porous~~
131 ~~and/or fractured~~ geological domain ~~(porous and/or fractured)~~ can provide ~~basic~~ insight
132 regarding overall fluid conduction in the domain, as a function of “conducting element”
133 density. We emphasize that without direct simulation of fluid flow ~~(as well as chemical~~
134 ~~transport)~~ in such a system, this type of analysis ~~is insufficient in terms of~~ ~~does not~~
135 ~~defining/delineate~~ the actual flow field and velocity distributions throughout the domain.

136 (2) Spatial information on, ~~in particular,~~ the hydraulic conductivity distribution at a continuum
137 scale, or solid phase distribution at the pore scale, throughout the domain, can be used to
138 *determine the flow field*. We then show that this is insufficient ~~in terms of~~ ~~to~~ ~~defining~~
139 chemical transport.

140 (3) Temporal information on chemical species migration, which quantifies distributions of
141 retention and release times (or rates) of chemicals by advective-dispersive-diffusive and/or
142 chemical mechanisms, can be used to *determine the full spatial and temporal evolution of*
143 *a migrating chemical plume*, either by solution of a transport equation or use of particle
144 tracking on the velocity field.

145 We comment, parenthetically, that in conceptual-philosophical terms, this hierarchy and the
146 “limitations” of each level are in a sense analogous to representation of geometrical constructs in
147 multiple dimensions: in principle, one can represent, as a *projection*, a d-dimensional object in d–
148 1 dimensions. But of course, by its very nature, a *projection* does not capture all features of the
149 construct in its “full” dimension. To illustrate, an ~~(imaginary)~~ 1d curve can represent a 2d Möbius
150 strip, a 2d perspective drawing can represent a 3d cube, and a 3d construct can represent a 4d object
151 (where the 4th dimension might be ~~considered~~ time) — and yet, none of these d–1 dimensional
152 representations contains all features of the actual d-dimensional objects. Similarly, despite our
153 frequent attempts to the contrary, one cannot properly describe (2) only from (1), or (3) only from

154 (2).

155

156

157 2 Fluid flow

158

159 ~~Prior to actually solving for fluid flow, to determine the underlying velocity field, efforts are~~
160 ~~sometimes invested in considering geometrical (structural) information, for example, when~~
161 ~~examining fracture networks in essentially impermeable host rock. Analysis of the geometry of~~
162 ~~structural elements in a domain can yield basic insights on fluid flow patterns. This approach is~~
163 ~~used, for example, when examining fracture networks in essentially impermeable host rock. As~~
164 ~~discussed below, however, full delineation of the underlying velocity field ultimately requires~~
165 ~~solution of equations for fluid flow.~~

166 In this context, percolation theory (Stauffer and Aharony, 1994) is particularly useful in
167 determining, statistically, whether or not a domain with N “conducting elements” (e.g. fractures)
168 ~~is~~ includes sufficient element density to form a connected pathway enabling fluid flow across the
169 domain. One can estimate, ~~for example in this context~~, the critical value, N_c , for which the domain
170 is “just” connected, as a function of fracture length distribution, or the critical average fracture
171 length as a function of N needed to reach domain connectivity (Berkowitz, 1995). Similarly,
172 percolation theory shows how the overall hydraulic conductivity of the domain scales as the
173 number of conducting elements, N , relative to the N_c critical number of conducting elements
174 required for the system to begin to conduct fluid. Percolation theory also addresses diffusivity
175 scaling behavior of chemical species. But, fundamentally, percolation is a statistical framework
176 suitable for large (“infinite”) domains, and provides universal scaling behaviors with no coefficient
177 of equality; ~~see e.g., Sahimi (2021) for detailed discussion.~~

178 Other approaches have been advanced to analyze domain connectivity, for example using
179 graph theory and concepts of identification of paths of least resistance in porous medium domains
180 (e.g. Rizzo and de Barros, 2017), ~~or topological methods (e.g. Sanderson and Nixon, 2015).~~ Like
181 percolation theory, such approaches provide useful information and “estimates” on the hydraulic
182 connectivity and flow field, and even on first arrival times of chemical species, without solving
183 equations for fluid flow and chemical transport. However, these methods do not provide full
184 delineation of the flow field and velocity distribution throughout a domain.

185 ~~These considerations indicate it is thus clear~~ that, in general, ~~there are~~ dynamic aspects of fluid
186 flow ~~are critical, over and above pure structure~~: knowledge of pure geometry is not sufficient, and
187 ~~we must actually solve for the flow field~~, at either the pore-scale or a continuum scale, to determine
188 the velocity field and actual flow paths throughout the domain. Delineation of a flow field and
189 velocity distribution by solution of the Navier-Stokes equations (or Stokes equation for small
190 Reynolds numbers), or by solution of the Darcy equation, may be considered “rigorous”, correct
191 and effective. But in the process of solving for the flow field, two *key* features arise, one more
192 relevant to pore-scale analyses, and the other more relevant to continuum-scale analysis, as
193 detailed in Sect. 2.1 and Sect. 2.2, respectively.

2.1 Pore-scale flow field analysis

Why is knowledge only of the geometrical “static” structure (spatial distribution of solid phase) insufficient to know the flow dynamics in a pore-scale domain? Consider the 2d domain shown in Figure 1, containing sparsely and randomly distributed obstacles (porosity of 0.9). Figure 1 shows solutions of the Navier-Stokes equations for two Reynolds number (Re) values. [Recall: $Re \equiv \rho v L / \mu$, where ρ and μ are density and dynamic viscosity of the fluid, respectively, v is fluid velocity, and L is a characteristic linear dimension. Here and throughout, the fluid is assumed to have constant viscosity.] Andrade et al. (1999) showed clearly that well-defined preferential flow channels at lower Re, while at higher Re, channeling is less intense and the streamline distribution is more spatially homogeneous in the direction orthogonal to the main flow. The domain shown in Fig. 1 is not intended to represent a natural geological domain, but rather to illustrate streamline behavior in even relatively simple pore-scale geometries.

Figure 1 demonstrates that the streamlines in individual pores change because of the interplay between inertial and viscous forces, given by Re. In other words, with a change in overall fluid velocity (or hydraulic gradient) across the domain, the actual flow paths can be altered, together with a change in overall and (spatially) local residence times of fluid molecules; the same factors also govern (and chemical species, as addressed below). Of course, the significantly lower porosities and more tortuous pore space configuration in natural, heterogeneous geological porous media may affect the impact of inertial effects, especially at the pore scale, but the principle remains relevant. [We note, too, parenthetically, that the behavior shown in Fig. 1 is relevant also to fluid flow within fracture planes, wherein the obstacles represent contact areas and regions of variable aperture.]

Clearly, then, except in highly idealized and simplified geometries, use of a purely analytical solution to identify the full velocity field and streamline patterns at the pore scale is not feasible. Moreover, the extent and changes in streamlines are not intuitively obvious without full numerical solution of the governing flow equations, for any specific set of porous medium structures and boundary conditions.

(a) $Re = 0.0156$

(b) $Re = 15.6$

Figure 1. 2d domain containing randomly distributed obstacles (squares and rectangles). Stream functions for (a) $Re = 0.0156$ and (b) $Re = 15.6$ are shown with constant increments between consecutive streamlines (modified from Andrade et al., 1999, <https://doi.org/10.1103/PhysRevLett.82.5249>; Copyright, American Physical Society). The different patterns of preferential pathways are clear and distinct. The three pairs of circles (red, blue, black) highlight three (of many) specific locations where the streamlines are seen to change as a function of Re .

