14 Abstract.

- 15 The Lake Chad Basin, located in the center of North Africa, is characterized by strong climate seasonality with a pronounced
- short annual precipitation period and high potential evapotranspiration. Individual evapotranspiration.
- 17 supply as well as for agriculture and groundwater related ecosystems. Thus, assessment of groundwater recharge is very
- 18 important although difficult, because of the strong effects of evaporation and transpiration as well as limited available data.
- 19 A simple, generalized approach, which requires only a small number of field data, freely available remote sensing data as well
- as well-established concepts and models, is tested for assessing groundwater recharge in the southern part of the basin. This
- 21 work uses the FAO-dual K_c concept to estimate E and T coefficients at six locations that differ in soil texture, climate, and
- 22 vegetation conditions. Measured values of soil water content and chloride concentrations along vertical soil profiles together
- with different scenarios for E and T partitioning and a Bayesian ca ion approach are used to numerically simulate water
- 24 flow and chloride transport. Average groundwater recharge rates and the associated model uncertainty at the six locations are
- assessed for the 2003-2016 time-period.
- 26 Model results show that interannual variability of groundwater recharge is generally greater than the uncertainty of the
- 27 modelled groundwater recharge. Furthermore, the soil moisture dynamics at cations are limited rather by water availability
- 28 for evaporation in the uppermost part of the soil and by water uptake in the root zone than by the reference evapotranspiration.

29 1 Introduction

- 30 The Lake Chad Basin (LCB) is one of the largest endorheic basins of the world with an area of approximately 2.5 million km².
- 31 The basin covers parts of Algeria, Cameroon, Central African Republic, Chad, Libya, Niger, Nigeria, and Sudan. According
- 32 to the Lake Chad Basin Commission (LCBC, 2012), 45 million inhabitants are settled in the basin. The study areas Salamat

- 33 and Waza Logone are located in the southern part of the LCB along the Chari-Logone, the major tributary river system to the
- 34 Lake Chad (Figure 1), which accounts for around 80-90% of the Lake Chad inflow (Bouchez et al., 2016).
- 35 Groundwater is an important source for drinking water supply as well as for agriculture and groundwater related ecosystems
- 36 in the LCB. The Lake Chad, the rivers, and the floodplains of the major rivers are characterized by strong seasonality, due to
- 37 a pronounced short annual precipitation period and high potential evapotranspiration. Groundwater recharge, evaporation,
- 38 transpiration, and the entire hydrological budget depend strongly on seasonality. However, the impact of transpiration as a
- 39 potentially significant process of the hydrological budget (Jasechko et al., 2013) has not yet been intensively explored in the
- 40 area (Bouchez et al., 2016).
- 41 Many studies were published concerning the hydrological behaviour and budget of the Lake Chad, due to its substantial and
- 42 frequent open water surface changes and related consequences to the population and the environment (e.g. Bouchez et al.,
- 43 2016; Lemoalle et al., 2012; Olivry et al., 1996; Vuillaume, 1981). Another important topic associated to Lake Chad is
- 44 groundwater recharge by infiltration of lake water into the Quaternary aquifer, which was estimated by isotopes studies (Fontes
- 45 et al., 1969; Fontes et al., 1970; Gaultier, 2004; Zairi, 2008), water and salt budgets (Bader et al., 2011; Carmouze, 1972;
- 46 Roche, 1980) or hydrogeological models (Isihoro et al., 1996; Leblanc, 2002). Local scale studies focusing on the hydrological
- 47 processes in the vadose zone are largely missing in the LCB. Recently Tewolde et al. (2019) published such a study using
- 48 stable isotope and chloride concentrations in partly the same soil profiles used in this work.
- 49 For vadose zone studies, partitioning evapotranspiration (ET) into its respective soil evaporation (E) and plant transpiration
- 50 (T) components is crucial for process-based understanding of fluxes (Anderson et al., 2017). There are a number of
- 51 measurement and modelling approaches that can be used to estimate E and T separately. Some of the measurements include
- 52 micro-lysimeter, soil heat pulse probes, Bowen ratio, and Eddy covariance to determine E; and sap flow, chambers, and
- 53 biomass-transpiration relationship to measure T (Kool et al., 2014). Evapotranspiration partitioning can also be estimated
- 54 directly by using stable isotopes to assess the ratio between E and T (Wu et al. 2016). Stable isotopes were used in combination
- 55 with Eddy covariance on semi-arid environments as well (Aouade et al., 2016).
- 56 The Food and Agricultural Organization of the United Nations (FAO) published a model (Allen et al., 1998) that uses an
- 57 empirically defined crop coefficient (K combination with a respect ET (ET₀) to calculate crop evapor irration (ETc).
- 58 There are two approaches for this method: single coefficient and dual crop coefficient. The FAO-dual Kc model is a validated
- 59 method for ET partitioning and the most commonly applied (Kool et al., 2014). It has been widely used with good results for
- 60 numerous crops under different conditions: e.g. wheat and maize in semi-arid regions (Shahrokhnia and Sepaskhah, 2013),
- 61 wheat in humid climate (Vieira et al., 2016), cherry trees in temperate continental monsoon climate (Tong et al., 2016), irrigated
- 62 eucalyptus (Alves et al., 2013), and canola in terrestrial climate (Majnooni-Heris et al., 2012).
- 63 Quantification of water fluxes in the vadose zone and linking atmospheric water and solute input at the upper boundary of the
- 64 soil with water and solute fluxes at different soil depths is frequently implemented using different type of models. Numerical
- 65 models need information on vadose zone properties for accurate parametrization to link fluxes with state variables such as
- 66 unsaturated hydraulic conductivity and water retention curve. Estimation of effective soil hydraulic parameters, which are

