Abstract. Reference crop evapotranspiration (ET_o) is calculated using a standard formula with temperature, vapor pressure, solar radiation, and wind speed as input variables. ET_o forecasts can be produced when forecasts of these input variables from numerical weather prediction (NWP) models are available. As raw ET_o forecasts are often subjective to systematic errors, calibration is necessary for improving forecast quality. The most straightforward and widely used approach is to directly calibrate raw ET_o forecasts constructed with the raw forecasts of input variables. However, the potential predictability of ET_o may not be fully explored by this approach, which ignores the non-linear interactions of input variables in constructing ET_o forecasts. We hypothesize that reducing errors in individual inputs as a precursor to ET_o forecast calibration will lead to more skillful ET_o forecasts. To test this hypothesis, we evaluate two calibration strategies, including i) calibration directly applied to raw ET_o forecasts constructed with raw forecasts of input variables, and ii) bias-correcting input variables first, and then calibrating the ET_o forecasts constructed with bias-corrected input variables. We calibrate ET_o forecasts based on weather forecasts of the Australian Community Climate and Earth System Simulator G2 version (ACCESS-G2). Calibrated ET_o forecasts with bias-corrected input variables (strategy ii) demonstrate lower bias, higher correlation coefficient, and higher skills than the calibration based on raw input variables (strategy i). This investigation indicates that improving raw forecasts of input variables could enhance ET_o forecast calibration and produce more skillful ET_o forecasts. This calibration strategy is expected to enhance future NWP-based ET_o forecasting.

1 Introduction

As a variable measuring the evaporative demand of the atmosphere, reference crop evapotranspiration (ET_o) has been widely used to estimate potential water loss from the land surface to the atmosphere (Hopson and Webster, 2009; Liu et al., 2019; Renard et al., 2010). Quantification of ET_o has been increasingly performed to support efficient water use and water management (Mushtaq et al., 2019; Perera et al., 2016). Forecasts of short-term ET_o (days to weeks) are highly valuable for real-time decision-making on farming activities and water allocation to competing users (Djaman et al., 2018; Kumar et al., 2012).

A plethora of methods with divergent statistical assumptions, dependence on observations, and requirements of weather forecasts have been developed to predict future ET_o (Bachour et al., 2016; Ballesteros et al., 2016; Karbasi, 2018; Mariito et

30 al., 1993). Since ETo is impacted jointly by temperature, vapor pressure, solar radiation, and wind speed (Bachour et al., 2016;
Luo et al., 2014), the inclusion of these input variables in statistical forecasting models could enable better representations of
physical processes regulating ETo and often improves ETo predictions (Torres et al., 2011). The increasing availability of
weather and climate forecasts based on numerical models has opened up new opportunities for ETo forecasting (Cai et al.,
2007; Srivastava et al., 2013; Tian and Martinez, 2014; Zhao et al., 2019a). Forecasts of temperature, vapor pressure, solar
35 radiation, and wind speed from numerical weather prediction (NWP) models/global climate models (GCMs) could be
conveniently translated into ETo forecasts using the Food and Agriculture Organization (FAO) ETo equation (Allen et al.,
1998; Cai et al., 2007).

Despite the advantages in modeling physical processes of the atmosphere, flexibility in temporal and spatial scales (Pelosi et
al., 2016), and high data availability (Er-Raki et al., 2010), NWP/GCM-based raw ETo forecasts often demonstrate systematic
40 errors (Turco et al., 2017). Limitations in schemes of NWP/GCM models, parameterization, and data assimilation often lead
to biases in raw forecasts of weather variables (Lim and Park, 2019; Vogel et al., 2018), with forecast skills only limited to a
few days in the future. As a result, raw ETo forecasts calculated directly with the raw forecasts of input weather variables (e.g.,
temperature, vapor pressure, solar radiation, and wind speed) typically demonstrate substantial inconsistencies with
observations (Medina and Tian, 2020; Zhao et al., 2019a), and need to be post-processed to improve forecast quality.

45 Unlike other weather variables directly inheriting errors from NWP models, errors in raw ETo forecasts are contributed jointly
by multiple input variables and their complex interactions (Traore et al., 2016; Yang et al., 2019). Effective calibration aims
to effectively correct these errors, and provide unbiased, reliable, and skillful calibrated forecasts. Theoretically, there are two
different calibration strategies that could be adopted to achieve this goal. The first strategy is to construct raw ETo forecasts
directly with the raw forecasts of the input variables and then calibrate the derived ETo forecasts with a post-processing model.
50 This strategy lumps errors from the input variables together in the raw ETo forecasts and then corrects combined errors directly
(Tian and Martinez, 2014; Zhao et al., 2019a). This strategy is straightforward and thus has been adopted by most existing
calibrations of NWP/GCM-based ETo forecasts. For example, Medina et al. (2018) used a linear regression bias-correction
method to calibrate ETo forecasts from three NWP models and achieved significant improvements in the quality of ETo
forecasts. Medina and Tian (2020) employed three probabilistic-based calibration methods to improve ETo forecasts of
55 multiple NWP models, and generated more skillful and reliable calibrated ETo forecasts than the calibration with a simple
regression bias-correction model. Another probabilistic post-processing method, the Bayesian Joint Probability (BJP) model,
was used to calibrate ETo forecasts across multiple sites in Australia and produced ETo forecasts markedly superior to raw
forecasts in accuracy and skills (Zhao et al., 2019a, 2019b).

Alternatively, the ETo forecast calibration could start with dealing with the errors in the raw forecasts of the input variables.
60 In this strategy, raw forecasts of input variables could be calibrated first, and raw ETo forecasts could then be constructed with
the improved input variables. After that, the derived raw ETo forecasts could be further improved through calibration. This
strategy is more computationally demanding than the one using uncorrected input variables. With the improved input variables,
errors in the constructed raw ETo forecasts could be significantly reduced (Nouri and Homaei, 2018; Perera et al., 2014).

65 However, there is no conclusion on whether improvements to raw ETo forecasts by calibrating input variables will eventually
add additional skills to calibrated ETo forecasts, when compared with the calibration using raw forecasts of input variables to
derive raw ETo forecasts (Medina and Tian, 2020).