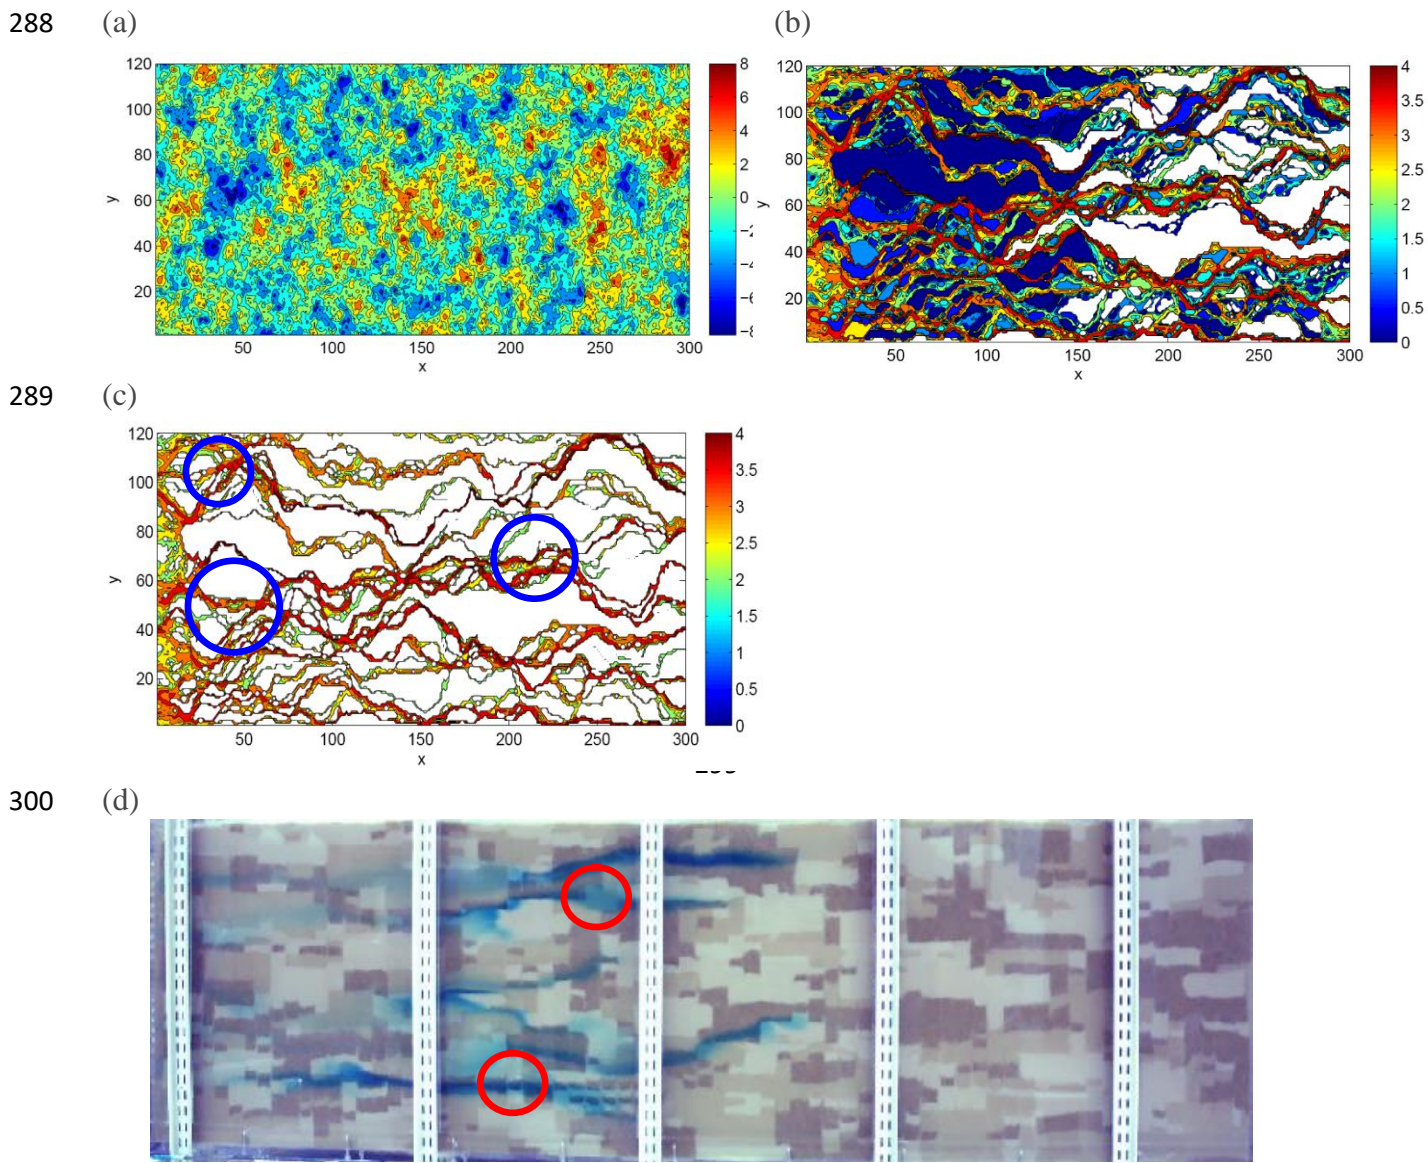

2.2 Continuum-scale flow field analysis

Considering now continuum-scale domains, but in analogy to the example shown in Sect. 2.1, we illustrate why knowledge only of the geometrical “static” structure (~~spatial distribution of the hydraulic conductivity~~) is insufficient to know the flow dynamics, without solution of the Darcy equation. Here, the geometrical structure refers to the spatial distribution of the hydraulic conductivity, K .

Figure 2 represents a realization of a numerically-generated (statistically homogeneous, isotropic, Gaussian) hydraulic conductivity (~~K~~) 2d domain. The Darcy equation solution for this domain yields values of hydraulic head throughout the domain; these are converted to local velocities, to enable delineation of the streamlines and preferential flow paths. The latter are highlighted by actually solving for chemical transport, by following the migration of “particles” representative of masses of dissolved chemical species injected along the inlet boundary of the flow domain; see Edery et al. (2014) for details. Of particular significance is that 99.9% of the injected particles travel in preferential pathways through a limited number of domain cells. We return to Figure 2 in Sect. 3.3.2, where we discuss a framework that effectively characterizes and quantifies chemical transport.

Unlike the pore-scale case shown in Sect. 2.1, at the Darcy/continuum scale, streamlines are not altered with changes in the overall hydraulic gradient, as long as laminar flow conditions are maintained. And yet, preferential flow paths are (possibly surprisingly) sparse and ramified, sampling only limited regions of a given heterogeneous domain, with the vast fraction of a migrating chemical species that interrogates the domain being even more limited. Significantly, except in highly idealized and simplified geometries (~~e.g. homogeneous media~~), delineation of these pathways is not intuitively obvious (e.g. by simple inspection of the hydraulic conductivity map in Fig. 2a) or definable from a priori analysis or tractable analytical solution. Rather, numerical solution of the governing flow equations is required, for any particular/specific set of porous medium structures and boundary conditions. [Note, too, that critical path analysis from percolation theory (discussed in Sect. 2) – again from purely “static” information without solution of the flow field – yields an incorrect interpretation, as shown in detail by Edery et al. (2014).]

278 We emphasize that the delineation of “preferential flow paths” is usually relevant only for
 279 study of chemical transport; if water *quantity*, alone, is the focus, then specific “flow paths”
 280 travelled by water molecules – and their advective and diffusive migration along and between
 281 streamlines, and into/out of less mobile regions – are of little practical interest. On the other hand,
 282 ~~†~~The movement of chemical species, ~~on the other hand,~~ which experience similar advective and
 283 diffusive, ~~and thus “dispersive”,~~ transfers, must be monitored closely to be able to quantify overall
 284 migration through a domain. We return to consider patterns of chemical migration in Sect. 3. ~~But~~
 285 ~~†~~This argument, too, reinforces the assertion that delineation of actual chemical transport cannot
 286 be deduced purely from spatial information and solution for fluid flow, but must be treated by
 287 solution of a transport equation.

311

312 **Figure 2.** Maps of (a) hydraulic conductivity, K , distribution in a domain with 300×120 cells, (b)
 313 preferential pathways for fluid flow (and chemical transport), and (c) preferential pathways through cells
 314 that each contain a visitation of at least 0.1% of the total number of chemical species particles injected into

315 the domain (flux-weighted, along the entire inlet boundary). Flow is from left to right. Note that the color
316 bars are in $\ln(K)$ scale for Figure 2a, and \log_{10} number of particles for Figures 2b,c (modified from Ederly
317 et al., 2014; © with permission from the American Geophysical Union 2014). (d) Laboratory flow cell, 2.13
318 m length, with an exponentially correlated K structure, showing preferential pathways for blue dye injected
319 near the inlet (flow is left to right); dark, medium, and light colored sands represent high, medium and low
320 conductivity, respectively (modified from Levy and Berkowitz, 2003; © with permission from Elsevier
321 2003). The circles shown in (c) and (d) highlight two (of many) regions in which the pathways are seen to
322 contain lower K “bottlenecks”.

323
324 It is significant, too, that fluid flow (and chemical transport) occurs in preferential pathways
325 that contain low conductivity sections (indicated by circles in Figs. 2c,d). How do we explain
326 passage through low hydraulic conductivity “bottlenecks” ~~(low hydraulic conductivity patches)~~
327 within the preferential pathways, rather than and that fluid (and chemicals) do not
328 migratemigration “only” through the highest conductivity patches?

329 To address this question, we ~~begin by first~~ considering what happens in a 1d path. Consider
330 two paths, each containing a series of five porous medium elements (or blocks), with distinct
331 hydraulic conductivity values, (K_i)-values. Consider Path 1, with a series hydraulic conductivity
332 values of 3, 3, 3, 3, 3, and Path 2, with values 6, 6, 1, 6, 6 (specific length/time units are irrelevant
333 here). The value of $K = 1$ represents a clear “bottleneck” in an otherwise higher K path than that
334 of Path 1. In a 1d series, however, the overall hydraulic conductivity (K_{overall}) of the path is given
335 by the harmonic mean of the conductivities of the elements comprising the path: $K_{\text{overall}} = 5 / (\sum_{i=1,5} 1/K_i)$;
336 significantly, in the two cases here, both paths have $K_{\text{overall}} = 3$. So a “bottleneck” ($K=1$)
337 can be “overcome” and does not cause necessarily eause a potential pathway to be less “desirable”
338 than a pathway without such “bottlenecks”. In other words, flow through pathways containing
339 some low K regions should be expected. Of course, in 2d and 3d systems, patterns of heterogeneity
340 and pathway “selection” by water/chemicals are significantly more “complicated”, but the
341 principle discussed here for 1d systems still holds, in the sense that lower hydraulic conductivity
342 (“bottleneck”) elements can (and do) exist in the preferential pathways (e.g. Margolin et al., 1998;
343 Bianchi et al., 2011).

344
345

346 **3 Chemical transport**

347

348 We now consider the next level of the “information hierarchy” outlined in Sect. 1.3. To quantify
349 the evolution of a migrating chemical plume, knowledge of the flow field is not generally
350 sufficient, and additional means to characterize and quantify the behavior are needed. Dynamic
351 aspects of chemical transport require us to think (also) in terms of *time*, not just *space* and physical
352 structure. Moreover, it is generally insufficient to determine the transport of the chemical plume
353 center of mass. Rather, in terms of water resource contamination and remediation, for example, it
354 is critical to characterize, respectively, the early and late arrival times at compliance (or
355 monitoring) regions downstream of the region (point, areal, or volumetric) region in which the
356 chemical species entered the system.

357 As we show below, it becomes clear that, ~~in general,~~ there are dynamic aspects of chemical
358 transport, ~~on~~ over and above the role of the flow field; ~~and we must actually solve for chemical~~
359 *transport*, at either the pore-scale or a continuum scale, to determine the ~~spatiotemporal~~ (spatial
360 plume and/or temporal breakthrough curve) evolution of the migrating chemical plume. In *both*
361 pore-scale and continuum-scale domains, the *critical* control that arises is that of time, ~~(in addition~~
362 ~~to space)~~. This is in sharp contrast to fluid flow at pore and continuum scales, as shown in Sect.
363 2.1 and Sect. 2.2: pore-scale fluid flow displays changing streamlines with changes in hydraulic
364 gradient, while continuum-scale fluid flow follows distinct but difficult to identify preferential
365 flow paths essentially independent of the hydraulic gradient.

366 We point out, too, that for both pore-scale and continuum-level scenarios, one can solve;
367 explicitly; a governing equation for transport. Alternatively, ~~though,~~ one can obtain an
368 “equivalent” solution by solving for (~~Lagrangian framework~~) “particle tracking” of transport along
369 the calculated streamlines, in a Lagrangian framework. In other words, particle tracking methods
370 essentially represent an alternative means to solve an ~~((integro-)partial differential)~~ equation for
371 chemical transport; such methods can be applied, too, when the precise partial differential equation
372 is unknown or the subject of debate. We also note that solution of the relevant equations for fluid
373 flow and chemical transport is sometimes achieved by (semi-)analytical methods, if the
374 flow/transport system can be treated sufficiently simply (e.g. as macroscopically, section-averaged
375 1d flow and transport in a rectangular domain).