parameters obtained from inverse modelling can be ambiguous, if multiple parameters are simultaneously considered and boundary conditions are not well known. Combining different state variables of water flow and solute transport in one objective function was found to be a strategy for appropriate parametrization (Groh et al., 2018; Sprenger et al., 2015) and for the transient simulation of water and solute fluxes. However, large amount of data are necessary to obtain accurate estimates of state variables, which are rarely available in remote areas of Africa, and measurement of related variables are associated with a huge effort in such environments. Pedotransfer functions (PTF) bridge available and needed data and are frequently used to quantify soil parameters (van Looy et al., 2017; Vereecken et al., 2016). PTF strive to provide a balance between data accuracy and availability (Vereecken et al., 2016). Since PTF usually do not consider soil structure, their results are better for homogeneous soils than for structured ones (Sprenger et al., 2015; Vereecken et al., 2010). Recharge occurs even in the most arid regions, mainly due to concentration of surface flow and ponding with lateral and vertical infiltration (Lloyd, 1986). Direct recharge by precipitation is possible in semi-arid regions, but intermittently, owing to the fluctuations in the periodicity and volume of precipitation that is inherent to such regions (Lloyd, 2009). Scanlon et al. (2006) synthesized recharge estimates for semiarid and arid regions globally. They found that recharge is sensitive to land use and cover changes, hence management of such changes are necessary to control recharge. Moreover, they stated that average recharge rates in semi-arid and arid regions range from 0.2 to 35 mm yr⁻¹, representing 0.1 to 5% of long-term average annual precipitation. Edmunds et al. (2002) estimated direct recharge rates from precipitation in the Manga Grasslands in NE Nigeria (western LCB) at rates between 16 mm year-1 and 30 mm yr-1. Using the same method, they appraised the regional direct recharge for north Nigeria at 43 mm year⁻¹, which highlights the importance of infiltration from precipitation to the groundwater table at regional scale. Recently, Cuthbert et al. (2019) investigated the relationship between precipitation and recharge in sub-Saharan Africa using multidecadal hydrographs. They found that focused recharge predominates in arid areas and is mainly controlled by intense rainfall and flooding events. Intense precipitation, even during years of lower annual precipitation, results in some of the largest years of recharge in dry subtropical locations. The Chloride Mass Balance (CMB) approach is a widely used technique for estimating groundwater recharge. Edmunds and Gaye (1994) used interstitial water chloride profiles from the unsaturated zone, in combination with measurements of chemical parameters from dug wells samples, to calculate groundwater recharge in the Sahel (mean annual rainfall 1970-1990 around 280 mm). A recharge rate of 13 mm year-1 over the studied area was obtained. They conclude that it is an inexpensive technique, which can be applied in many arid and semi-arid areas. Tewolde et al. (2019) applied the CMB on soil profiles of the LCB, which are partly used in this study. They estimated generally lower annual recharge in Salamat (3 to 19 mm year⁻¹) compared to Waza Logone (50 to 118 mm year⁻¹). One major difficulty of CMB is the choice of a representative chloride concentration, or the concentration that prevails at large depths, when evapotranspiration effects extinguish, particularly for soils with a strong vertical chloride concentration variability.

valid at the modelling scale, might be laborious. Furthermore, parameter estimation might vary significantly depending on the

measurement method (Mertens et al., 2005), when water and solute fluxes dynamics are considered. Hydraulic and transport

In general, time series of relevant data for estimating groundwater recharge is scarce in the LCB. A simple, generalized 100 101 approach, which requires only a small number of field data, freely available remote sensing data, and well-established concepts 102 and models is tested for assessing groundwater recharge in the semi-arid part of the LCB. This work applies the FAO-dual K_c 103 concept to estimate E and T coefficients at six locations, which differ in soil texture, climate, and vegetation conditions. 104 Measured values of soil water content and chloride concentrations along vertical soil profiles, partly published by Tewolde et al. (2019), together with different scenarios for E and T partitioning and a Bayesian calibration approach are used to 105 106 numerically simulate water flow and chloride transport as well as produce time series of recharge. Average potential 107 groundwater recharges and the associated model uncertainty are assessed for the 2003-2016 time-period.

2 Data and methods

2.1 Study sites

108

109

- The LCB is a Mesozoic basin and a major part of its geology comprises sedimentary formations from the Tertiary and Quaternary periods (LCBC, 1993). The Quaternary sediments form a continuous layer of fluviatile, lacustrine and aeolian sands. These medium to fine-grained sands act as an unconfined transboundary aquifer, as do all aquifers in the LCB, and are isolated from underlying aquifers by a thick layer of Pliocene clay (Leblanc et al., 2007; Vassolo, 2009). The Tertiary formation (Continental Terminal) consists of sandstones and argillaceous sands and is a classic example of a confined aquifer system that becomes artesian in the surroundings of the Lake Chad (Ngatcha et al., 2008). The availability of water from precipitation as well as the deposition characteristics of the aquifer play an important role in the recharge of the upper unconfined sands
- 117 (Vassolo, 2009).
- 118 The study sites (Figure 1, Table 1) are located in the Salamat and Waza Logone floodplains in the southern Sahel zone and
- 119 correspond to those published by Tewolde et al. (2019) for these areas, except for site ST4. Site ST4 is located far from any
- 120 floodplain, which is the focus of this research, and its soil composition and vegetation are very similar to those from site ST3.
- Thus, including the location would not provide any additional information.
- 122 Sites ST1 and ST2 in Salamat as well as WL1 and WL3 in Waza Logone are annually flooded over three months, site WL2
- 123 located at the edge of the Waza Logone wetland is flooded only one month whereas site ST3, although close to ST1 in Salamat,
- 124 is never flooded. In the Salamat region, mainly sorghum is grown with trees such as Acacia albida, A. scorpioides and A.
- 125 sieberana present along the margins of the floodplains (Bernacsek et al., 1992). In the Waza Logone area, vegetation depends
- on the duration of submersion, being the grass savannahs flooded for longer periods of time (Batello et al., 2004).

2.2 Climate data

- 128 Monthly precipitation and potential evapotranspiration data from 1970 to 2019 for the specific sites in Salamat and Waza
- 129 Logone are extracted from the CRUTS 4 database (Harris et al., 2020). The potential evapotranspiration is calculated using
- 130 the Penman-Monteith method and is considered herein as the reference evapotranspiration (ET₀). Wind speed at 10 m above

https://doi.org/10.5194/hess-2021-581

Preprint. Discussion started: 19 November 2021

© Author(s) 2021. CC BY 4.0 License.