70 Which calibration strategy produces more skillful calibrated forecasts is a critical question in NWP-based ETo forecasting, but
the answer remains unclear. There is a pressing need to investigate the necessity of improving raw forecasts of the input
variables as part of ETo forecast calibration. We hypothesize that reducing errors in individual inputs as a precursor to ETo
forecast calibration will lead to more skillful ETo forecasts. To test this hypothesis, we compare two calibration strategies,
including i) directly calibrating raw ETo forecasts constructed with raw forecasts of input variables, and ii) bias-correcting raw
forecasts of each input variable first, and then calibrating the ETo forecasts constructed with bias-corrected variables. NWP
forecasts from the Australian Community Climate and Earth System Simulator G2 version (ACCESS-G2) model across
Australia are used for this investigation. Objectives of this study are to i) Calibrate ETo forecasts across Australia based on
75 two different strategies, ii) evaluate the contribution of bias-correcting input variables to NWP-based ETo forecasting.

2 Method

2.1 Reference data and forecasts

80 In this study, we use the ETo data derived from the Australian Water Availability Project (AWAP)'s gridded data of
temperature, vapor pressure, and solar radiation (Jones et al., 2007, 2014), and wind speed data developed by Mcvicar et al.
(2008), as observations for ETo forecast calibration. Weather forecasts from the ACCESS-G2 model are compiled to generate
ETo forecasts. We modify the spatial resolution of ACCESS-G2 data to match the AWAP data's grid spacing. The 3-hourly
ACCESS-G2 forecasts during 4/2016-3/2019 are aggregated to the daily scale to match the timeframe of the original site
observations used to generate the AWAP data. AWAP ETo during 4/1999-3/2019 is used for parameter inference, and data
during 4/2016-3/2019 is selected for forecast calibration and evaluation.

85 2.2 Calculation of ETo

We calculate ETo forecasts and AWAP ETo using the FAO56 equation (Allen, et al., 1998):

$$ET_o = \frac{0.408\Delta(R_n - G) + \gamma \frac{900}{T + 273} u_2 (e_s - e_a)}{\Delta + \gamma(1 + 0.34u_2)} \quad (1)$$

90 where ET_o is the reference crop evapotranspiration (mm/day); Δ is the slope of the vapor pressure curve ($kPa \text{ } ^\circ C^{-1}$); R_n is net
radiation at the crop surface ($MJ \text{ } m^{-2} \text{ } day^{-1}$); G is soil heat flux density ($MJ \text{ } m^{-2} \text{ } day^{-1}$); γ is the psychrometric constant
($kPa \text{ } ^\circ C^{-1}$); T is average air temperature ($^\circ C$); u_2 is the wind speed at the height of 2m ($m \text{ } s^{-1}$); e_s and e_a are saturated and
actual vapor pressure (kPa), respectively.

AWAP and Mcvicar et al. (2008) have all the variables needed for developing ETo observations. For the ETo forecasts,
temperature and solar radiation are readily available from the ACCESS-G2 outputs. To obtain the wind speed forecasts, we

95 first use the forecasts of zonal velocity (u) and the meridional (v) components from ACCESS-G2 to calculate wind speed forecasts at 10m, and then estimate wind speed at 2m using the equation recommended by FAO (Allen, et al., 1998). In addition, we use the ACCESS-G2 forecasts of air pressure and specific humidity to obtain the vapor pressure forecasts.

2.3 Calibration of ETo forecasts

100 The calibration model used in this study is the newly developed Seasonally Coherent Calibration (SCC) model, which is found to be effective in calibrating NWP-based ETo forecasts (Yang et al., 2021b). For the calibration across Australia with a spatial resolution of 0.05 degree, we process 281,655 grid cells in total. We apply the SCC model for ETo forecast calibration to each grid cell and lead time separately.

Table 1. Four sets of ETo forecast calibrations

Calibrations	Construction of raw ETo forecasts	Application of the SCC model
Calibration 1	Raw forecasts of input variables	SCC calibration based on anomaly and climatological mean
Calibration 2	Bias-corrected forecasts of input variables	SCC calibration based on anomaly and climatological mean
Calibration 3	Raw forecasts of input variables	The SCC model applied directly to ETo forecasts
Calibration 4	Bias-corrected forecasts of input variables	The SCC model applied directly to ETo forecasts

105

We conduct four sets of calibrations to evaluate how the two different calibration strategies would affect the calibrated ETo forecasts. Our recent investigation suggests that ETo forecast calibration based on anomaly and climatological mean produces more skillful calibrated forecasts than calibrating ETo forecasts directly (Yang et al., 2021b). As a result, in this study, we primarily focus on calibrations based on ETo anomalies (Calibrations 1 and 2). The comparison between Calibrations 1 and 2 is to investigate whether the bias-correction of input variables would further improve ETo forecasts when working with ETo anomalies. We also conduct additional calibrations applying the SCC model to ETo forecasts directly (Calibrations 3 and 4), to test whether the contribution of improving the input variables to ETo forecast calibration, if there is any, will depend on how ETo forecasts are calibrated (based on anomalies vs. based on original ETo forecasts). In this study, we primarily analyze results from Calibrations 1 and 2, and only briefly introduce results from Calibrations 3 and 4 in the main text.

115 2.3.1 Bias-correction of input variables

For ETo forecast calibration employing strategy ii (Calibrations 2 and 4 in Table 1), we use a non-parametric quantile mapping method (QUANT) to correct raw forecasts of the input variables. This method has been widely used in hydrological and climatological investigations for correcting bias in raw data (Boe et al., 2007). To use QUANT, we first build up the empirical cumulative density function (CDF) of both raw forecasts and AWAP data for each variable. We then calculate the percentile of each record in raw forecasts in their CDF. Next, these percentiles are used to search values in the corresponding AWAP data, which is then treated as the bias-corrected forecasts. Values in between the percentiles are approximated using a linear interpolation method (Boe et al., 2007).