376 We first discuss principal features of pore-scale (Sect. 3.1) and continuum-scale (Sect. 3.2)
377 chemical transport, and in Sect. 3.3, we focus on effective model formulations. We focus on
378 conservative chemical species, and mention chemical reaction effects only peripherally. Note that
379 other factors such as temporally/spatially changing fluid viscosity and surface tension, or
380 mechanical and wetting properties of the solid phase, represent further complexities that are not
381 considered here.

384 3.1 Pore-scale chemical transport analysis

386 To illustrate why knowledge only of ~~only~~ the flow field is insufficient for full quantification of
387 chemical transport, consider the three porous medium domains shown in Fig. 3. Each domains is
388 comprised of pore-scale images of a natural rock, modified by enlarging the solid phase grains, to
389 yield three different configurations: a statistically homogeneous system domain, a weakly
390 correlated system, and a structured, strongly correlated system (see Nissan and Berkowitz (2019)
391 for details). Fluid flow was determined by solution of the Navier-Stokes equations (Fig. 1a).
392 Transport of a conservative chemical species was then simulated via a (Lagrangian) streamline
393 particle tracking method, for an ensemble of particles that advance according to a Langevin
394 equation. Transport behavior was determined for two values of macroscopic (domain average)
395 Péclet number (Pe). [Recall; $Pe \equiv vL/D$, where v is fluid velocity, L is a characteristic linear
396 dimension, and D is the coefficient of molecular diffusion.] Here, the macroscopic Pe is based on

397 the mean particle velocity and mean particle displacement distance per transition (or “step”).

398 Figure 3 shows that regardless of possible (pore-scale) streamline changes as a function of
399 hydraulic gradient (recall Sect. 2.1, considering different values of Re), the choice of *macroscopic*
400 Péclet number in a given domain plays a significant role in the evolution of the migrating chemical
401 plume. In particular, the relative effects of advection and diffusion, which vary locally in space,
402 are critical, as is the overall residence time in the domain. We stress here, (and return to this key
403 point in discussion below,) that the spatially (and in some cases temporally) *local* changes in
404 relative effects of advection and diffusion – characterized by the *local* Pe – dominates
405 determination of the plume evolution. This can be understood from study of Fig. 3, for two choices
406 of macroscopic Pe values in each of the three heterogeneity configurations, ~~for two choices of~~
407 ~~macroscopic Pe values~~; the different patterns of longitudinal and transverse spreading are observed
408 clearly.

409 The behavior shown in Fig. 3 is essentially well-known from extensive simulations and
410 experiments appearing in the literature. This behavior is described here to stress the importance of
411 *temporal* effects, and to point out that information only of the advective velocity field – as
412 discussed in Sect. 2.1 and Sect. 2.2 – is not sufficient to “predict” chemical transport.

413

414

416 **Figure 3.** Fluid velocities and chemical migration in three porous media configurations (from left to right):
417 homogeneous system, randomly heterogeneous system, and structured heterogeneous system. The upper
418 row shows the (normalized) velocity field for the three configurations; the color bar represents relative
419 velocity, with dark blue being lowest. The middle and lower rows show, respectively, numerically-
420 simulated particle tracking patterns of an inert chemical species (blue dots) at $Pe = 1$ (middle row) and Pe
421 $= 100$ (lower row) for the three configurations (white color indicates solid phase; black color indicates
422 liquid phase). Note: The particles plumes are shown at 10% of the final time of each simulation; absolute
423 travel times differ among the plots. The insets in the left side plots of the middle and lower rows show the
424 pore-scale chemical species distributions; note the more diffuse pattern for $Pe = 1$ (from Nissan and

425 Berkowitz, 2019, <https://doi.org/10.1103/PhysRevE.99.033108>; © with permission from American
426 Physical Society 2019).

428

429 3.2 Continuum-scale chemical transport analysis

430

431 The aspects discussed in Sect. 3.1 are relevant, analogous and applicable essentially also to
432 chemical transport at the continuum scale. Consider the two laboratory experiments shown in Fig.
433 4 and Fig. 5. Each flow cell was filled with a different clean, sieved sand configuration; see Levy
434 and Berkowitz (2003) for details. Figure 4 shows a uniform (“homogeneous”) packing of clean
435 sand, while Fig. 5 shows a “coarse” sand containing a randomly heterogeneous arrangement of
436 rectangular inclusions consisting of a “fine” sand. The flow cells, fully saturated with water,
437 enabled macroscopically (section-averaged) 1d, steady-state flow, with a mean gradient parallel to
438 the horizontal axis of the cell. As seen in the two figures, neutrally-buoyant, inert red dye was
439 injected at seven (Fig. 4) and five (Fig. 5) points near the inlet side, to illustrate the spatiotemporal
440 evolution of the chemical plumes.

Figure 5. Photographs of dye transport in a flow cell (internal dimensions $0.86 \times 0.45 \times 0.10$ m) containing a randomly heterogeneous packing of quartz sand, under a constant flow rate with $Pe > 1$, at three times. The rectangular inclusions comprise sand with an average grain diameter $\sim 0.5\times$ smaller, and hydraulic conductivity $\sim 3\times$ lower, than the surrounding sand matrix (modified from Levy and Berkowitz, 2003; © with permission from Elsevier 2003).

Most notably, in both Fig. 4 and Fig. 5: (i) each of the plumes has a different, unique pattern, which continues over the duration of the plume migration; and (ii) none of the plumes is “elliptical”, as expected in classical Fickian transport theory and embodied in solutions of the classical advection-dispersion equation (ADE). Indeed, vertical averaging of each plume shown in Fig. 4 and Fig. 5, at each time, does not yield Gaussian (normally distributed) concentration profiles, but rather asymmetrical, “heavy-tailed” profiles.

At this juncture, note that here and below we use the terms “non-Fickian”, or “anomalous” – others sometimes use the terms “pre-asymptotic” or “pre-ergodic” – to denote any chemical transport behavior that differs from that described by the classical ADE or similar type of continuum-scale formulation. Typically, though, non-Fickian transport is characterized by early and or late arrival times of migrating chemical species to some control or measurement plane/point, relative to those resulting from solution of the ADE. The ADE applies to so-called Fickian behavior, in the sense that it accounts for mechanical dispersion as a macroscopic form of Fick’s law; mechanical dispersion arises as an “effective” (or “average”) quantity that describes local fluctuations around the average (advective) fluid velocity. Thus, in this formulation, a pulse of chemical introduced into a macroscopically 1d, uniform velocity, for example, leads to temporal and spatial concentration distributions that are equivalent to a normal (Gaussian) distribution.

It is in this context that the term “homogeneous” packing used above is placed in quotation marks, to indicate that in natural geological media, “homogeneity” does not really exist. Any natural geological sample of porous medium contains multiple scales of heterogeneity; and at each particular scale of measurement, “unresolved” heterogeneities that are essentially unmeasurable are present (~~even scanning electron microscopy and atomic force microscopy have limits of spatial resolution, for example!~~). And thus, as seen in Fig. 4 for example, the overall transport pattern

513 even in an “homogeneous” system can be non-Fickian (anomalous). *We therefore emphasize that*
514 *because natural heterogeneity in geological formations occurs over a broad range of scales,*
515 *“normal” (Fickian) transport tends to be the “anomaly”, whereas “anomalous” (non-Fickian)*
516 *transport is ubiquitous, and should be considered “normal”.*

517 Moreover, as noted in Sect. 2.2, streamlines are not altered with changes in the overall
518 hydraulic gradient, at the continuum (Darcy) scale, as long as laminar flow conditions are
519 maintained, because increasing the hydraulic gradient increases the fluid velocity along the
520 existing, (“predefined”) streamlines by the same factor. However, the character of chemical
521 transport can be altered, as the change in residence time in the domain affects the relative effects
522 of advection and diffusion space. And in domains with heterogeneous distributions of hydraulic
523 conductivity, the local Pe (Sect. 3.1) can vary more strongly, too.

524 Thus, we argue that patterns of chemical transport cannot be fully determined from information
525 only on the velocity field; solution of an appropriate continuum-scale transport equation cannot be
526 avoided. In conclusion, then, and with particular reference to the (conceptually and theoretically
527 beautiful) classical ADE – and to “conventional” conceptual understanding and quantitative
528 description of chemical transport – we suggest that one must separate mathematical convenience
529 and wishful thinking from the reality of experiments: there is a definitive need for more powerful
530 formulations of transport equations. In this context, one is reminded of the quotation by the
531 biologist Thomas Henry Huxley: “The great tragedy of science—the slaying of a beautiful theory
532 by an ugly fact.” (*President's Address to the British Association for the Advancement of Science,*
533 *Liverpool Meeting, 14 Sep 1870*).

534

535

536 **3.3 Modeling chemical transport, and the myth that “fewer parameters is always better”**

537

538 So how *do* we effectively model chemical transport?

539 As noted at the outset of Sect. 2, solution of the Navier-Stokes or Darcy equations to determine
540 the full *flow* field and velocity distribution in a given porous medium domain has been proven
541 correct and effective in most applications, and is well-accepted in the literature. However,
542 modeling of chemical transport is more contentious, the reasons for which we expand upon below.

543 We argue here that modeling of chemical species transport requires us to think in terms of *time*,
544 not just *space*. To assist the reader to enter this frame of thinking, and to sharpen our
545 conceptualization, we provide two examples to illustrate aspects of time and space in the context
546 of chemical transport dynamics:

547 (1) The classical example of the brachistochrone (ancient Greek: “shortest time”), or path of
548 fastest descent, is the curve (path) that would carry an idealized point-like body, starting at
549 rest and moving along the curve, without friction, under constant gravity, to a given end
550 point in the shortest time. (~~Correct solution: Johann Bernoulli, 1697~~) Somewhat non-
551 intuitively, the path that leads to the shortest travel time is not a straight line, but, rather, a
552 special curve that is longer than a straight line (a cycloid)[!], as demonstrated by Johann

553 [Bernoulli in 1697](http://old.nationalcurvebank.org/brach/brach.htm); (See: <http://old.nationalcurvebank.org/brach/brach.htm>).