- 131 ground for Salamat and Waza Logone were obtained from Didane et al. (2017). To adjust these values for 2 m above ground,
- 132 a correction factor of 0.7479 was applied, based on a logarithmic wind speed profile (Allen et al., 1998).
- 133 Average annual precipitation in Salamat and Waza Logone are 807 mm and 709 mm, respectively. The rainy season is typically
- 134 from May to September with maximum precipitations in July and August. Average annual values of ET₀ are 1718 mm in
- 135 Salamat and 2011 mm in Waza Logone, exceeding annual precipitation by more than twice. However, in the second half of
- 136 the rainy season the monthly water balance is positive. The average water balance for July until September between 2003 and
- 137 2016 is 131 ± 101 mm month⁻¹ and 90 ± 63 mm month⁻¹ for Salamat and Waza Logone, respectively (Figure 2).
- 138 Chloride concentration in ponding water was measured in four samples in Salamat. It varies between 2.5 mg l⁻¹ and 25 mg l⁻¹.
- 139 Precipitation was sampled using a Hellmann rainwater collector in N'Djamena. This devise has been design to reduce to a
- 140 minimum evaporation by using a narrow soft polypropylene plastic tube of 4 mm inner diameter to connect the funnel on top
- 141 of the devise with the bottom of the 3 l collection bottle (Gröning et al., 2012). Once precipitation starts, water rises in the
- bottle and into the tube decoupling the atmosphere from the bottle headspace to prevent evaporation. To ensure that evaporation
- is as low as possible, sampling took place event wise. Chloride concentration in precipitation was measured in 42 out of 147
- samples collected in N'Djamena between 2014 and 2020 for different precipitation events and stages of the rainy season. Not
- 145 all rain samples could be analyzed for chloride concentration, due to limited sample amount in minor events at the beginning
- and end of the rainy season.
- 147 Average chloride concentration in May is 2.5 ± 2.3 mg Γ^{1} (3 samples). Precipitation in June to September have relatively low
- 148 chloride concentrations declining from 0.6 ± 0.3 mg 1^{-1} to 0.26 ± 0.12 mg 1^{-1} and 0.38 ± 0.14 mg 1^{-1} at the end of the season.
- 149 Strong rain events in July and August have chloride concentrations between 0.2 and 0.3 mg l⁻¹. The annual wet chloride
- deposition sums to 1.8 ± 0.5 kg ha⁻¹. The measured values are in the range of published data (Goni et al., 2001; Laouali et al.,
- 151 2012; Gebru and Tesfahunegn, 2019). Dry deposition of chloride is estimated between 10 30% of wet deposition (Bouchez
- 152 et al. 2019).

153 **2.3 Soil and vegetation data**

- 154 At each study site, vertical soil profiles were core-drilled using a hand auger. In Salamat, soil profiles were sampled in 2016
- 155 (Tewolde et al., 2019) and 2019. In Waza Logone soil samples were sampled in 2017 only (Tewolde et al., 2019), due to
- 156 security reasons in 2019. Each of the soil profiles were sampled in 10 cm intervals and filled into headspace glass vials and
- 157 plastic bags.
- 158 Each soil fraction was tested for grain size distribution using sieving and sedimentation standard procedures (Tewolde, 2017).
- 159 Classification follows the soil texture triangle by the US Department of Agriculture (Šimůnek et al., 2011).
- 160 Chloride concentration was analyzed after aqueous extraction from oven dried (105°C for 24 hours) soil samples following
- the standard guideline DIN EN 12457-1 (Tewolde, 2017).
- 162 Gravimetric water content is the mass of water contained in a sample as a percentage of the dried soil mass. It was obtained
- by weighting the moist sample, oven drying it at 105°C for 24 to 48 hours, and weighting it again. Since bulk densities were

- 164 not measured in the field, volumetric water contents are obtained multiplying the gravimetric water contents for each soil type
- and location by typical bulk densities obtained from the Global Gridded Surfaces of Selected Soil Characteristics database
- 166 (Global Soil Data Task Group, 2000).
- 167 The type of vegetation and the annual cycle of crops, length of the flooding period, and vegetation throughout the dry period
- 168 were mapped during field work and documented by surveying resident population. In addition, MODIS vegetation indices data
- 169 (Didan, 2015) were used to justify the documented annual cycle of phenology (Figure 3).

170 3 Modelling methodol =

- 171 Our approach assumes that groundwater recharge is controlled by precipitation, evaporation, and transpiration (surface runoff
- 172 can be neglected due to the flat topography). Soil moisture and chloride concentration along the soil profile at a certain time
- are indicators for evaporation and transpiration processes within the root zone of soils. Chloride concentration in soil depends
- on its input via precipitation and washing out of dry deposition as well as on the amount of evaporation and transpiration on
- the soil surface and in the root zone.
- 176 The first estimation of evapotranspiration was carried out using the FAO-dual crop coefficient approach that assesses E and T
- 177 individually. The uncertainty of E and T partitioning on soil water and chloride concentration in the six soil profiles was
- assessed by considering scenarios of mean, maximum, and minimum E and T coefficient (see 3.1). Calculated time series of
- 179 E and T for the site-specific vegetation were used to estimate soil water and chloride concentration profiles at the sampling
- 180 time in each of the six locations using Hydrus-1D. A Bayesian approach was applied to consider uncertainties in chloride
- 181 concentrations of precipitation and dry deposition, in partitioning E and T as well as in the parametrisation of the soil hydraulic
- 182 model.

183

3.1 Partitioning of evaporation and transpiration

- 184 Evapotranspiration (ET) is the combination of two main processes driven by atmospheric demand: evaporation from the soil
- 185 (E) and transpiration through the stomata of plants (T) and is an important component of the water balance, especially in semi-
- arid areas. The FAO provides a model (Allen et al., 1998) for estimating crop evaporation (ETq ed on an empirically
- defined crop coefficient (K mbined with a reference evapotranspiration (ET proposal proposal
- 188 coefficient and dual crop coefficient. The latter was applied in this work.
- The dual Kc method (Allen et al., 1998) is the sum of two coefficients, the basal crop coefficient (Kcb) that describes plant
- 190 transpiration and the soil water evaporation coefficient (Ke) that depicts evaporation from the soil surface. Kcb is defined as
- 191 the ratio of crop evapotranspiration over reference evapotranspiration (ET_c/ET_0), when the soil surface is dry and transpiration
- 192 occurs at a potential rate (i.e. unlimited water availability for transpiration). Ke is maximal when the topsoil is wet, but
- 193 diminishes with drying out of topsoil to become zero, if no water remains near the soil surface for evaporation.
- 194 The parameters required for the estimation of monthly ET_c are the monthly reference evapotranspiration (ET₀), the monthly
- basal crop coefficient (Kcb) and the monthly soil water evaporation coefficient (Ke):

© Author(s) 2021. CC BY 4.0 License.