2.3.2 Key steps of ETo forecast calibration using the SCC model based on ETo anomaly and climatological mean

After we construct the raw ETo forecasts, based on either raw (Calibrations 1 and 3) or bias-corrected (Calibration 2 and 4) forecasts of the input variables, we employ the SCC model to further calibrate the ETo forecasts. For the calibrations (Calibrations 1 and 2 shown in Table 1) applying SCC to ETo anomaly, the first step is to derive the observed daily climatological mean using the 20-year AWAP ETo. Calibrations 3 and 4 skip this step and apply the SCC model to ETo forecasts directly. We use the method developed by Narapusetty et al. (2009) and adopt trigonometric functions and harmonics to simulate the annual cycle of AWAP ETo to derive the climatological mean:

$$y_{cm}(t) = a_0 + \sum_{j=1}^H [a_j \cos(w_j t) + b_j \sin(w_j t)] \quad (2)$$

where $y_{cm}(t)$ is the climatological mean at the daily scale; H is the number of harmonics. Here we use $H=4$ following Narapusetty et al. (2009); a_0 , a_j , and b_j are coefficients, estimated through minimizing the mean squared differences between climatological mean and observations; $w_j=2\pi j/P$, and P is days in one year.

Once we obtain the daily climatological means of the observed ETo, we then remove them from both raw forecasts and AWAP ETo to generate anomalies. We calibrate the derived anomalies of raw ETo forecasts against the anomalies of AWAP ETo using the SCC model, which is composed of four key components: i) a joint probability model to characterize the connection between raw forecasts and observations, ii) reconstruction of seasonal patterns in raw forecasts based on the long-term reference data, iii) reparameterization to obtain parameters for short-archived raw forecasts, and iv) generation of calibrated forecasts with the parameters and the joint model. The SCC model has been introduced in detail in our site- and continental-scale calibration of NWP precipitation and ETo forecasts (Wang et al., 2019; Yang et al., 2021a, 2021b).

In this study, we use the Yeo-Johnson transformation method to transform the anomalies of forecasts and reference data to approach a normal distribution (Yeo and Johnson, 2000):

$$\hat{x} = \begin{cases} (\lambda x + 1)^{\frac{1}{\lambda}} - 1, & (x \geq 0, \lambda \neq 0) \\ \exp(x) - 1, & (x \geq 0, \lambda = 0) \\ -(\lambda - 2)x + 1)^{\frac{1}{2-\lambda}} + 1, & (x < 0, \lambda \neq 2) \\ -\exp(-x) + 1, & (x < 0, \lambda = 2) \end{cases} \quad (3)$$

145 where λ is a transformation parameter; x refers to anomalies of daily raw ETo forecasts or AWAP ETo (mm day^{-1}); \hat{x} is the transformed x through the Yeo-Johnson transformation.

We assume that the transformed anomalies of ETo forecasts ($f(t)$) and AWAP ETo ($o(t)$) are drawn from a bivariate normal distribution:

$$[f(t), o(t)] \sim \text{BN}(f(t), o(t) | \mu_f(m(t)), \sigma_f^2(m(t)), \mu_o(m(t)), \sigma_o^2(m(t)), \rho(m(t))) \quad (4)$$

150 where $m(t)$ returns the month k ($k=1$ to 12) of daily forecasts or observations of day t ; $\mu_f(m(t))$ and $\sigma_f(m(t))$ refer to the marginal distribution's mean and standard deviation of $f(t)$ in month $m(t)$, respectively; $\mu_o(m(t))$ and $\sigma_o(m(t))$ are the mean and standard deviation of the marginal distribution of $o(t)$ in month $m(t)$; $\rho(m(t))$ is the correlation between $f(t)$ and $o(t)$ of month $m(t)$.

155 With the long-term (20-year) AWAP ETo data, we can directly estimate $\mu_o(m(t))$ and $\sigma_o(m(t))$ based on a maximum likelihood optimization. Calculation of the mean ($\mu_f(m(t))$) and standard deviation ($\sigma_f(m(t))$) using the short-archived raw ETo forecasts (3-year) is subjected to significant sampling errors. Instead, we indirectly estimate them using the following linearly regressions:

$$\mu_f(k) = a + b\mu_o(k) \quad (5)$$

$$\sigma_f(k) = c + d\sigma_o(k) \quad (6)$$

160 $\rho(k) = r \quad (7)$

where k is a month k ($k=1$ to 12); a , b , c , and d are parameters characterizing the linear relationships; $\rho(k)$ denotes the correlation coefficient between raw forecast anomaly and anomaly of AWAP ETo for each month; r is the correlation coefficient between anomalies of raw forecasts and observations in the transformed space (Wang et al., 2019).

165 Once we obtain all the parameters for the BN distribution (equation 4), a conditional distribution is established for $o(t)$ when a raw forecast ($f(t)$) is provided. From this conditional distribution, we randomly draw 100 values. These values are then treated as the calibrated ensemble forecasts for that raw forecast. Finally, the calibrated anomalies are back-transformed to their original space and added back to the climatological mean to produce calibrated ETo forecasts.

2.4 Evaluation of calibrated forecasts

- 170 We evaluate the performance of the ETo forecast calibration using a strict leave-one-month-out cross-validation strategy, in which each of the 36 months during 4/2016 to 3/2019 and the same month in the 20-year reference data (4/1999 to 3/2019) are left out in parameter inference. Optimized parameters are then used to calibrate raw forecasts of this specific month. This process is repeated until all 36 months are processed. This strategy is to make sure that calibrated forecasts are produced with data not used for parameter optimization.
- 175 We also produce climatology forecasts based on the monthly mean and standard deviation parameters of AWAP ETo listed in equation (4). The randomly sampled climatology is used as the baseline to evaluate the calibrated forecasts generated with the SCC model. We evaluate the calibrated forecasts by checking bias, reliability, temporal variability, and skill score in raw and calibrated forecasts. The evaluation metrics are further introduced in detail as follows.

2.4.1 Bias

- 180 We evaluate the accuracy of the raw and calibrated forecasts relative to AWAP-based ETo using the following equation:

$$Bias = \frac{1}{T} \sum_{t=1}^T (x(t) - y(t)) \quad (8)$$

- where *Bias* refers to the bias in average ETo (mm day⁻¹); *T* is total days during the 3-year validation period (4/2016-3/2019); *x(t)* is raw or calibrated forecasts of ETo (mm day⁻¹), and *y(t)* is the corresponding AWAP ETo of the same period. We also compare the absolute bias of calibrated forecasts from Calibrations 1 and 2 to evaluate how bias-correction of input variables
- 185 affects the accuracy of calibrated ETo forecasts.