- 554 (2) What error can be introduced when “averaging” in terms of “space”? Consider the case of
555 driving a total distance of 100 km, by first traveling 50 km at 1 km h⁻¹, and then traveling
556 50 km at 99 km h⁻¹. If we average the speed in terms of space (distance), then we traveled
557 two segments of 50 km at two speeds, so the average speed is $(1 + 99) / 2 = 50$ km h⁻¹. In
558 this framework, the total time to travel the 100 km “should” only have been 2 h. However,
559 in terms of *time*, the travel time is actually 50.5 h.

560 These simple examples help to emphasize the errors introduced by traditional conceptual
561 thinking, wherein the effects of *spatial* transport and domain heterogeneity are quantified only on
562 the basis of spatial characteristics. It is worth recalling, too, Einstein’s quantitative treatment of
563 Brownian motion (Einstein, 1905). Prior to his analysis, researchers applied – with puzzlement –
564 a time-dependent velocity, v , to quantify experimental measurements. Einstein (1905) instead
565 examined a recursion relation and expansion that led to a diffusion equation whose solution
566 showed, for the first time, that the root mean squared displacement of particles undergoing
567 Brownian motion is proportional to \sqrt{t} , and not to vt as had been assumed traditionally. An
568 astounding conceptual breakthrough over a century ago, this nature of diffusive motion is now
569 “common knowledge”.

570 In this same framework of focusing on *time*, the examples shown in Fig. 4 and Fig. 5 emphasize
571 that for chemical transport, we must recognize the critical role of “rare events”. These rare events
572 involve chemical species (~~–~~ migrating “particles” or “packets”) ~~–~~ that are held up or retained ~~in~~
573 (~~while traveling through,~~ or in/out of) lower velocity regions (~~pore-scale or continuum-scale~~)
574 in the porous domain, over various periods of time. Such events can have a dominant impact on
575 overall transport patterns, at both pore and continuum scales. In this context, one must exercise
576 caution with simple averaging of “small velocity fluctuations” and effects of molecular diffusion.
577 Rather, small-scale heterogeneities (~~in both space and time~~) do not necessarily “average out” or
578 become insignificant at larger scales; rather, the effects of “rare events” (e.g. temporary trapping
579 of even small amounts of chemical species via diffusion into and out of low velocity regions) and
580 fluctuations can propagate and become magnified, *within and across* length scales from pore to
581 aquifer.

582 Armed with these thoughts, we suggest that modeling chemical transport has been debated in
583 the literature ~~contentious~~ for at least three reasons:

- 584 1. The desire to work with spatial averaging approaches and equations: The research
585 community was (and still is) split over the need to recognize and incorporate, *explicitly*,
586 influences of temporal mechanisms caused largely by spatial heterogeneity (as
587 characterized by the domain hydraulic conductivity), when formulating “effective” (or
588 “averaged”) equations. And even when recognized, debate remains as to appropriate
589 mathematical formulation.
- 590 2. The lack of data: At least part of the difficulty in developing appropriate models is the lack
591 of availability of high-resolution laboratory data and field measurements against which
592 chemical transport models can be tested. Indeed, many elaborate theoretical developments

593 have been advanced over the decades, with accompanying, analytical and numerical
594 solutions — and yet, remarkably, comparative studies against actual laboratory data remain
595 limited, and tests with field measurements are even sparser (see also Sect. 4 for further
596 discussion of this point).

597 3. The choice of approach to, and purpose of, chemical transport modeling: Two overarching
598 approaches to quantifying chemical transport can be defined, focusing on (i) quantification
599 of “effective”, “overall” chemical transport behavior without requiring high-resolution
600 discretization and numerical solution of the domain, and, alternatively, (ii) high-resolution
601 hydrogeological delineation and then intensive numerical simulation on highly discretized
602 grids. We address approaches (i) and (ii) individually, below, in the context also of points
603 (1) and (2).

604 The debate in the literature between “effective” and high-resolution hydrogeological modeling,
605 as well as various preconceptions and misconceptions discussed below and in Sect. 4, lead
606 naturally to consideration of the (often incorrectly invoked) argument that “fewer model
607 parameters is better”.

608 We first discuss briefly aspects of high-resolution hydrogeological modeling in Sect. 3.3.1,
609 and then focus on “effective” transport equation modeling in Sect. 3.3.2. We emphasize that the
610 latter approach is applicable to both small- and large-scale domains. The former approach is
611 generally intended for large- (field-)scale systems, ~~(although, in a sense, the same approach~~ is in
612 some sense often applied for detailed pore-scale modeling); this approach is not particularly
613 contentious, per se, but is hampered by the complexity and cost associated with the demand for
614 highly detailed hydrogeological information. Therefore, research work remains heavily invested
615 in “effective” transport equation modeling.

616
617

618 **3.3.1 High-resolution domain delineation and modeling**

619

620 Efforts to resolve large-scale aquifer systems, to delineate the hydraulic conductivity distribution
621 at increasingly higher resolutions, began in earnest in the 1990s. Analysis of field sites emphasized
622 ~~(relatively)~~ high-resolution discretization of domain structure (e.g. “blocks” of the order of 10 m^3
623 at the field scale (Eggleston and Rojstaczer, 1998); $200 \times 200 \times 1\text{ m}^3$ at large regional scales
624 (Maples et al. 2019)). These efforts, first focusing on determining the fluid flow field, and
625 subsequently on delineating pathways for chemical transport, began largely because of
626 dissatisfaction with results of application of 1d, 2d, 3d forms of an “effective” (averaged) ADE
627 (see further discussion in Sect. 3.3.2). Acquiring high-resolution measurements of structural (e.g.
628 mineralogy, porosity) and hydrological properties (e.g. hydraulic conductivity) was made more
629 feasible in recent years by advances in hydrogeophysics, and as well as by advances in
630 computational capabilities that enable incorporation of this information in finely-discretized
631 meshes, and numerical solution for fluid flow and chemical transport.

632 In these highly resolved, ~~(high-resolution)~~ gridded domains, the flow field can be determined

633 from solution of Darcy’s law. Chemical transport is then simulated either by use of streamline
634 particle tracking methods, ~~by~~ (accounting for advection and diffusion in a Lagrangian framework,) ~~or~~
635 or via solution of a local, (mesh element) continuum-scale transport equation. For chemical
636 transport, use of an advection-*diffusion* equation might appear preferable – given that it requires
637 no estimate for the local dispersivity ~~—~~, but some researchers apply an advection-*dispersion*
638 equation, which necessitates use of mesh-scale dispersivity values that are either assumed or
639 estimated from local measurements. The latter case assumes mesh-scale transport to be fully
640 Fickian (recall Sect. 3.2) ~~to quantify overall transport~~. More recently, ~~we note that~~ alternative
641 formulations of a governing transport equation that incorporates broad temporal effects ~~more~~
642 broadly can also be used in this type of modeling approach; see, e.g. Hansen and Berkowitz (2020)
643 for incorporation of a continuous time random walk method (discussed in Sect. 3.3.2) ~~into this~~
644 modeling framework.

645 [Parenthetically, we note that “analogous”, high-resolution measurements are made at the
646 pore-scale – in mm to decimeter rock core samples – as a basis for computationally-intensive
647 modeling of fluid flow and chemical transport at these scales. Similar to the evolution of this
648 approach for field-scale studies, high-resolution measurements advanced from use of 2d rock
649 micrographs to advanced micro-computed tomography protocols (e.g. Thovert and Adler, 2011;
650 Bijeljic et al., 2013; recall Sect. 2.1).]

651 This approach is attractive in terms of the ability to “reproduce” detailed heterogeneous
652 hydraulic conductivity structures, and can provide useful “overall assessments” of fluid flow and
653 chemical transport pathways, and migration of a chemical plume. Moreover, solutions for fluid
654 flow and chemical transport can be considered “exact”, at least at the scale at which the domain is
655 discretized; ~~(and they can thus also capture at least some aspects of non-Fickian transport)~~. But
656 even at this type of spatial resolution, the ability to effectively quantify actual chemical transport,
657 even relative to the limited available field measurements, remains a question of debate; ~~—~~ ~~and~~ the
658 research community, as well as practicing engineers, still often prefer to analyze chemical transport
659 in a domain by use of relatively simple (often 1d, section-averaged) model formulations.

660 Finally, we point out ~~here~~ that in the context of efforts to obtain increasing amounts of
661 structural and hydrological information at a given field site, due consideration should also be given
662 to the “worth” of data. Thus – for example – in an effort to quantify fluid flow or conservative
663 chemical transport in an aquifer, do we really need “full”, detailed knowledge of the system (e.g.
664 porosity, hydraulic conductivity) at every point in the formation? Possibly non-intuitively, the
665 adage “more data is better” is often not true, and model incorporation of statistical uncertainty can
666 offer equally satisfactory solutions with less costly, less measurement- and computationally-
667 intensive, detail (e.g. Dai et al., 2016).

668

669

670 3.3.2 “Effective” characterization and modeling

671

672 At least since the 1960’s, the research community has focused enormous efforts on formulation of

673 “averaged”, or “effective” (often macroscopically, section-averaged 1d) transport equations to
674 quantify chemical transport, without requiring high-resolution discretization and
675 ~~(computationally-intensive)~~ numerical solution of the domain. The ~~(now “classical”)~~ ADE was
676 advanced as the governing ~~(partial differential)~~ equation; see also further discussion on “effective
677 scales of interest”, in the context of “upscaling” (Sect. 4). Recall that as discussed in Sect. 3.2, the
678 ADE assumes Fickian transport behavior, in the sense that mechanical dispersion – which is
679 defined as an average quantity to describe local fluctuations around the average (advective) fluid
680 velocity – is treated macroscopically by Fick’s law. The classical ADE then specifies coefficients
681 of longitudinal and transverse dispersivity, which by definition are constants.

682 Solutions of the ADE were compared against conservative tracer experiments in laboratory
683 columns (generally 10-100 cm) to produce breakthrough curves ~~of (concentration vs. time, at a set~~
684 ~~outlet distance)~~; but even from the outset, the applicability of the ADE was questioned by some
685 researchers (e.g. Aronofsky and Heller, 1957; Scheidegger, 1959). Subsequent flow cell
686 experiments demonstrated, for example, that the dispersivity constants are not actually constant,
687 and change with length scale – even over tens of centimeters – to achieve even *approximate* fits to
688 the measurements (e.g. Silliman and Simpson, 1987). Moreover, solutions of the ADE appear
689 inadequate when compared to transport in laboratory flow cells with distinct regions of different
690 hydraulic conductivities (e.g. Maina et al., 2018). In a sense, then, it can be considered somewhat
691 surprising that this form of the ADE was subsequently assumed to apply, over several decades, in
692 a rather sweeping fashion for a wide range of hydrogeological scenarios and length scales. Detailed
693 discussions of these aspects appear in, e.g. Berkowitz et al. (2006, 2016). [Parenthetically, we
694 stress again here that if one has complete information at the pore-scale, then solution of the Navier-
695 Stokes and advection-*diffusion* equations within the pore space can capture the true chemical
696 transport behavior, i.e. purely spatial information is sufficient to describe chemical transport. But
697 at continuum scales, time and unresolved heterogeneities became critical, and an “averaged”
698 equation like the ADE with a “macrodispersion” concept is problematic.]