196
$$ET_c = ET_0 * K_c = ET_0 * (K_{cb} + K_e)$$
, (2)

197 Onsite information on vegetation and phenology, such as month of planting, full emergence of crop, and harvesting was used 198 to define the monthly variation of vegetation at the study sites. These different vegetation periods were combined with crop 199 specific Kcb for sorghum and grass provided in Allen et al. (1998) for sub-humid climate with relative humidity of 45% and average moderate wind speed of 2 m s⁻¹. To comply with the local semi-arid climate conditions in Salamat and Waza Lagone, 200 the coefficients Kcb for mid and end vegetation periods were adjusted as proposed by Allen et al. (1998). Monthly Kcb values 201 202 for acacia were estimated based on Do and Rocheteau (2003) and Do et al. (2008). Site-specific monthly variation of ground cover and flooding periods with ranges of crop coefficient (Kcb), soil water evaporation coefficient (Ke), and root depth are 203 204 provided in Table S1.

3.2 Modelling water flow and solute transport

3.2.1 Model concept, setup, and initial conditions

The chloride profiles measured in soil at a certain time represent the input histor water and solute budget from past 207 precipitation events and can be estimated by transient water flow and solute transport modelling. The model concept assumes 208 209 that atmospheric chloride input is restricted to solute in precipitation and that the chloride concentration profile results from 210 solute enrichment in the soil, due to evaporation and transpiration. A precise parametrization of the unsaturated flow and 211 transport model as well as a robust quantification of groundwater recharge are not possible with the available data and hence 212 cannot be the scope of this study. However, the model results estimate groundwater recharge magnitude and variability based 213 on information regarding soil texture and vegetation as well as associated results uncertainty. This proposed approach is 214 appropriate for locations with limited availability of long-term soil water measurements.

- The free software package Hydrus-1D version 4.17.0140 was used to simulate transient water flow and solute transport in the six variably saturated soil profiles. Hydrus-1D numerically solves the Richards (1931) equation for variably saturated water
- 217 flow, advection-dispersion equations for heat, and solute transport (Šimůnek et. al, 2009):

218
$$\frac{\partial \theta(h)}{\partial t} = \frac{\partial}{\partial z} \left[K(h) \left(\frac{\partial h}{\partial z} + \cos \alpha \right) \right] - S(h)$$
 (3)

219 with:

205

- 220 h soil water pressure head [L]
- 221 θ volumetric water content [L³L⁻³]
- 222 t time [T]
- 223 z spatial coordinate [L] (positive upwards)
- 224 S sink term $[L^3L^{-3}L^{-1}]$
- 225 α angle between flow direction and vertical axis
- 226 K(h) unsaturated hydraulic conductivity function [LT⁻¹]

- 227 The processes simulated in the six research sites were water flow, solute transport, and root water uptake. Because Hydrus-1D calculates with daily time step and data were only available at monthly scale, daily rate re calculated by dividing monthly 228 229 data by month-specific days and assumed constant over the whole month. Model running ended at the soil sampling time 230 (December 2016 and July 2019 for Salamat and June 2017 for Waza Logone). Progressive root growth was considered in all profiles except for ST2, in which the roots of the acacia trees were distributed along the whole profile and assumed invariant 231 over the simulation period. Since initial conditions of soil moisture and resident chloride concentration are unknown, arbitrary 232 233 values were adopted. To account for different residence times of water and chloride, due to different degrees of 234 evapotranspiration and unknown initial conditions, each model was run over a period of time long enough to allow the 235 exchange of at least one water column volume. Thus, total modelling periods are different depending on soil type at site: ST1, ST2 start in 1910, ST3 in 2010, WL1 and WL2 in 1990, and WL3 in 1970. All profiles were discretized into 101 nodes and 236
- 238 **3.2.2 Water flow**

- 239 For calculation of water retention (θ) and unsaturated hydraulic conductivity functions (K(h)), the Mualem-van Genuchten
- 240 (MVG) model (van Genuchten, 1980) was applied:

$$241 \quad \theta(h) = \begin{cases} \theta r + \frac{\theta s - \theta r}{[1 + |\alpha h|^n]^m} & h < 0 \\ \theta s & h > 0 \end{cases} \tag{4}$$

different horizons according to the soils types interpreted from the individual grain size distributions.

- 243 $k(h) = ksSe^{-1}[1 (1 Se^{l/m})^m]$ (5)
- 244 where:

- 245 $m = 1 \frac{1}{n}$; n > 1
- $246 \quad Se = \frac{\theta(h) \theta r}{\theta s \theta r}$
- 247 with
- 248 θ water content [-]
- 249 h hydraulic head [L]
- 250 residual water content
- 251 θ s saturated water content
- 252 α inverse of the air-entry value, empirical [L⁻¹]
- 253 n pore-size distribution index, empirical [-]
- 254 *l* pore-connectivity parameter, empirical ≈ 0.5 [-]
- 255 Se effective saturation [-]

Preprint. Discussion started: 19 November 2021

© Author(s) 2021. CC BY 4.0 License.

- 256 The initial parametrization of these functions was realized using pedotransfer fun simplemented in Rosetta (Schaap et al.,
- 257 2001), which is a dynamically linked library coupled to Hydrus-1D. The input parameters for each profile were the percentages
- of sand, silt, clay, and bulk density at several depths. Whenever consecutive layers of a profile showed almost the same grain
- 259 distribution (texture) and soil moisture, the layers were lumped in one and parameter averages were used in the model. The
- 260 tortuosity parameter 1 [-] of the MVG was set to 0.5 as proposed by Mualem (1976).
- 261 The upper boundary condition was defined as variable atmospheric condition, whereas the lower one was set to zero-gradient
- with free drainage of water for all profiles, except WL3 where confined groundwater conditions prevailed below the confining
- 263 clay layer encountered at 3.9 m depth. During drilling, groundwater was hit at 3.9 m depth, but rapidly rose to 2.6 m below
- surface. Consequently, a constant head condition was implemented at 2.6 m depth.