2.4.2 Reliability

To evaluate the reliability of calibrated forecasts, we calculate the probability integral transform (PIT) value using the following equation:

$$\pi(t) = F(t, x = y(t)) \quad (9)$$

- 190 where $F(t, x)$ is the cumulative density function of the ensemble forecast, and $y(t)$ is the AWAP ETo. For reliable forecasts, $\pi(t)$ follows a uniform distribution. We use the alpha index (α) to summarize the reliability in each grid cell using the following equation to check the spatial patterns of forecast reliability (Renard et al., 2010):

$$\alpha = 1 - \frac{2}{n} \sum_{t=1}^n \left| \pi^*(t) - \frac{t}{n+1} \right| \quad (10)$$

- where $\pi^*(t)$ is the sorted $\pi(t)$, $t=1,2,\dots,n$, in ascending order, and n is the total number of days during 4/2016-3/2016. The α
- 195 index measures the total deviation of calibrated forecasts from the corresponding uniform quantile. Perfectly reliable forecasts should have an α index of 1, and forecasts with no reliability would have an α index of 0.

2.4.3 Temporal variability

We use the Pearson correlation coefficient (r) between calibrated forecasts and observations to evaluate their consistency in temporal variability. For the calibrated ensemble forecasts, we use the ensemble mean of the 100 ensemble members for the calculation of r :

$$r = \frac{\sum_{t=1}^n (x(t) - \bar{x})(y(t) - \bar{y})}{\sqrt{\sum_{t=1}^n (x(t) - \bar{x})^2} \sqrt{\sum_{t=1}^n (y(t) - \bar{y})^2}} \quad (11)$$

where $x(t)$ is raw or calibrated forecasts of ETo (mm/day), \bar{x} is the average of $x(t)$ (mm day⁻¹); $y(t)$ is the corresponding AWAP ETo of the same period, and \bar{y} is the average of $y(t)$ (mm day⁻¹).

2.4.4 Skills of the raw and calibrated forecasts

We use the continuous ranked probability score (CRPS) to measure skills in the raw and calibrated forecasts (Grimm et al., 2006):

$$CRPS(t) = \int \{F(t, x) - H(x - y(t))\}^2 dx \quad (12)$$

$$\overline{CRPS} = \frac{1}{n} \sum_{t=1}^n CRPS(t) \quad (13)$$

where $F(t, x)$ is the cumulative density function of an ensemble forecast, and $y(t)$ is the observation at time t ; H is the Heaviside step function ($H = 1$ if $x - y(t) \geq 0$ and $H = 0$ otherwise); the overbar represents averaging across the n days. For deterministic forecasts, CRPS is reduced to absolute errors.

We further calculate the CRPS skill score ($CRPS_{SS}$) to measure the skills relative to climatology forecasts using the following equation:

$$CRPS_{SS} = \frac{CRPS_{reference} - CRPS_{forecasts}}{CRPS_{reference}} \times 100 \quad (14)$$

where $CRPS_{reference}$ is the CRPS value of climatology forecasts; $CRPS_{forecasts}$ refers to CRPS value of raw or calibrated forecasts. For $CRPS_{SS}$ of Calibrations 1 and 2, climatology forecasts from Calibration 1 are used; For $CRPS_{SS}$ of Calibrations 3 and 4, climatology forecasts from Calibration 3 are used. Positive skill scores indicate better skills than the climatology forecasts and vice versa.