699 To mMoveing beyond the ADE, and the definitive need for effective transport equations that
700 quantify non-Fickian, ~~(as well as Fickian)~~ transport (recall Figs. 4 and 5), we consider an
701 alternative approach. The idea is to account for the temporal distribution that affects chemical
702 ~~migration-of-chemical-species~~, in addition to thea spatial distribution, at a broad continuum level,
703 and employ a transport equation in the spirit of a “general purpose” ADE. This approach
704 necessarily leads to transport behaviors that are more general than those indicated by a “general
705 ADE”, ~~(i.e. in the context of an overall, averaged 1d transport scenario for example)~~.

706 To explain this approach, we refer to the continuous time random walk (CTRW) framework,
707 which is particularly broad and general (Berkowitz et al., 2006). Significantly, and conveniently,
708 ~~it should be recognized that it turns out that~~ special, ~~(or limit)~~ cases of a general CTRW formulation
709 lead to other well-known related “subset” formulations that can also quantify various types of non-
710 Fickian transport, as explained in, e.g., Dentz and Berkowitz (2003) and Berkowitz et al. (2006).
711 These “subsets” include mobile-immobile (e.g. Feehley et al., 2000), multirate mass transfer (e.g.
712 Haggerty and Gorelick, 1995; Harvey and Gorelick, 1995; Carrera et al., 1998), and time-fractional

713 derivative formulations (e.g. Barkai et al., 2000; Schumer et al., 2003; Metzler and Klafter, 2004);
 714 ~~as explained in, e.g., Dentz and Berkowitz (2003) and Berkowitz et al. (2006).~~ Indeed, in spite of
 715 ~~requent~~ references to these model formulations as being “different”, they are closely related, with
 716 clear mathematical correspondence. Each formulation has advantages, depending on the domain,
 717 problem and objectives of model use; but model selection must first be justified physically, and it
 718 is inappropriate, for example, to apply a mobile-immobile (two domain) model to interpret
 719 chemical transport in a “uniform, homogeneous” porous medium when it displays non-Fickian
 720 transport behavior (recall Fig. 4).

721 Here, we describe only briefly the principle and basic aspects of the CTRW formulation;
 722 detailed explanations and developments are available elsewhere (e.g. Berkowitz et al., 2006).

723 To introduce “temporal thinking” in the context of non-Fickian transport, we begin by
 724 mentioning the analogy between a classical random walk (RW) – which leads to Fick’s law – and
 725 the CTRW. A classical random walk is given in Eq. 1:

$$726$$

$$727 P_{n+1}(\ell) = \sum_{\ell'} p(\ell, \ell') P_n(\ell') \quad (1)$$

$$728$$

729 where $p(\ell, \ell')$ represents the probability of a random walker (“particle”) advancing from location
 730 ℓ' to ℓ , $P_n(\ell')$ denotes the probability of a particle being located at ℓ' at (fixed) time step n , and
 731 $P_{n+1}(\ell)$ denotes the probability of the particle then being located at ℓ at step $n+1$. With this
 732 formulation in mind, Einstein (1905) and Smoluchowski (1906a,b) demonstrated that for n
 733 sufficiently large and a sufficient number of particles undergoing purely (statistically) random
 734 movements *in space*, the spatial evolution of the particle distribution is equivalent to the solution
 735 of the (Fickian) diffusion equation. This elegant discovery demonstrated that a partial differential
 736 equation and its solution can be represented by following, numerically, the statistical movement
 737 of particles (i.e. particle tracking) following a random walk. Remarkably, random walk
 738 formulations are “generic” in the sense that they can be applied in a broad range of phenomena in
 739 physics, chemistry, mathematics, and life sciences; here, they describe naturally migration of
 740 chemical species (dissolved “particles” or “packets”) in water-saturated porous media.
 741 Generalizing the partial differential equation to include transport by advection, solution of the
 742 ADE under various boundary conditions can then be determined by an appropriate random walk
 743 method.

744 The simple random walk given in Eq. 1 can be generalized by accounting for time, replacing
 745 the particle transition (or iteration) counter n by a time distribution. The generalized formalism in
 746 Eq. 2, with the joint distribution $\psi(\mathbf{s}, t)$, called “continuous time random walk” and applied to
 747 transport, was first introduced by Scher and Lax (1973):

$$748$$

$$749 R_{n+1}(\mathbf{s}, t) = \sum_{\mathbf{s}'} \int_0^t \psi(\mathbf{s} - \mathbf{s}', t - t') R_n(\mathbf{s}', t') dt' \quad (2)$$

$$750$$

751 where $R_{n+1}(\mathbf{s}, t)$ is the probability per time for a particle to just arrive at site \mathbf{s} at time t after $n+1$
 752 steps and $\psi(\mathbf{s}, t)$ is the probability rate for a displacement from location \mathbf{s}' to time \mathbf{s} with a difference

753 of arrival times of $t-t'$. It is clear that $\psi(\mathbf{s}, t)$ is the generalization of $p(\ell, \ell')$ in Eq. 1, and that the
 754 particle steps can each now take place at different times. Indeed, it is precisely this explicit
 755 accounting of a distribution of temporal contributions to particle transport, not just spatial
 756 contributions, that offers the ability to effectively quantify transport behaviors as expressed by,
 757 e.g. heavy-tailed, non-Fickian particle arrival times.

758 To where does the generalization in Eq. 2 lead us? In a mindset similar to that of Brownian
 759 motion, and Einstein's 1905 breakthrough mentioned above at the outset of Sect. 3.3, a puzzle
 760 arose about seven decades later for researchers attempting to interpret observations of electron
 761 transit times in disordered semiconductors. The electron mobility (defined as velocity per unit
 762 electric field), which was considered an intrinsic property of the material, was found to depend on
 763 variables that changed the duration of the experiment, such as sample length or electric field. Scher
 764 and Montroll (1975), considering Eq. 2, discovered that the mean displacement $\bar{\ell}$ of the electron
 765 packet does not advance as $\bar{\ell} = vt$, but rather as $\bar{\ell} \sim t^\beta$.

766 In the context of chemical transport in geological formations, the behavior $\bar{\ell} \sim t^\beta$ can be
 767 attributed to a wide distribution of transition times in naturally disordered geological media. In the
 768 CTRW formulation, the transition time distribution is characterized by a power law of the form
 769 $\psi(t) \sim t^{-1-\beta}$ for $t \rightarrow \infty$ and $0 < \beta < 2$; significantly, the resulting transport behavior is Fickian for
 770 $\beta > 2$. At large times, for this $\psi(t)$ dependence, the mean displacement $\bar{\ell}(t)$ and standard deviation
 771 $\bar{\sigma}(t)$ of the migrating chemical plume $c(\mathbf{s}, t)$ scale as $\bar{\ell}(t) \sim t^\beta$ and $\bar{\sigma}(t) \sim t^\beta$ for $t \rightarrow \infty$, $0 < \beta <$
 772 1 (Schlesinger, 1974). Moreover, for $t \rightarrow \infty$ with $1 < \beta < 2$, the plume scales as $\bar{\ell}(t) \sim t$ and
 773 $\bar{\sigma}(t) \sim t^{(3-\beta)/2}$. These behaviors are notably different than that of Fickian transport models, for
 774 which (from the central limit theorem), $\bar{\ell}(t) \sim t$ and $\bar{\sigma}(t) \sim t^{1/2}$.

775 With the concepts described here, and using the generally applicable decoupled form $\psi(\mathbf{s}, t) =$
 776 $p(\mathbf{s})\psi(t)$, where $p(\mathbf{s})$ is the probability distribution of the transition lengths and $\psi(t)$ is the
 777 probability rate for a transition time t between sites, Eq. 2 can be developed into an (integro-)partial
 778 differential equation. Thus, the ADE given by

$$779 \frac{\partial c(\mathbf{s}, t)}{\partial t} = -[\mathbf{v}(\mathbf{s}) \cdot \nabla c(\mathbf{s}, t) - \mathbf{D}(\mathbf{s}) : \nabla^2 c(\mathbf{s}, t)] \quad (3)$$

781 where $c(\mathbf{s}, t)$ is the concentration at location \mathbf{s} and time t , $\mathbf{v}(\mathbf{s})$ is the velocity field and $\mathbf{D}(\mathbf{s})$ is the
 782 dispersion tensor, is replaced by the more general CTRW transport equation:

$$783 \frac{\partial c(\mathbf{s}, t)}{\partial t} = - \int_0^t M(t-t') [\mathbf{v}_\psi \cdot \nabla c(\mathbf{s}, t') - \mathbf{D}_\psi : \nabla \nabla c(\mathbf{s}, t')] dt' \quad (4)$$

784 where \mathbf{v}_ψ and \mathbf{D}_ψ are generalized particle velocity and dispersion, respectively, and $M(t)$ is a
 785 temporal memory function based on $\psi(t)$.

786 The strength of this type of formulation is that it effectively quantifies (non-Fickian) early
 787 arrivals and late time tailing of migrating chemical species, and the spatial evolution of chemical
 788 plumes in heterogeneous media. For example, recalling the scenario in Fig. 2, wherein 99.9% of
 789

792 the inflowing particles traverse the preferential pathways seen in Fig. 2c, detailed numerical
793 simulations indicate that concentration breakthrough curves exhibit significant, non-Fickian, long-
794 time tails (Edery et al., 2014). Choice of an appropriate power-law form of $\psi(t)$ was then shown
795 to capture this behavior; moreover, a functional form defining the value of the power-law exponent
796 β in $\psi(t)$ was identified, based on statistics of the hydraulic conductivity and particle interrogation
797 of the domain (Edery et al., 2014).