3.2.3 Root water uptake and root growth

- 266 The sink term (S) in the Richards' equation, defined by Feddes et al. (1978) as the volume of water removed from a unit
- 267 volume of soil per unit time due to plant water uptake, was considered in all soil profiles according to the prevailing vegetation
- 268 (Table S1). The Feddes' default parameters for grass were used in ST3 and Waza Logone profiles. In ST1, where sorghum
- 269 was planted, Feddes' parameters for corn were used because sorghum is not available in the list. According to Righes (1980)
- 270 sorghum and corn roots extract water from approximately the same soil depths and have similar average root density
- 271 distribution.

265

- 272 An average root depth of 1 m was adopted in ST1for the initial and end seasons, and 2 m for development and mid seasons. In
- 273 the case of acacia in ST2, the adopted parameters correspond to deciduous trees. The root depth of the acacia tree was
- 274 considered as constant over the whole simulation period with maximum root distribution at 0.5 m and decreasing distribution
- down to 2 m (Beyer et al., 2016). In ST3, the vegetation was defined as grass, while in WL1, WL2 and WL3 as grass with a
- 276 flooding period of 3 months in WL1 and WL3, but only one month in WL2. Rooting depth values used in these sites range
- 277 from 0.1 m to 0.5 m, depending on the growth stage of grass. The median maximum rooting depth value of annual grass in
- water-limited ecosystems is 0.37 m with a 95% of confidence in an interval of 0.26 m-0.55 m (Schenk and Jackson, 2002).

279 **3.2.4 Solute trans**

- 280 The chloride concentration in soil water was simulated using an equilibrium advection-dispersion model implemented in
- 281 Hydrus1-D. Hydrodynamic dispersion was implemented considering dispersivity values of 10 the individual layer
- 282 thickness in the soil model, a molecular diffusion coefficient of 1.3 x 10^{-9} , and a tortuosity factor as defined by Millington
- and Quirk (1961). Adopted dispersivity values are within reported ranges of 0.8 cm to 20 cm (Vanderborght and Vereecken,
- 284 2007; Stumpp et al, 2009, 2012).
- 285 A time-dependent concentration boundary condition was applied to the upper boundary and a zero-gradient boundary condition
- 286 to the lower boundary. The transient liquid phase concentration of infiltrating water follows measured chloride concentration

- 287 in precipitation sampled in N'Djamena. Chloride concentration of ponding water correspond to four values measured in
- 288 Salamat that range from 2.5 mg l⁻¹ to 25 mg l⁻¹ with an average of 9 mg l⁻¹.

289 3.2.5 Crop evapotranspiration scenario def

- 290 Since crop evapotranspiration was not measured, values were simulated using Kce, and root depth instead. Because these
- 291 parameters are given in ranges (Table S1), seven scenarios with different combination of Kcb, Ke, and root depth were
- developed to assess ranges of crop evaporation (Table 2). Scenario "Mean" corresponds to the average value of all parameters.
- 293 Scenarios "Min" and Max" combine the minimum and maximum values, respectively. Scenario "Mix-1" combines minimum
- 294 Kcb with average Ke and root depth, scenario "Mix-2" minimum Ke with average Kcb and root depth whereas scenario "Mix-
- 295 3" combines minimum root depth with average Ke and Kcb.

3.2.6 Bayesian model calibration

- 297 Based on the crop evapotranspiration scenarios, the models were calibrated and model uncertainty was estimated using a
- 298 Bayesian calibration. Bayesian analysis is a combination of the data likelihood and the prior distribution using the Bayes
- 299 theorem (ter Braak and Vrugt, 2008). The sum of likelihood functions for soil moisture and chloride concentration was
- 300 implemented to calculate the log-likelihood of a simulation given the observations and standard deviations at each calibration
- 301 step. The posteriori parameter distribution was estimated using the Differential Evolution Markov Chain Monte-Carlo (DE-
- 302 MCzs) algorithm with three sub-chains (ter Braak and Vrugt, 2008) implemented in the R package BayesianTools (Hartig et
- 303 al., 2019). The number of iterations was defined individually according to a Gelman-Rubin reduction factor < 1.2.
- 304 In the calibration, scaling factors ranging from 0.75 to 1.25 for the MVG parameters (saturated volumetric water content,
- 305 alpha, and n) were adopted individually. However, ranges for MVG model parameter n were constraint to n > 1.01. Log-
- 306 transformed saturated hydraulic conductivity for each layer was considered with ranges from -0.5 to 0.5. The scaling factor
- 307 for transpiration was used as divisor for evaporation simultaneously to remain within the calculated rate of ET₀. From all
- 308 accepted model runs, 100 were randomly selected at each individual location to evaluate average model results and standard
- 309 deviations.

296

310 **4 Resul**

311 **4.1 Grain size distrib**

- 312 Soil textures were defined based on grain size distributions of the six profiles (Figure 4) according to the US Department of
- 313 Agriculture soil texture triangle. Most of them are fine-grained soils (clay, sandy clay) and fine-grained soils with intercalation
- 314 of thin sand and loam layers. Only soil profile ST3 is dominated by sand and sandy clay loam.

4.2 Model parametrization

The calibrated parametrization of the MVG model for each layer of the six sampling locations are plausible (Table 3). The posterior distributions of the Bayesian calibration show the sensitive parameters of the model fit. For ST1, these are negative conductivity is less sensitive (Fig. S1). For ST2, the sensitivities of the model parameters are similar with the saturated hydraulic conductivity of the upper layer being sensitive and the influence of chloride concentration being less significant (Fig. S2) compared to the other locations. The model fits of the data from site ST3 are generally insensitive. Only the model parameters alpha, n, a turated hydraulic conductivity of the upper layer as well as chloride concentration in precipitation show tighter posteriori distributions (Fig. S3). For site WL1, the model parameters n of layers 1, 2, and 3 and as well as the saturated water content of layers 3 and 5, and subordinately of layer 4, are sensitive. The parameters alpha for layers 1 to 5, the chloride concentration, and the fraction of transpiration are hardly sensitive in the range of the prior distribution (Fig. S4). For WL2, the model parameters n of all layers, the saturated hydraulic conductivity of layer 3, and the saturated water content of layers 2 and 3 are sensitive (Fig. S5). For WL3, the saturated water contents of layer 2, the saturated hydraulic conductivity of layers 1 and 2, and the fraction of transpiration in evapotranspiration are sensitive (Fig. S6).