3 Results

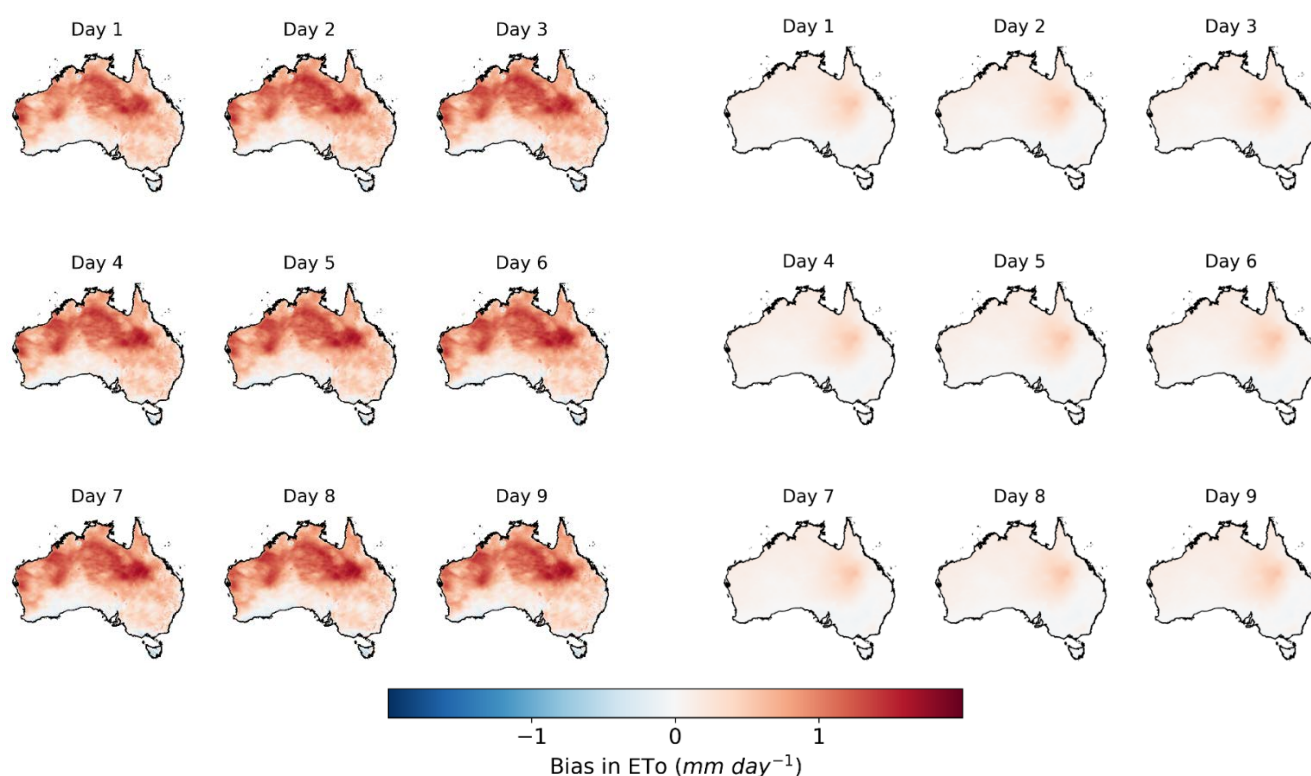

3.1 Bias in input variables and raw ETo forecasts

Raw forecasts of the five input variables demonstrate significant inconsistencies with the corresponding AWAP data (Figures S1-S5). In most parts of Australia, daily maximum temperature (Tmax) forecasts are lower than AWAP data by 1-2 °C. Overpredictions in Tmax are only found in coastal areas of north-western Australia. The daily minimum temperature (Tmin) is underpredicted in western and central parts of Australia by the raw forecasts, but overpredicted in eastern and southern Australia. Forecasted wind speed is higher than the reference data by more than 1m/s in most parts of Australia. Similarly, raw

solar radiation forecasts are also higher than AWAP data across Australia. Vapor pressure is underpredicted in western and central regions by the raw forecasts, but demonstrates positive biases in coastal areas of south-eastern Australia. For each of the five variables, spatial patterns of biases in raw forecasts are consistent across the 9 lead times, demonstrating systematic errors in the raw NWP forecasts.

230 The quantile mapping effectively corrects biases in raw forecasts of the input variables. Through the bias correction, the significant overpredictions and underpredictions in raw forecasts of the five variables are effectively corrected, resulting in biases close to zero for all 9 lead times across Australia (Figures S1-S5).

235

Figure 1: Bias in (left three panels) raw ETo forecasts constructed with raw forecasts of input variables and (right three panels) raw ETo forecasts constructed with bias-corrected input variables.

240 Raw ETo forecasts constructed with the bias-corrected input variables are much more accurate than those calculated with raw forecasts of these variables (Figure 1). When raw ETo forecasts are constructed with raw forecasts of input variables, biases in input variables are translated into errors of the raw ETo forecasts, which demonstrate substantial positive biases in the central and northern regions of the country. Correcting biases in the input variables leads to more accurate estimations of ETo. In the raw ETo forecasts calculated with bias-corrected input variables, biases are close to zero in most parts of Australia,

245 except for inland regions of Queensland, where biases in ETo are close to 0.3 mm/day. However, the remaining biases are significantly lower than those in the raw ETo forecasts constructed with uncorrected input variables.

3.2 Bias in calibrated ETo forecasts

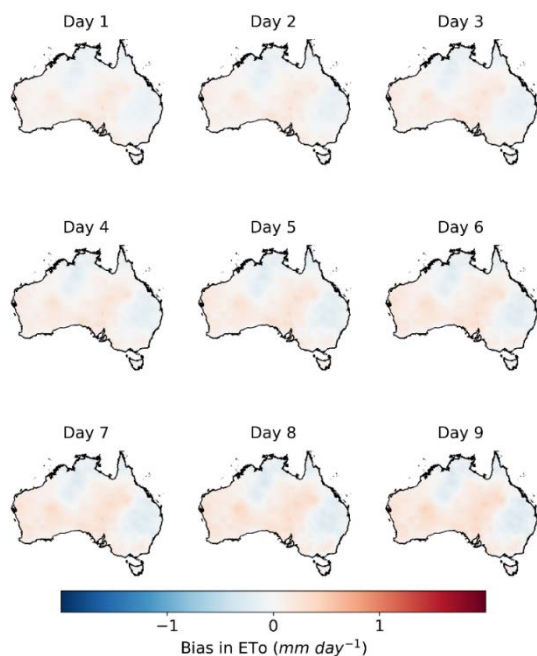

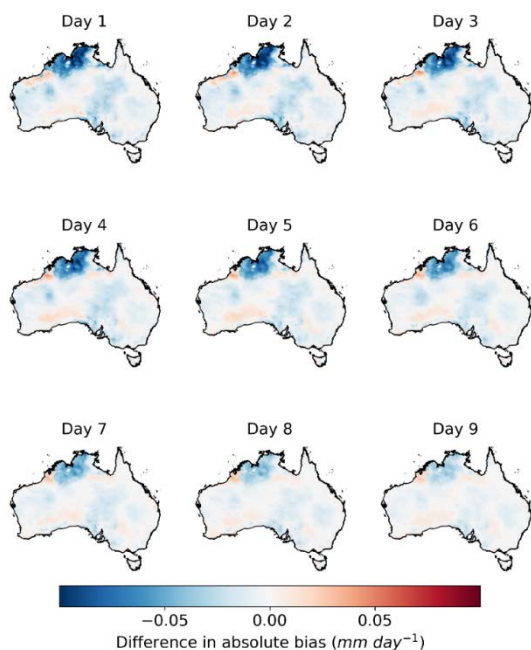

Figure 2: Bias in calibrated ETo forecasts from Calibration 2, which constructs raw ETo forecasts with bias-corrected input variables.

250

Figure 3: Differences in absolute bias between calibrated ETo forecasts from Calibration 2 with those from Calibration 1.

The calibration with the SCC model further reduces biases in ETo forecasts (Figure 2). The calibrated ETo forecasts from Calibration 2 show low biases close to zero across all grid cells and lead times. Overpredictions in Queensland in the raw ETo forecasts calculated with the bias-corrected input variables are effectively corrected (Figures 1 and 2). Compared with the calibration constructing raw ETo forecasts with raw forecasts of input variables (Calibration 1), the post-processing based on bias-corrected input variables (Calibration 2) produces more accurate calibrated ETo forecasts (Figure 3). Specifically, calibrated ETo forecasts from Calibration 2 demonstrate smaller absolute biases than those of Calibration 1 across large areas of northern Australia, particularly in coastal regions of the Northern Territory. The improvements are more pronounced for short lead times (Days 1-3) than long lead times (Days 7-9).