798 Equation (4) is essentially an ADE weighted by a temporal memory. When $\psi(t)$ is an
799 exponential function (or power law but for $\beta \geq 2$), $M(t) \rightarrow \delta(t)$ and we recover Fickian transport
800 described by the ADE; thus, the ADE assumes, implicitly, that particle transition times are
801 distributed exponentially. But with a power law form $\psi(t) \sim t^{-1-\beta}$ for $0 < \beta < 2$, the transport is
802 non-Fickian. A wide range of functional forms of $\psi(t)$ can be chosen, including, e.g. truncated
803 power law forms that allow evolution to Fickian transport at large times or travel distances (e.g.
804 [DentzBerkowitz et al., 20046](#)), as well as Pareto (e.g. Hansen and Berkowitz, 2014) and curved
805 (or inverse gamma; e.g. Nissan and Berkowitz, 2019) temporal distributions. Other, generally
806 simpler, choices of $\psi(t)$ or $M(t)$ lead to mobile-immobile, multirate mass transfer, and time-
807 fractional derivative formulations, as mentioned above. We note, too, that the elegant result
808 derived by Gelhar and Axness (1983) and others, discussed in Sect. 1.2, is valid only at an
809 asymptotic limit, wherein transport is Fickian and there is no residual non-Fickian memory in the
810 plume advance.

811 A plethora of related studies have examined a range of perspectives and applications that
812 explore CTRW formulations. These studies address, for example, numerical simulations (e.g. Le
813 Borgne et al., 2008; Berkowitz and Scher, 2010; Hansen, 2020; Kang et al., 2014; Rhodes et al.,
814 2008; Edery, 2021), fractured formations (e.g. Geiger et al., 2010; Wang and Cardenas, 2017),
815 stream transport (e.g. Boano et al., 2007), and laboratory measurements at difference scales (e.g.
816 Le Borgne and Gouze, 2008; Major et al., 2011). Other studies have explored space-fractional
817 differential equations (e.g. Benson et al., 2000; Wang and Barkai, 2020).

818 Each of these power law forms of course requires one or more parameters – at least β – and in
819 some cases, other parameters that define, e.g. a transition time from non-Fickian to Fickian
820 transport (Berkowitz et al., 2006; Hansen and Berkowitz, 2014; Nissan et al., 2017). These
821 parameters have physical meaning, and are not purely empirical; perspectives on “numbers of
822 parameters” associated with all models are discussed in Sect. 3.3.3. The question of how model
823 parameter values are determined is addressed in Sect. 4.1.

824 The efficacy of formulations that incorporate, whether explicitly or implicitly, some type of
825 power-law characterization of temporal aspects of chemical transport, is now generally recognized
826 in the literature. Indeed, applications of mobile-immobile, multirate mass transfer, time-fractional
827 advection-dispersion, and general CTRW formulations have been applied quite extensively and
828 successfully. In particular, solutions of Eq. 4 and related variants have interpreted a wide range of
829 chemical transport scenarios: (i) pore-scale to meter scale laboratory experiments, field studies,
830 and numerical simulations, in (ii) porous, fractured, and fractured porous domains, (iii) accounting
831 for constant and time-dependent velocity fields, and (iv) for both conservative and reactive

832 chemical transport scenarios. Solutions to address some of these scenarios are more easily obtained
833 by use of particle tracking methods that incorporate the same considerations and power-law form
834 of $\psi(t)$, as embedded in Eq. 4.

835 ~~It should be recognized that,~~ Like the ADE, Eq. 3, the formulation given in Eq. 4 represents a
836 continuum-level mechanistic model ~~(as derived in, e.g., Berkowitz et al. 2002), in the sense that~~
837 ~~both equations contain clear advective and dispersive contributions. The occurrence of a broad~~
838 ~~distribution of transition times, fundamental to CTRW and related approaches, emanates from a~~
839 ~~variety of physical controls.~~ Discussion in the literature about the need for “mechanistic models”
840 often uses the term rather loosely: “mechanistic” transport model equations are based on
841 fundamental laws of physics, with ~~(constant)~~ parameters that have physical meaning (e.g.
842 hydraulic conductivity, diffusivity, sorption), and thus offer process understanding. But to quantify
843 the spatiotemporal evolution of a migrating chemical plume, additional parameters are needed. ~~We~~
844 ~~argue that, b~~Because of the nature of geological materials, a transport equation should of course
845 capture the relevant physical ~~mechanisms that influence the transport, (as well as and~~ chemical
846 ~~mechanisms;~~ if the species is reactive) ~~mechanisms that impact the transport;~~ but to do so, we
847 must *also* capture the uncertain characterization of hydrogeological properties due to the reality of
848 unresolved, ~~(unmeasurable)~~ heterogeneities at any length scale of interest. Thus, we suggest that a
849 *mechanistic-stochastic equation formulation* such as given in Eq. 4 **is required. Such an equation**
850 ~~(which (i)~~ incorporates a probability density function to account for temporal transitions that
851 cannot be determined only from spatial information) **is required, (ii)** descri~~bing~~
852 mechanisms ~~(and with physically meaningful parameters)~~, and **(iii)** account~~s~~
853 unknowable!) information.

854 We note here, too, that other stochastic continuum averaging methods have been proposed in
855 the literature, in the same context of efforts to formulate a “general”, “effective” transport equation
856 at a specific scale of interest (see further discussion on “effective” equations and “upscaling” in
857 Sect. 4). In many cases, though, sophisticated stochastic averaging and homogenization
858 approaches have led to transport formulations that are essentially intractable, in terms of solution,
859 and/or have remained at the level of hypothesis without being tested successfully against actual
860 data.

861
862

863 3.3.3 Are fewer parameters always better? (Answer: No!)

864

865 The term “modeling” is used in many contexts and with differing intents. However, in the
866 literature dealing with chemical transport in subsurface hydrological systems, there are frequent
867 ~~but (often misguided)~~ “arguments” regarding “which model is better“, with a major point of some
868 authors being the claim that “fewer parameters is always best”. Not always. Indeed, some models
869 involve more parameters than others, but if these parameters have physical meaning and are needed
870 as factors to quantify key mechanisms, then “more parameters” is not a “weakness”. We
871 emphasize, too, that when weighing use of *any* specific ~~(any!)~~ model, “better” also depends, ~~(at~~

872 least in part), on what the modeling effort is addressing. Clearly – and regardless of the number
873 of parameters – a “back-of-the-envelope” calculation using a simple model is sufficient if, for
874 example, one requires only an order of magnitude estimate of the center-of-mass velocity of a
875 migrating contaminant plume, (or in other words, no need for artillery to swat a mosquito!). [In
876 this context, quoting Albert Einstein regarding his simplification of physics into general relativity:
877 “Everything should be made as simple as possible, but not simpler.”]

878 Considering chemical transport in subsurface geological formations, and the aim of
879 quantifying (modeling) the evolution of a migrating chemical plume in both space and time, we
880 return to focus on the ADE- and CTRW-based formulations discussed in Sect. 3.3.2. As noted in
881 the preceding sections, CTRW and related formulations ~~have been demonstrated repeatedly to can~~
882 describe ~~a-transport-system behaviors~~ effectively, ~~with sufficient parameters to account for the~~
883 ~~various mechanisms~~. Most significantly, the seminal work of Scher and Montroll (1975) showed
884 that the β exponent ~~has-must-to~~ be included because the mean displacement is not linear with time
885 (i.e. the mean displacement $\bar{\ell}$ of the electron packet does not advance as $\bar{\ell} = vt$, but rather as
886 $\bar{\ell} \sim t^\beta$). Similarly Thus, a corresponding parameter, relative to an ADE formulation invoking
887 Fickian transport, is unavoidable ~~when transport is non-Fickian in such cases. In a sense, too, one~~
888 ~~can argue that this parameter is not an “additional” parameter relative to the ADE; rather, a~~
889 ~~decision to invoke the ADE to quantify a transport problem simply assigns a value to this~~
890 ~~parameter, implicitly, as $\beta \geq 2$.~~

891 It should be recognized that ~~—while not (yet?) standard practice in the research community—~~
892 quantitative model information criteria, or model selection criteria, can be used to assess and
893 compare various model formulations that are applied to diverse scenarios (such as fluid flow,
894 chemical transport) in subsurface geological formations. These information criteria include AIC
895 (Akaike, 1974), AICc (Hurvich and Tsai, 1989), and KIC (Kashyap, 1982) measures, as well as
896 the Bayesian (or Schwarz) BIC (Schwarz, 1978). They are formulated to rank models, or assign
897 (probabilistic) posterior weights to various models in a multimodel comparative framework, and
898 therefore focus on model parameter estimates and the associated estimation uncertainty. As such,
899 these information criteria discriminate among various models according to (i) the ability to
900 reproduce system behavior, and (ii) the structural complexity and number of parameters.
901 Discussion of theoretical and applied features of these criteria is given elsewhere (e.g. Ye et al.,
902 2008). Using such measures Specifically in the context of the ADE and CTRW formulations,
903 with an accounting also of chemical reactions, ~~for example,~~ it was shown that while solution of an
904 ADE can fit measurements from some locations quite closely, the CTRW formulation offers
905 significantly improved predictive capabilities ~~(in the context of model assessment in the presence~~
906 ~~of uncertainty)~~ when examined against an entire experimental data set (Ciriello et al., 2015). In
907 addition, focusing on the most sensitive observations associated with the CTRW model provides
908 a stronger basis for model prediction, relative to the most sensitive observations corresponding to
909 the ADE model.

910 To conclude this section: Notwithstanding the above arguments, some readers might continue
911 to argue that the approach discussed here – viz., the need for time considerations as well as space

912 ~~such~~ (as embodied in the CTRW framework and related formulations) – is “inelegant” because it
913 requires more parameters relative to the classical ADE. In response, the reader is encouraged to
914 recall the words of Albert Einstein following criticism that his theory of gravitation was “far more
915 complex” than Newton’s. His response was simply: “If you are out to describe the truth, leave
916 elegance to the tailor”.

919 **4 The holy grail of upscaling, and myths about “a priori” parameter determination**

921 We begin by defining the term “upscaling” in the context of the discussion here on chemical
922 transport. As defined in the Introduction, Sect. 1.2, we use the term “upscaling” to describe the
923 effort to develop and apply chemical transport equations at large length scales, and identify
924 corresponding model parameter values, based on measurements and parameter values obtained at
925 significantly smaller length scales.