4.3 Soil water content, chloride concentration and groundwater recharge

330 Measured and simulated water content and chloride concentration profiles for individual scenarios are shown in Fig. 5. The average root mean squared error (RMSE) of simulated wa ontent for all individual scenarios ranges from 0.02 to 0.06 331 332 (Table 4). In general, the models reproduce well the water content and chloride concentrations. However, dynamic of measured and simulated water contents differ considerably for ST1 and partly for ST2, although maximum values do match. The models 333 334 do not represent the high chloride concentrations in the uppermost part of soil profiles for ST3, WL1, and WL2. The standard 335 deviations in chloride concentration of the randomly selected model runs are exceptionally high in the lower part of ST2 that 336 corresponds to the poor sensitivity of the chloride concentration at the upper boundary and the comparably wide range of 337 measured chloride concentration in ponding water in the Salamat region (2.5 mg l^{-1} – 25 mg l^{-1}). 338 The interannual variability of modelled groundwater recharge differs considerably among locations (Figure 6, Table 5). In 339 general, interannual groundwater recharge variability depends on vegetation and soil texture with related water retention 340 capacity. Vegetation with deep roots on soil with comparably high water retention capacity have a stronger interannual variability, e.g. ST1, ST2 where recharge occurs only in years with high precipitation. Fine textured soils with shallow rooting 341 342 vegetation have an intermediate variability (WL1, WL2, and WL3), where years without recharge occur only during drought 343 periods. The coarser textured soils with grass cover has low interannual recharge variability (ST3) and recharge occurs each year. Years with high precipitation, e.g. 2006, 2007, and 2008 in Waza Logone as well as 2010 in Salamat, produced strong 344 345 groundwater recharge.

346 The highest average annual recharge (93 mm) was calculated for ST3 in Salamat (Table 6), where water balance during the 347 rainy season (July-September) is higher compared to the Waza Logone region and shallow rooting vegetation on comparably coarse soil texture with low water retention capacity and higher hydraulic conductivity prevail. The other locations in Salamat 348 349 have lower calculated annual recharge, due to deep rooting vegetation and higher soil water retention capacity. The impact of soil texture on annual groundwater recharge becomes apparent by comparing the three location in Waza Logone with the same 350 vegetation on soils with different water retention capacities and hydraulic conductivities. Groundwater recharge expressed as 351 352 fraction of precipitation is between 1% and 4% (Table 5) and thus, within the range of 0.1 to 5% published by Scanlon et al. 353 (2006). Only at WL2 (8%) and ST3 (12%), where coarse soil textures enhance recharge, a comparably high fraction is 354 estimated. 355 Chloride concentration and water budget of the soils over the simulated time-period are rather unstable and differ for the six 356 locations. At location ST2 with clay loam soil covered by Acacia and grass, accumulation of chloride takes place over several 357 years, due to the high transpiration related to the effective field capacity (Figure 7). However, in high precipitation years, most 358 of the accumulated chloride is leached to groundwater and soil concentration diminishes. It should be noted that at this site, 359 the measured chloride concentrations cannot be reconstructed, if only input via precipitation is considered. The measured 360 profile can only be plausibly modelled with an additional input via ponding water. Chloride input at the upper boundary is consequently six-times higher at ST2 compared to the other locations considered in this study. 361 362 At location ST3, the chloride accumulation is much lower compared to the other locations. Chloride budget is controlled by 363 the fast groundwater recharge response to precipitation, which flushes chloride from the soil towards groundwater annually. The majority of chloride infiltrated with precipitation remains in the vadose zone over years and is leached towards 364 365 groundwater mainly during years with precipitation or water infiltration above threshold values (Figure 7). Chloride accumulation is highest in profiles with clay soils and high effective field capacity (ST1, WL1, and WL3). 366 Chemical memory effects are subject to the dynamics of the water and chl balance. Therefore, steady-state assumptions 367

4.4 Evaporation and transpiration

- The transpiration amount depends on the availability of water in the root zone and the type of vegetation cover. At ST1, annual transpiration presents two peaks: one related to sorghum and the other to grass (Figure 8). At each location and in every
- 372 simulation year, soil water content in the root zone reaches the wilting point defined by the specific parametrization of the root
- 373 water uptake model.

368

369

- 374 The actual evaporation rate depends mainly on the availability of water in the upper soil zone (Table 6). Clay and clay-loam
- 375 with relatively high water storativity have larger amounts of evaporated water compared to sand and loam soils. During dry
- seasons, the uppermost part of the soils dries up annually, which restricts evaporation strongly.

are unsuitable. Accurate estimations are only possible with transient assumptions.

Actual evapotranspiration is lower than the reference evapotranspiration most of the year. During and shortly after the rainy season, when sufficient soil water is available, actual evapotranspiration is comparable to or higher than ET₀ depending on the vegetation.

Soil texture information is helpful to limit possible MVG parameter ranges while searching for realistic parameter sets

407 408 (Sprenger et al., 2015). However, poor representation of soil moisture dynamic using MVG parameters derived using Rosetta are reported (Sprenger et al., 2015) and indications are given that soil structure has to be taken into account (Vereecken et al., 2010), especially for soils where high rock content influences water flow due to inherent heterogeneity (Sprenger et al., 2015). The soils at the locations considered in this study belong to Quaternary sediments in the Lake Chad basin and heterogeneity, due to rock fragments is largely absent. Furthermore, soil moisture dynamics over the year are much higher in soils of the Waza Logone floodplain compared to soils from the more humid regions in the south, where precipitation, although large, occurs over 4-5 months and lacks over the rest of the year. It is expected that high soil moisture dynamics, rather homogeneous soils, and the monthly resolution of climate data result in minor impact of soil structure on MVG parametrization and groundwater recharge as shown in section 3.2. Soil moisture dynamics at all locations considered in this study are limited by water availability for evaporation in the uppermost part of the soil and by water uptake in the root zone, but not by the reference evapotranspiration. However, because time resolution of precipitation and evapotranspiration data is monthly, the models probably underestimate soil moisture dynamics. Calculated chloride concentrations for the soil profiles give indications of appropriate MVG parametrization as well as evaporation and transpiration partitioning. However, uncertainty of chloride input and its transient variability in particular is expressed in rather wide and partly bimodal distribution of the scaling factor (sc_Conc) included in the calibration (Figures S1-S6 in supplement material). On one hand, measured chloride concentration in precipitation are in agreement with other studies in central Africa (Goni et al., 2001; Laouali et al., 2012; Gebru and Gebru and Tesfahunegn, 2019) and its transient behaviour within the rainy season is considered in the applied model. On the other hand, impact of dry deposition is unknown, because of data scarcity and potential lateral flow of periodical flooding. Furthermore, due to the monthly resolution of the atmospheric boundary condition, extreme rain events that cause surface runoff cannot be reflected in the model. The variability of chloride concentration in some of the soil profiles, which cannot be completely reproduced by the model, indicates either a higher variability of chloride input and/or a larger variability in soil physics. Bouchez et al. (2019) identified a chloride deficit between deposition and river export in the Chari-Logone river system of 88% (only 12% of the deposited chloride is exported via river water). They refer to the chemical memory effect, which can play an important role in arid regions. Our simulations show the importance of the vadose zone for storage of chloride over longer periods of time, which explains the fate of chloride in the basin and confirms the chemical memory effect. In this context, it must be noted that the thickness of the vadose zone at the locations considered in this study is between 4 m and 21