260

3.3 Reliability of calibrated ETo forecasts

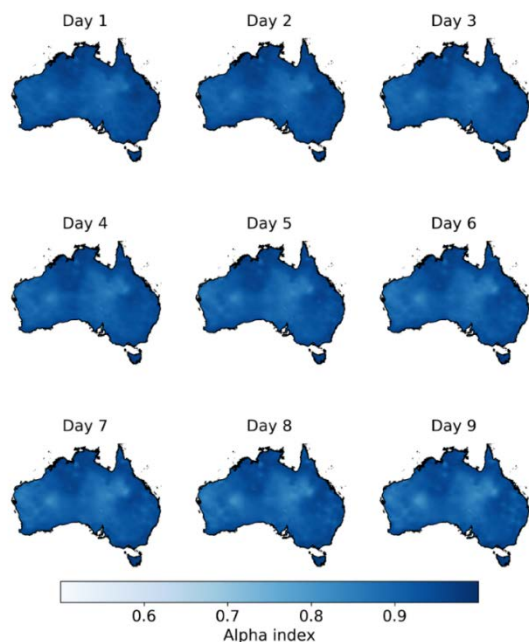

Figure 4: Alpha index of calibrated ETo ensemble forecasts from Calibration 2.

265

The calibrated ensemble ETo forecasts from Calibration 2 demonstrate high reliability (Figure 4). In addition to correcting bias, the calibration model adopted in this study converts deterministic raw forecasts to ensemble forecasts, with 100 ensemble members for each forecast. The ensemble forecasts provide forecast users with uncertainty information of future ETo. Figure 4 demonstrates highly reliable ensemble spreads in calibrated forecasts across all 9 lead times. In most grid cells, the α index is over 0.9, indicating reasonable representations of ETo uncertainties by the ensemble spread, which is neither too narrow nor too wide (Figure 4).

270

Calibrated forecasts from Calibration 1, which uses uncorrected input variables, demonstrate similar reliability as those from the calibration with bias-corrected input variables (Calibration 2). Differences in α index of the calibrated ETo forecasts from Calibrations 1 and 2 are almost negligible (Figure S6), indicating that bias-correcting raw forecasts of input variables does not lead to significant changes in the reliability of calibrated ETo forecasts.

275

3.4 Correlation between calibrated ETo forecasts and AWAP ETo

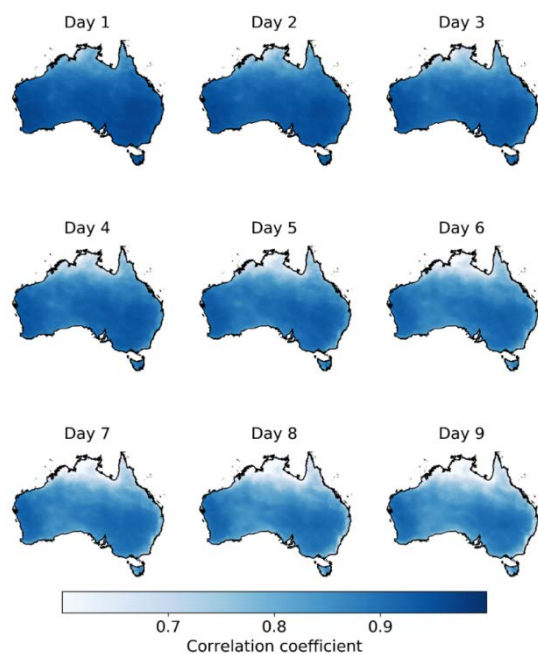

Figure 5: The correlation coefficient between calibrated ETo forecasts from Calibration 2 and AWAP ETo data.

280 We further examine the representation of temporal variability of ETo by calibrated forecasts. The correlation coefficient (r)
between calibrated ETo forecasts from Calibration 2 and AWAP ETo demonstrates high consistency in temporal variability
(Figure 5). The correlation coefficient is mainly above 0.85 across Australia for the first three lead times. With increases in
lead time, r values tend to decrease but remain above 0.7 in most parts of the country, even at lead time 9. Coastal areas of
northern Australia have lower r values than other regions of the country, demonstrating higher uncertainties in ETo forecasts
285 in regions with a dynamic tropical/subtropical climate system.