926 We attempt “upscaling” in the hope of developing governing equations for chemical transport
927 at larger and larger scales, from pore, to core, to plot, and to field length scales. Clearly, then,
928 “upscaling” is relevant to the modeling approach discussed in Sect. 3.3.2 – which focuses on use
929 of “averaged”, or “effective” (often 1d, or section-averaged) transport equations – and not to the
930 high-resolution domain delineation and modeling approach of Sect. 3.3.1.

931 However, in light of the discussion in Sect. 2 and Sect. 3, we argue that “upscaling” of chemical
932 transport equations is very much an unattainable holy grail. Particularly in light of recognizing
933 temporal effects, in addition to spatial characterization, we maintain that it is necessary to
934 formulate and, calibrate ~~and apply~~ models, and then apply them, using measurements at similar
935 measurement scales of interest, ~~in both space and time~~. Of course, similar equation *formulations*
936 can be applied at different spatial scales. But parameter values for transport equations cannot
937 generally be determined a priori or from purely spatial or flow-only measurements; *measurements*
938 *with a temporal “component”, at the relevant length scale of interest, are required.*

939 In Sect. 4.1, we briefly discuss aspects of model calibration. This leads naturally to our
940 discussion of upscaling in Sect. 4.2.

943 **4.1 Parameter determination and model calibration**

945 First, it is prudent to offer some words about the need for parameter estimation, or model
946 calibration. Unless one is dealing with first principles calculations of a physical process such as
947 (e.g., molecular diffusion) in a perfectly homogeneous domain, *a priori* determination of model
948 parameters – for *any* model equation formulation – requires calibration against actual experimental
949 measurements. In some limited cases, detailed numerical simulations can be used at small (pore)
950 scales, (e.g. using an advection-diffusion equation ~~with the fluid phase~~, together with solution of
951 the Navier-Stokes equations to first determine the precise flow field in the pore space); but this

952 [also necessitates detailed measurements of the pore structure such as obtained by computed](#)
953 [tomography measurements \(e.g. Bijeljic et al., 2013\)](#). Indeed, then, at any realistic problem or scale
954 of interest, *all* chemical transport models require calibration.

955 This fundamental tenet should be clear and well-recognized, yet the literature contains all-too-
956 frequent – and both misguided and misleading – “criticism” of various model formulations,
957 claiming that “parameters are empirical because they are estimated by calibration (fitting) to
958 experiments”; additional “criticisms” follow, for example, that such as a model is therefore not
959 “universal”, and/or “it therefore has no predictive capability”. We address these latter “criticisms”
960 in Sect. 4.2. Parameters are *not* “empirical” simply because their values are determined by
961 matching to an experiment¹. Moreover, it should be recognized that application even of the
962 classical ADE at various column and larger scales requires estimates – obtained by calibration –
963 of dispersivity coefficients; (and for high-resolution domain delineation and modeling as discussed
964 in Sect. 3.3.1, [calibrated](#) “block-scale” dispersivities are needed). [Note: ~~And if~~ dispersivities are
965 not actually determined for a specific experiment, but selected from on the literature for “typical”
966 values of dispersivity, there is still a reliance on calibration from previous “similar” studies¹.]
967 Moreover, with reference to the desire for model parameters that represent fundamental, *spatial*
968 hydrogeological properties of the domain, note that even the classical ADE dispersivity parameter
969 is not uniquely identified with such properties; rather, it varies even in a given domain as a function
970 of chemical plume travel distance or time.

971 With regard to model “universality”, recall that, for example, percolation theory (discussed at
972 the beginning of Sect. 2) offers “universal” exponents in scaling relationships. But even for this
973 type of convenient and useful, statistical model, such scaling relationships, too, can only advance
974 from “scaling” (e.g. $A \sim B$) to a full “equation” (e.g. $A = kB$) by calibration of a coefficient of
975 equality (k) against actual measurements. So even in “simple” models, model calibration cannot
976 be avoided.

977 To address “empiricism” – here enters the question of whether parameters of a particular model
978 (in this case, equations for chemical transport) have a physical meaning. As discussed in Sect.
979 3.3.2, a *mechanistic-stochastic equation formulation* such as given in Eq. 4 incorporates a
980 probability density function to describe known transport mechanisms in a stochastic sense; but
981 stochastic does not mean “unphysical”, and the parameters as given in, e.g., particular functional
982 forms of $M(t)$ or $\psi(t)$ are indeed physically meaningful. For example, the key β exponent
983 characterizing the power law behavior can be linked directly to the statistics of the hydraulic
984 conductivity field (Edery et al., 2014), or, in a fracture network, be determined from the velocity
985 distribution in fracture segments (Berkowitz and Scher, 1998), which is related directly to physical
986 properties of the domain. Similarly, corresponding parameters appearing in “subset” formulations
987 to quantify non-Fickian transport – e.g. mobile-immobile, multirate mass transfer, and time-
988 fractional derivative formulations – can be understood to have physical meaning (e.g. [Haggerty](#)
989 [and Gorelick, 1995](#); [Harvey and Gorelick, 1995](#); [Carrera et al., 1998](#); [Dentz and Berkowitz, 2003](#);
990 [Berkowitz et al., 2006](#)). These parameters, too, of course require determination by model
991 calibration to experimental data² (or where appropriate², to results of numerical simulations²), just

992 as for ~~ADE and~~ any other model, ~~including ADE~~ formulations.
993
994

995 4.2 Upscaling, the scale of interest, and predictive capabilities 996

997 Upscaling of *fluid flow* “works” because ~~pressure propagation is essentially instantaneous.~~ At
998 the Darcy scale – which is the “practical” scale for most applications – flow paths and streamlines
999 do not change with increasing gradient (as long as a transition to turbulent flow is not reached).
1000 The equation formulation remains valid, and the fluid residence time in a domain is irrelevant
1001 because self-diffusion of water does not affect overall fluid fluxes. ~~Pore-scale flow analyses are~~
1002 ~~local and more specialized, and “upscaling” is not per se an objective.~~

1003 For chemical transport, though, the situation is totally different. Why? Because “upscaling”
1004 entails some kind of “coupled” averaging ~~or in-parameterization in~~ both space *and* time, and it is
1005 far from clear how, if at all, this can be achieved. Moreover, small-scale concentration fluctuations
1006 do not necessarily “average out”, but instead propagate from local to larger spatial scales. To
1007 illustrate another aspect of the complexity, the Péclet number (Pe) in heterogeneous media, with
1008 preferential pathways, varies locally in space (recall Fig. 3 and the discussion in Sect. 3.1).
1009 Averaging to obtain a macroscale (“upscaled”) Pe must address the relative, locally varying effects
1010 of advection and diffusion in space, as well as the overall residence time in the domain; after all,
1011 it is these effects that dominate determination of the plume evolution. Thus, upscaling requires
1012 spatial averaging, but (at least an) *implicit* temporal averaging must also be included. It can be
1013 argued that no single, effective Pe can be defined for the entire domain; whether or not it is
1014 possible, and how, it is possible to average local Pe values to achieve a single, meaningful domain-
1015 scale Pe remains an open question. And whether we like it or not, even with complete information
1016 on the spatial (local) Pe distribution, the impact on the overall transport pattern evolution cannot
1017 be determined without actually solving for transport in the domain.

1018 For chemically reactive species, the transport situation becomes even more complex, because
1019 the local residence time, not just the local Pe, must be taken into consideration. Moreover, when
1020 precipitation or dissolution processes are present, the velocity field will change locally, introducing
1021 additional local temporal and spatial variability. And when sorption is present but tapers off ~~(for~~
1022 ~~example,~~ when the cation exchange capacity is met, ~~for example),~~ even the diffusion coefficient
1023 itself changes. These factors further complicate attempts to upscale. [In this context, too, it should
1024 be noted that for chemically-reactive systems, it is well-known ~~(e.g. White and Brantley, 2003)~~
1025 that there is often a significant lack of correspondence between laboratory and field-based
1026 estimates of geochemical reaction rates and rates of rock weathering, with field-scale estimates –
1027 often based on macroscopically Fickian, ADE-like transport formulations – being generally
1028 significantly smaller ~~(e.g. White and Brantley, 2003).~~]

1029 Thus, we suggest that focusing efforts on attempting to develop upscaling methodologies for
1030 chemical transport, based on any transport equation formulation, appears to be doomed largely to
1031 failure – as evidenced, too, by decades of research publications. Rather, we argue that because of

1032 the subtle effects of temporal mechanisms, and their close coupling to spatial mechanisms, use of
1033 an “effective”, or “averaged” continuum-level equation to describe chemical transport (~~as opposed,~~
1034 ~~e.g. to intensive numerical simulation using a streamline particle tracking method in a high-~~
1035 ~~resolution hydraulic conductivity field~~) requires calibration of a suitable model at the appropriate
1036 scale of interest, with model parameter values calibrated at essentially the same scale. [The model](#)
1037 [can then be applied to examine transport behaviors over spatial scales with relatively similar orders](#)
1038 [of magnitude.](#)

1039 We emphasize, though, that as stated at the outset of Sect. 4, we do argue that similar
1040 (continuum-level) transport equation *formulations* can be applied at different spatial scales, as long
1041 as they are mechanistically correct, (with a *temporal* component), and the parameter values are
1042 based on *measurements at the relevant length scale of interest.*

1043 Now, in the context of the above arguments regarding “upscaling” and model application, we
1044 return to the ideas presented in Sect. 3.3.2 and consideration of model formulations that account
1045 for both spatial and temporal effects. We first mention use of the ADE. As pointed out in Sect. 3.2
1046 and extensive literature, the “constant” (as required by the ADE formulation) “intrinsic”
1047 dispersivity parameter changes significantly even over relatively small (~~e.g. 10’s of cm’s, Silliman~~
1048 ~~and Simpson, 1987~~) increases in length scales (e.g. 10’s of cm’s; Silliman and Simpson, 1987) –
1049 and therefore also over time scales—seales; ~~so that it~~ [therefore](#) makes no real sense to attempt to
1050 define an “upscaled” dispersivity parameter for larger scales. Even in the framework of high-
1051 resolution domain delineation and modeling, discussed in Sect. 3.3.1 – which is not “upscaling”
1052 as defined here – the question remains as to what dispersivity values are relevant for field-scale
1053 aquifer “blocks” of the order of 100 to 1000’s of m³.