409 m, where important amounts of chloride can be potentially stored leading to a strong delay of the chemical signal from

410 precipitation to groundwater.

In general, the calculated mean annual groundwater recharge values are within the ranges of 0.2 to 35 mm yr⁻¹ estimated by 411

412 Edmunds et al. (2002) using the CMB method in seven chloride profiles in northern Nigeria. The larger values (90 mm yr⁻¹ in

ST3 and 54 mm yr⁻¹ in WL2) are due to local coarse soil. 413

417

420

421 422

423

424

425

415 The quantitative estimation of groundwater recharge in the LCB is difficult, due to the scarce data availability and the expected low recharge quantities. Estimation of low recharge amounts in arid and semi-arid areas are usually ambiguous, because the 416 immanent measurement inaccuracies lead to uncertainties during data processing and modelling. Quantification of water and

solute fluxes in the vadose zone is often implemented using long-term time series of soil moisture, pressure heads, and 418 419 concentration data in combination with appropriate models. Monitoring of soil moisture and solute concentration over longer

periods at different depths and sites is difficult in the LCB, due to limited infrastructural prerequisites and challenging climatic

boundary conditions. The presented approach combines soil moisture and chloride concentration quantified along vertical soil

profiles in different locations within the LCB with numerical models and freely accessible data, while considering data

uncertainty. Calculated chloride concentrations for the soil profiles give indications of appropriate MVG parametrization as

well as evaporation and transpiration partitioning. Although dynamic of measured and simulated for both water contents and

chloride concentration differ considerably in profiles ST1 and partly ST2, their magnitudes agree largely. This is especially

426 important for chloride concentration in the middle and deeper parts of the profiles, where seasonal effects are mainly averaged.

427 Thus, the estimates of soil water balance and especially of groundwater recharge as well as the adopted soil physical parameters

428 are plausible.

429 Mean groundwater recharge values estimated in this study are different to those published in Tewolde et al. (2019). This is

due to the more extensive availability of chloride concentration data in precipitation for this study. In addition, Tewolde et al. 430

431 (2019) roughly estimated one value of saturated porosity for each profile. This parameter is rather sensitive in the Bayesian

432 calibration and several values along each of the profiles were considered in this study. In contrast to the assessment of

433 groundwater recharge with the CMB (Tewolde et al., 2019), the method used here allows not only estimates of mean recharge,

434 but also its interannual dynamics, variability, and the classification of the uncertainties of the input data and modelling results.

435 The interannual variability of groundwater recharge is generally higher than the uncertainty of the modelled groundwater

recharge. The soil moisture dynamics at all locations considered in this study are limited by water availability for evaporation 436

437 in the uppermost part of the soil and by water uptake in the root zone and not by the reference evapotranspiration.

438 Simulations show the importance of the vadose zone for storage of chloride over longer time-periods and explain the fate of

chloride in the basin. The thickness of the vadose zone at the locations considered in this study varies between 4 m and 21 m. 439

Important amounts of chloride can be potentially stored delaying strongly the chemical signal from precipitation to

441 groundwater.

- 442 Upscaling of the results to larger areas must be interpreted with caution since the considered combinations of soils and
- 443 vegetation probably do not cover all combinations present in Salamat and Waza Logone regions.

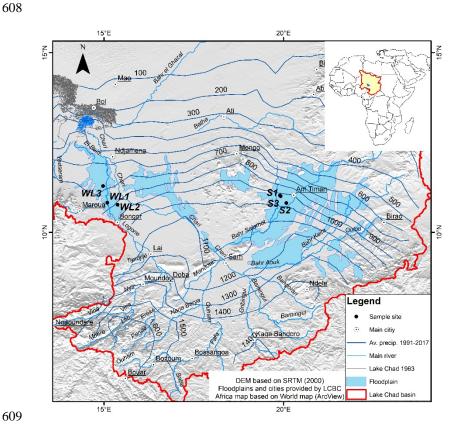

Figure 1: Location of the six soil sampling sites within the Logone and Salamat basins in the Lake Chad catchment. The map inlet shows the location of the Lake Chad basin in Africa.

614

615

616

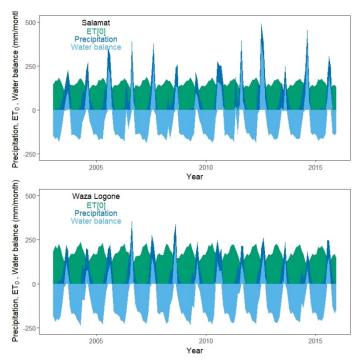

Figure 2: Monthly precipitation, reference evap spiration from the CRUTS 4 database (NCAR, 2017) and derived water balance for Salamat and Waza Logone.

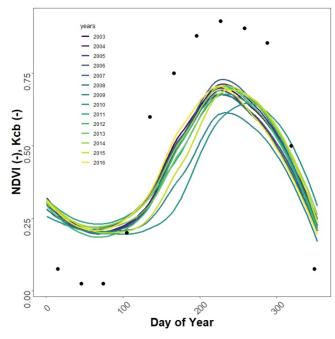

Figure 3: Average Normalized Difference Vegetation Index (NDVI, MODIS 16 interval and 250 m spatial resolution) measured between 2003 and 2016 in the Salamat region and estimated monthly basal crop coefficient (Kcb, black points) for location S3.