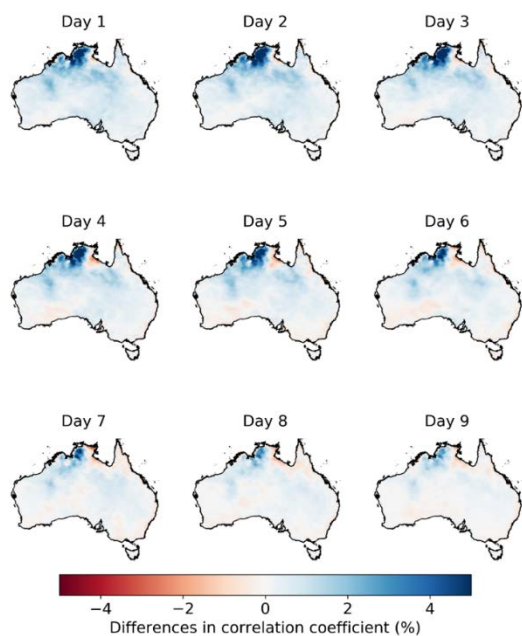

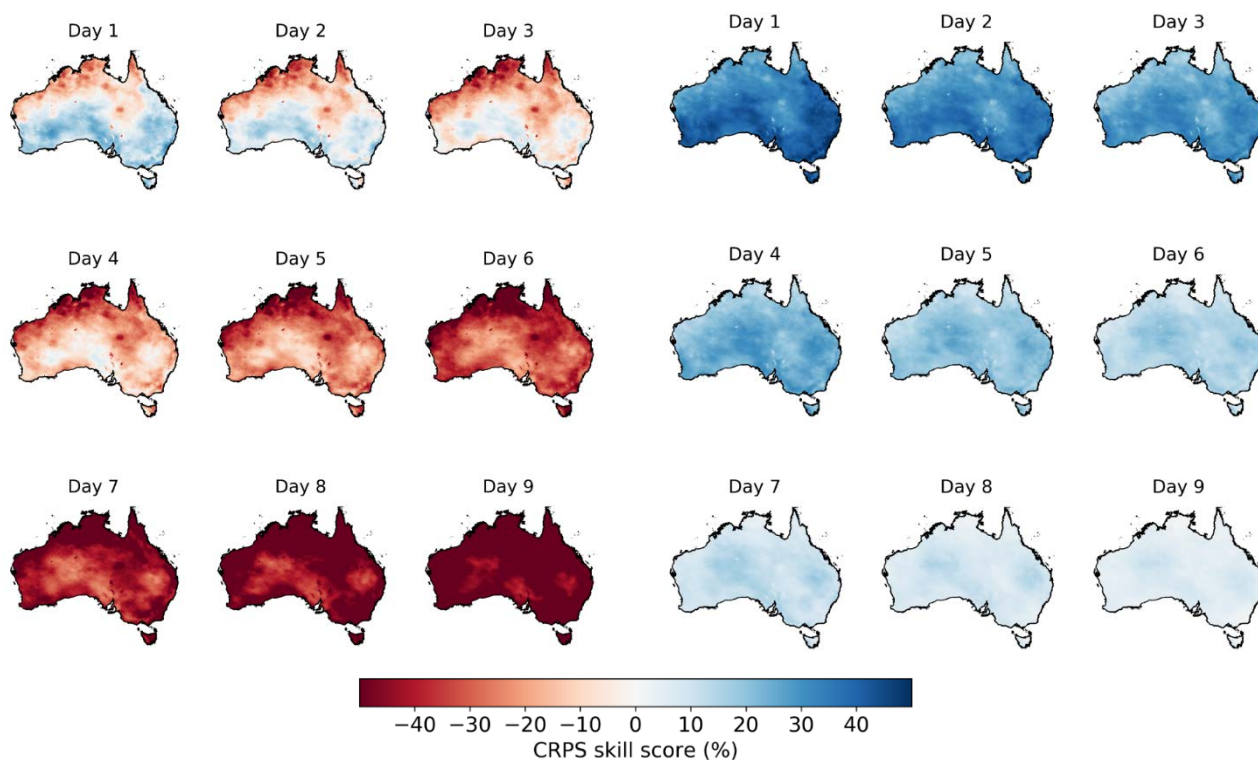

Figure 6: Differences in the correlation coefficient (calibrated forecasts vs. observations) between Calibrations 2 and 1.

290 The adoption of bias-correction to raw forecasts of input variables results in better representation of ETo variability in calibrated ETo forecasts (Figure 6). The comparison of r between AWAP ETo and calibrated ETo forecasts from Calibration 2 with that from Calibration 1 shows increases in r , after applying bias-correction to input variables. Increases in r are more significant for short lead times. Specifically, for the first three lead times, increases in r are mainly around 2% in central and northern parts of Australia, with more pronounced (>4%) increases found in coastal regions of the Northern Territory. For lead
295 times 4 to 6, increases in r values are mainly above 1%. For the remaining 3 lead times (7 to 9), we can still see slight increases in r , mainly in Northern Territory. Spatial patterns of r increases from Calibration 1 to Calibration 2 are consistent across the 9 lead times, with more significant increases occurring in northern parts of Australia.

3.5 Improvements in forecast skills

300

Figure 7: CRPS skill score in the (left three panels) raw ETo forecasts calculated with bias-corrected input variables and (right three panels) calibrated forecasts from Calibration 2.

The calibration of ETo forecasts with the SCC model significantly improves forecast skills. The raw ETo forecasts calculated with bias-corrected input variables demonstrate low skills, even at short lead times (Figure 7). Specifically, for the first two lead times, central and southern Australia show skills better than the climatology forecasts by 10% to 20%. However, in most parts of northern Australia, raw forecasts are worse than randomly sampled climatology. Skills in raw ETo forecasts decrease quickly with lead time. Regions with positive skills shrink substantially at lead times 3 and 4, and disappear at longer lead times. At lead time 9, skills of raw forecasts are mainly below -40%.

The calibration significantly improves forecast skills for all 9 lead times. Results from Calibration 2 show that the CRPS skill score of calibrated ETo forecasts is mainly above 40% at lead time 1 across Australia, and lead times 2 and 3 show skills generally above 30%. Since ETo forecasts have been widely used to inform real-time decision making for irrigation, high skills in calibrated ETo forecasts for the short lead times are expected to be highly valuable for activities such as determining the timing and frequency of irrigation. Although skills of calibrated forecasts also decrease with lead time, they remain above zero for the remaining lead times (Figure 7).

315

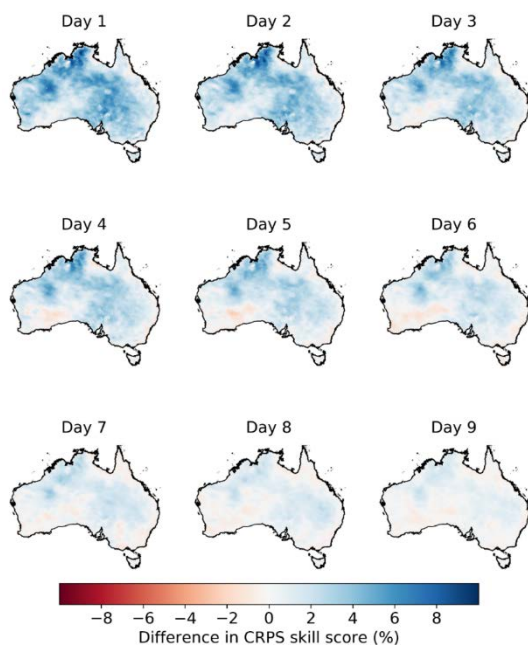

Figure 8. Differences in CRPS skill scores between the calibrated forecast from Calibration 2 with those from Calibration 1.