1054 In contrast, CTRW and related transport formulations with explicit accounting of time effects,
1055 as outlined in Sect. 3.3.2, can be applied meaningfully to interpret real measurements and transport
1056 behavior at “all” scales. We *can* use the same equation formulation at different scales, with
1057 different but relevant parameters at each scale. We emphasize, too, that we do not argue for “hard”
1058 length scales; ~~so that~~ in principle, e.g., an appropriate (~~CTRW-based~~) model calibrated at 20 cm
1059 will be applicable to 100 cm scales, and a model calibrated on a 100 m scale data set can be
1060 applicable at a kilometer scale (e.g. Berkowitz and Scher, 1998, 2009; Rhodes et al., 2008; Geiger
1061 et al., 2010; Ederly, 2021). The point, though, is that it makes no sense to calibrate at a centimeter
1062 scale and then expect to somehow “upscale” parameters to apply the same model at a kilometer
1063 scale. [Note: As an aside, over very large field-length and field-time scales, we point out that
1064 homogenization effects of molecular diffusion *may* become more significant, lessening impacts of
1065 some preferential pathways.] Similarly, a CTRW-based approach can be applied over a range of
1066 *time* scales, because the power law accounting for temporal effects can be as broad as needed. In
1067 these cases, temporal effects are critical, because at the continuum (Darcy) scale, streamlines do
1068 not change but residence times do. Specifically, for example, a model formulation with a fixed set
1069 of parameters can interpret transport measurements in the same domain, but acquired under
1070 different hydraulic gradients or (~~fluid velocities~~), and thus domain residence times (Berkowitz and
1071 Scher, 2009). Indeed, because of the temporal accounting, CTRW has been applied successfully

1072 over scales from pores (e.g. Bijeljic et al., 2013) to kilometers (e.g. Goeppert et al., 2020), with
1073 parameter calibration at the relevant scale of interest. In principle then, ~~too,~~ a calibrated model
1074 shown to be ~~effective/~~ meaningful over one region of a porous medium or geological formation can
1075 offer at least a reasonable estimate of transport behavior elsewhere in the medium/formation, at a
1076 similar length/time scale, and as long as the medium/formation can be expected to have reasonably
1077 similar hydrogeological structure and properties.

1078 ~~And f~~Finally, another critical aspect must be pointed out with regard to *continuum-scale*
1079 transport models as outlined in Sect. 3.2. The preceding discussion leads to the stated need and
1080 desire – at least in principle – to achieve model “prediction”. This term appears often, but it is
1081 often used incorrectly. Fitting a model solution to data is of course not “prediction”. On one hand,
1082 using specific experiments and data sets, models can be used to *characterize* transport behavior,
1083 e.g., is transport Fickian or non-Fickian?, or, is a migrating chemical plume compact or elongated
1084 and ramified?, which is of fundamental importance. But if *prediction* is the ultimate goal
1085 (recognizing that addressing *prediction uncertainty* is yet another consideration), then we require
1086 multiple data sets from the same porous medium or geological formation, in the sense that we need
1087 measurements over a range of length scales, and/or over a range of time scales (i.e. same distance,
1088 different flow rates). An intended model can then be calibrated against one part of the data set; the
1089 calibrated model is then applied “as is” and the resulting solution, a (“prediction”), is compared
1090 against other (“previously unknown”) measurements. At the laboratory scale, such a protocol is
1091 feasible, but rarely executed. Rather, the literature generally reports fits of transport equation
1092 solutions *at specific scales* ~~(individual data sets at a given length scale),~~ and not over a range
1093 of scales, so that no real testing of “upscaling” or “prediction” is achieved. Thus, even at laboratory
1094 scales, true “predictive capability” of a model is rarely examined or reported. [Note: A similar
1095 approach to “prediction” can be done in a purely numerical/computational study, using “ground
1096 truth simulations” that are *assumed* correct (e.g. Darcy flow calculations and then streamline
1097 particle tracking for chemical transport in a highly-resolved domain; recall Sect. 3.3.1), and then
1098 comparing solutions from a continuum (e.g. partial differential equation) model solution. But it
1099 should be recognized that results from *assumed* simulation methods are often unsatisfactory when
1100 compared against experimental measurements and field observations.]

1101 And at the field scale, the situation is even less satisfying; large-scale field tests for chemical
1102 transport are difficult and expensive to execute, so that systematic data sets that enable testing of
1103 model “prediction” ~~– as well as even initial calibration of a transport model –~~ are essentially non-
1104 existent. Moreover, while larger-scale structural features can be identified in principle via non-
1105 invasive geophysical methods, higher resolution sampling and measurements of hydraulic
1106 conductivity and geochemical parameters are ~~Moreover, at the field scale, there are~~ necessarily
1107 highly limited. As a result, numbers of measurements, so that oft-used, (and non-unique)
1108 interpolation of sparse concentration measurements is employed to yield (ideally 3d) contour maps
1109 of hydrogeological parameters and actual chemical concentrations; but interpolation will
1110 unrealistically smooth and dampen existing non-uniform, ramified and irregular preferential
1111 pathways (recall Fig. 2). Thus, notwithstanding the extensive research efforts reported in the

1112 literature, truly comparative studies using field measurements – to genuinely test proposed
1113 “upscaling” methodologies – are essentially non-existent (e.g. Berkowitz et al., 2016)⁴. In this
1114 context, then, we note that criticism in the literature that a given continuum model “demonstrates
1115 no predictive capability” is in fact not generally based on its assessment relative to sufficiently
1116 resolved, representative, and real data sets.

1117 Finally, it is important to recognize that models are most commonly tested against 1d, section-
1118 averaged concentration breakthrough curves, which can be (i) measured directly in laboratory
1119 column experiments, (ii) estimated or derived in 2d/3d laboratory flow cells by averaging over
1120 control planes, or (iii) estimated from limited monitoring well measurements (single or multi-level
1121 sampling with depth) at a fixed number of locations. The latter case, in particular, requires
1122 extensive interpolation and/or assumption of a large-scale, essentially 1d and uniform,
1123 macroscopic flow field. Moreover, chemical transport model discrimination often requires
1124 breakthrough curves that extend over the late time tailing, which are particularly difficult to
1125 determine in field conditions, due both to interruptions or lack of practicality in well monitoring
1126 at long times, and to detection limits of measurement methods. While reliance on such 1d (section
1127 averaged, over some control plane) breakthrough curves may not be ideal, it is often the reality
1128 in terms of feasible data acquisition. As a direct consequence, model selection, model parameter
1129 fits, and model calibration results may each (and all) be non-unique and lead to confusing or
1130 conflicting conclusions. It is therefore critical that we at least select from mechanistic-stochastic
1131 models based on fundamental laws of physics, with parameters that have physical meaning, as
1132 discussed in Sect. 3.3.2, rather than from models invoking purely statistical distributions or
1133 assumptions known to be incorrect.

1134

1135

1136 **5 Concluding remarks**

1137

1138 The ideas, arguments and perspectives offered here represent an effort to somehow summarize
1139 and synthesize an understanding of existing approaches and methods proposed to quantify
1140 chemical transport in subsurface hydrological systems. The literature on this subject is vast,
1141 extending over decades, and measurements and observations of chemical transport range from
1142 pore-scale microfluidic laboratory cells to aquifer field scales. A similarly broad range of model
1143 formulations has been proposed to quantify and interpret these measurements/observations. And
1144 yet, outcomes of these efforts are often largely unsatisfactory.

1145 We contend that modeling obstacles arise largely because domain heterogeneity – in terms of
1146 porosity, hydraulic conductivity, and geochemical properties – is present over multiple length
1147 scales, so that “unresolved”, practically unmeasurable heterogeneities and preferential pathways
1148 arise at every length scale. Moreover, while *spatial* averaging approaches are effective when
1149 considering overall fluid flow – wherein pressure propagation is essentially instantaneous and the
1150 system is “well mixed” – purely *spatial* averaging approaches are far less effective for chemical
1151 transport, essentially because well-mixed conditions do not prevail. We assert here that an explicit

1152 accounting of *temporal* information, under uncertainty, is an additional – but *fundamental* –
1153 component in an effective modeling formulation. As a consequence, we argue that for continuum-
1154 scale analysis, mechanistic-stochastic models such as those outlined in Sect. 3.2 must be invoked
1155 to account explicitly for both “additional” temporal effects and unresolved heterogeneity. Clearly,
1156 no single model is “best” for all situations and objectives, but any selected model must be
1157 physically relevant and justified.

1158 We further assert, as an outcome of these arguments, that “upscaling” of chemical transport
1159 equations – in the sense of attempting to develop and apply chemical transport equations at large
1160 ~~(length)~~ scales based on measurements and model parameter values obtained at significantly
1161 smaller length scales – is very much an unattainable holy grail. Rather, because probabilistic
1162 considerations required to account for small-scale fluctuations do not necessarily “average out” –
1163 ~~(and can propagate from local to larger spatial scales);~~ – we maintain that it is necessary to
1164 formulate and, calibrate ~~and apply~~ models, and then apply them, using measurements over spatial
1165 scales with at similar orders of magnitude measurement scales of interest, in both space and time.

1166 In all of our efforts to reasonably model chemical transport in subsurface hydrological systems,
1167 we should recognize and accept the objective of advancing our science by integrating theory,
1168 computational techniques, laboratory experiments and field measurement, with the aim of
1169 extracting broadly applicable insights and establishing practical, functional tools. In this context,
1170 as a close colleague and mentor said to me many, many years ago, “remember, this is hydrology,
1171 with very real problems to address...we’re not doing string theory”¹.

1172 We have included many points for discussion and open thought. Understandably, ~~t~~The reader
1173 may not agree with all arguments and conclusions raised here, but scholarly debate is critical: it is
1174 hoped that this contribution will stimulate further discussion, assist in ordering classification of
1175 the (often confusing) terminologies and considerations, and identify the most relevant, real
1176 questions for analysis, implementation and future research.

1177 We hope that the above thoughts and illustrations (i) encourage careful consideration prior to
1178 data collection, ~~(whether from field measurements, laboratory experiments, and/or numerical~~
1179 ~~simulations)~~, (ii) assist in experimental design and subsequent analysis, and, even more
1180 significantly, (iii) influence the research agenda for the field by challenging researchers to ask and
1181 address appropriately formulated questions. In terms of “modeling” efforts: recall the statement
1182 by Manfred Eigen (Nobel prize chemistry, 1967): “A theory has only the alternative of being right
1183 or wrong. A model has a third possibility: it may be right, but irrelevant.”