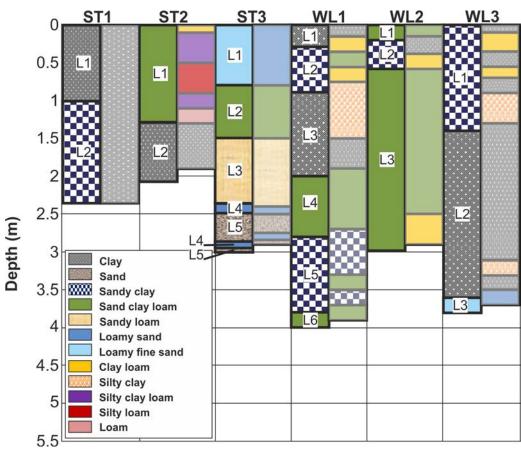

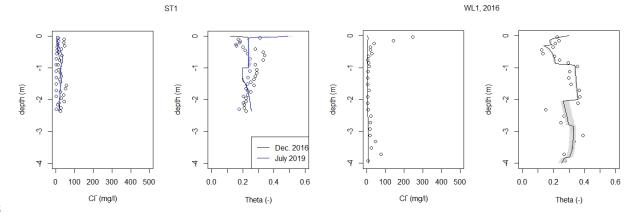

Figure 4: Soil textures used in the model (left column) defined according to grain size distribution analysis (right column) for each of the six soil profiles.

623

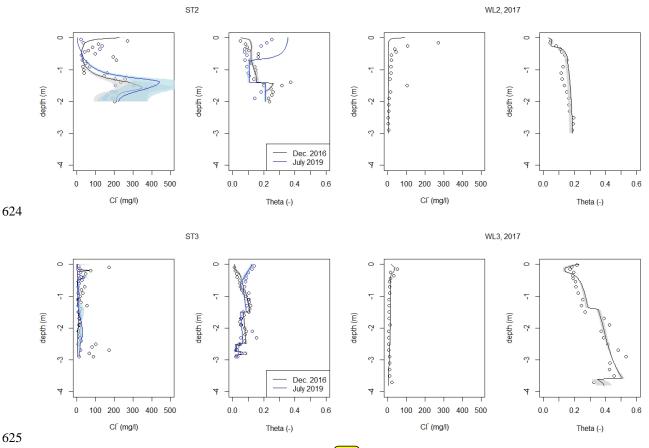

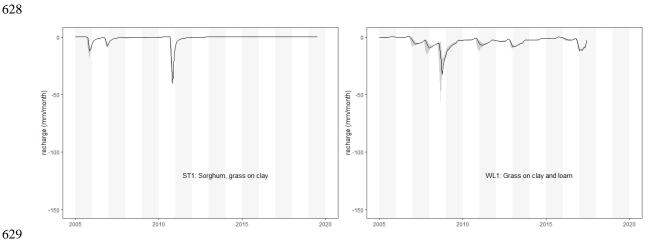

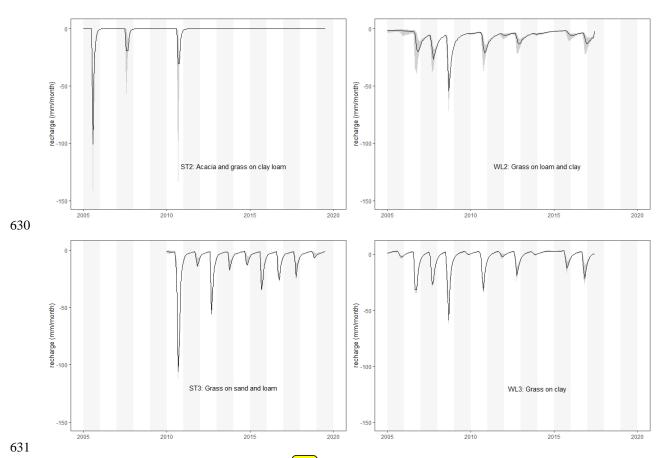

Figure 5: Measured and simulated scenarios of chloride entration and water content for all six soil profiles. Shaded areas represent standard deviation of 100 randomly selected model runs.

632 Figure 6: Calculated groundwater recharge for parios and sampling locations with indication of vegetation and soil texture.

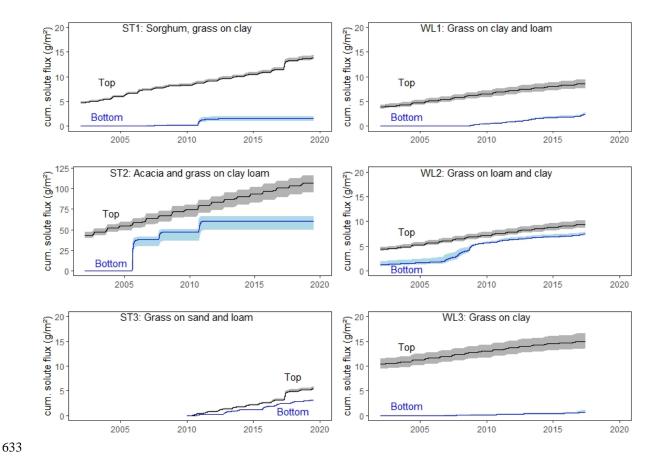

Fig. 7: Cumulative solute flux on the upper and lower boundary of the mode he shaded areas represents the standard deviation of 100 randomly selected model runs. Note the different y-axis scales between sites.

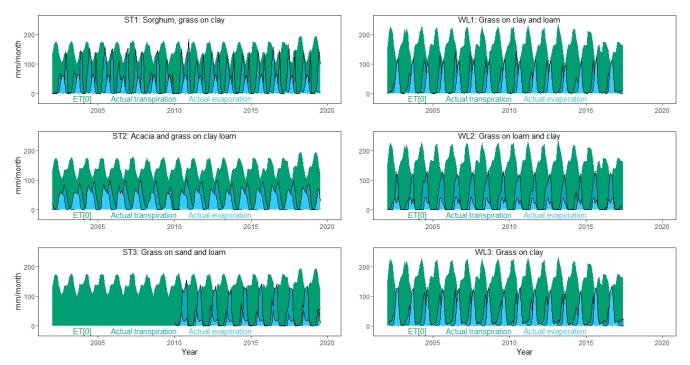

Fig. 8: Reference evapotranspiration from the CRUTS 4 database (NCAR 2017) a as modelled average actual evaporation and transpiration of 100 randomly selected model runs.

Table 1: Names and geographic coordinates of the sampling locations with indication of average depth to groundwater.