320 We further compare skills of calibrated ETo forecasts between Calibrations 2 and 1. The differences in forecast skills between the two sets of calibrated forecasts clearly demonstrate the importance and necessity of improving input variables (Figure 8). We find significant increases in CRPS skill scores with the adoption of bias-correction to input variables, particularly for short lead times. For the first three lead times, CRPS skill score is increased by more than 6% when forecasts of input variables are bias-corrected. For lead times 4 to 6, the CRPS skill scores are increased by 4% in many regions across Australia, with more
325 significant increases found in the central and northern parts of the country. Although the differences become less noticeable at lead times 7 to 9, they are generally above zero in most parts of Australia. The differences in CRPS skill score between Calibration 2 and 1 across the 9 lead times are in line with that of the absolute bias (Figure 3) and correlation coefficient (Figure 6), which all show more significant improvements at short lead times than long lead times.

We also compare the CRPS skill score of calibrated forecasts from Calibrations 3 and 4, to evaluate whether we can obtain
330 similar improvements through the bias-correction of input variables if we conduct the ETo forecast calibration in a different way (without using climatological mean and anomalies). Results show similar improvements in CRPS skill score in magnitude, spatial patterns, and trend along the lead times, when input variables are bias-corrected before combined calibration (Figure S7). This additional comparison further confirms the necessity of improving forecasts of input variables as part of the calibration of ETo forecasts.

335 4 Discussion

4.1 Importance of improving forecasts of input variables for calibrating ETo forecasts

Forecasting of future ETo based on NWP outputs is gaining popularity as a result of high data availability, flexible forecast horizons, and timeliness (Perera et al., 2014, 2016; Silva et al., 2010; Yang et al., 2019). As for forecasts of other weather variables, statistical calibration plays an important role in improving the quality of raw ETo forecasts (Medina and Tian, 2019).
340 Although existing investigations using raw forecasts of input variables to construct the raw ETo forecasts for calibration often achieved significant improvements in skills, it is still unclear whether improving forecasts of input variables could further enhance ETo forecast calibration (Medina and Tian, 2020). How the raw ETo forecasts should be constructed represents an important knowledge gap in the area of NWP-based ETo forecasting.

Results of this investigation provide strong evidence for the necessity of improving raw forecasts of input variables prior to
345 constructing raw ETo forecasts. Each of the input variables demonstrates high non-linearity and non-stationary (Paredes et al., 2018). When a bias-correction method is applied to the input variables, the final calibrated ETo forecasts demonstrate higher accuracy and skills than the calibration based on uncorrected input variables. The results suggest that complex interactions of these input variables may lead to errors in raw ETo forecasts that could not be effectively corrected through statistical calibration. Bias-correction of input variables could help prohibit the propagation of errors from input variables to ETo
350 forecasts (Zappa et al., 2010). More importantly, a further evaluation based on a different way of implementing the calibration model demonstrates similar improvements in calibrated ETo forecasts with the adoption of bias-correction to input variables (Calibrations 3 and 4). This additional analysis suggests that additional skills have been added to ETo forecasts before they are calibrated through the bias-correction of input variables. Consequently, we recommend that the future NWP-based ETo forecasting could take this extra step into account to improve the quality of calibrated ETo forecasts.

355 4.2 Implications for forecasting of integrated variables and future work

This investigation also provides valuable implications for the forecasting integrated variables, which need to be calculated with multiple NWP/GCM variables. Variables such as drought index (Zhang et al., 2017), bushfire danger index (Sharples et al., 2009), and severe weather index (Rabbani et al., 2020), are often derived from multiple NWP/GCM variables. Our investigation suggests that improving the input variables may help correct errors that could not be fixed when calibrating the
360 integrated variables directly. This extra step could help improve the potential predictability of integrated variables.

We anticipate that the ETo forecasts could be further improved if a more sophisticated calibration model is applied to raw forecasts of the input variables. In this study, we adopt a simple bias-correction method to the input variables rather than using a sophisticated calibration model. Limitations of quantile-mapping have been reported (Schepen et al., 2020; Zhao et al., 2017). Our analyses also demonstrate that the raw ETo forecasts calculated with the bias-corrected input variables still contain biases
365 and have low forecast skills, particularly at long lead times (Figure 7). As a result, the adoption of a more sophisticated

calibration method to correct errors in input variables, is expected to further improve forecasts of these input variables, resulting in more significant improvements in the final calibrated ETo forecasts. Moreover, calibration of the input variables with a sophisticated model will benefit other forecast users. Well-calibrated forecasts of input variables, such as temperature, vapor pressure, solar radiation, and wind speed, could be useful for forecast users such as crop modelers and bushfire managers.

370 Although we've conducted thorough analyses on the contribution of improving input variables to ETo forecast calibration, further investigation is needed to validate the findings of this investigation in the future. First, the two calibration strategies should be tested using other NWP models. In this study, we use one NWP model to investigate a critical knowledge gap in NWP-based ETo forecasting. Additional investigations based on other NWP models are necessary to further enrich our understanding of the impacts of improving input variables on NWP-based ETo forecasting. Second, further investigations

375 based on other calibration models are needed to validate the conclusions of this investigation. Our analyses based on two different methods (based on ETo anomalies vs. based on original ETo) find similar improvements in calibrated ETo forecasts by correcting input variables. Additional investigations using other calibration models will help clarify whether the improvements will hold for other calibration models.

5 Conclusions

380 NWP outputs have been increasingly used for ETo forecasting. As for other weather variables, statistical calibration plays an essential role in improving the quality of raw ETo forecasts. However, it is unclear whether improving raw forecasts of input variables is necessary for the calibration of ETo forecasts. We aim to fill this knowledge gap through a thorough comparison of calibrations with and without the adoption of bias-correction to input variables.

This investigation clearly suggests the necessity of improving the input variables as part of the NWP-based ETo forecasting.

385 With this extra step, the bias, correlation coefficient, and skills the calibrated ETo forecasts are all improved, particularly for the short-lead-time forecasts. Further investigation indicates that the contribution of improving input variables to the ETo forecasting tends to be independent of the calibration method applied to raw ETo forecasts. As a result, we anticipate that future calibration of NWP-based ETo forecasts could benefit from adopting this extra step to produce skillful calibrated ETo forecasts.

390 Short-term ETo forecasts are highly valuable for real-time decision making for water resource management and planning of farming activities. Forecasting of the highly variable ETo is often challenging. Our investigation provides a feasible method for advancing calibrations of the NWP-based ETo forecasts. This strategy is also expected to be useful in enhancing the forecasting of other integrated variables that are calculated using multiple NWP/GCM variables.
