

1 **Water sharing policies conditioned on hydrologic variability to inform reservoir** 2 **operations**

3 Guang Yang¹, Paul Block²

4 **Abstract** Water resources infrastructure is critical for energy and food security, however, the development
5 of large-scale infrastructure, such as hydropower dams, may significantly alter downstream flows,
6 potentially leading to water resources management conflicts and disputes. Mutually agreed upon water
7 sharing policies for the operation of existing or new reservoirs is one of the most effective strategies to
8 mitigate conflict, yet this is a complex task involving the estimation of available water, identification of
9 users and demands, procedures for water sharing, etc. A water-sharing policy framework that incorporates
10 reservoir operating rules optimization based on conflicting uses and natural hydrologic variability,
11 specifically tailored to drought conditions, is proposed. First, the trade-off between downstream and
12 upstream water availability utilizing multi-objective optimization of reservoir operating rules is
13 established. Next, reservoir operation with the candidate (optimal) rules is simulated, followed by their
14 performance evaluations, and the rules selections for balancing water uses. Subsequently, a relationship
15 between the reservoir operations simulated from the selected rules and drought-specific conditions is built
16 to derive water-sharing policies. Finally, the reservoir operating rules are re-optimized to evaluate the

17 effectiveness of the drought-specific water sharing policies. With a case study of the Grand Ethiopian
18 Renaissance Dam (GERD) on the Blue Nile River, it is demonstrated that the derived water sharing policy
19 can balance GERD power generation and downstream releases, especially in dry conditions, effectively
20 sharing the hydrologic risk in inflow variability among riparian countries. The proposed framework offers
21 a robust approach to inform water sharing policies for sustainable management of water resources.

23 Grand Ethiopian Renaissance Dam.

24 **1. Introduction**

25 Rapid population growth and socio-economic development exacerbate stress on the management of
26 water resources globally (Vörösmarty et al., 2000;WWAP, 2019). Surface-water reservoirs and their
27 effective management is one of the most efficient means to reduce this stress by reallocating water
28 resources spatially and temporally (Gaudard et al., 2014). Thus in recent decades, many models and
29 strategies have been investigated to inform and improve reservoir operation decision-making (Chaves and
30 Chang, 2008;Cancelliere et al., 2002;Herman and Giuliani, 2018;Karamouz and Houck, 1982;Giuliani et
31 al., 2014;Oliveira and Loucks, 1997). For example, Karamouz and Houck (1982) optimize monthly
32 reservoir releases by deterministic dynamic programming and build a linear reservoir operation model
33 conditioned on the relationship between optimal releases and reservoir state variables. Cancelliere et al.
34 (2002) built a non-linear reservoir operation model by using neural network techniques to improve
35 reservoir irrigation water supply during drought conditions. Herman and Giuliani (2018) design a tree-
36 based policy which is flexible and interpretable for reservoir operation over multiple timescales. In general,
37 reservoir decisions (e.g., water releases and power generation) are determined using reservoir operating

38 rules with available input variables including reservoir state (e.g., reservoir water level) and hydrological
39 conditions (e.g., reservoir inflow) (Oliveira and Loucks, 1997).

40 Reservoir operating rules are typically derived using fitting-based and simulation-optimization-based
41 approaches. In fitting-based rules derivation (policy fitting), reservoir operation decisions are optimized
42 and subsequently fitted with input variables using linear regression (Bhaskar and Whitlatch Jr, 1980),
43 artificial neural networks (Cancelliere et al., 2002), fuzzy inference (Chang and Chang, 2001), and
44 decision trees (Wei and Hsu, 2008). In simulation-optimization methods, the parameters of reservoir
45 operating rules are optimized with an iterative simulation-based search algorithm in which the
46 performance is evaluated directly from reservoir operation simulations (Le Ngo et al., 2007; Rani and
47 Moreira, 2010). For example, Giuliani et al. (2015a) approximated reservoir operating rules by using
48 artificial neural networks and radial basis functions (RBFs) and optimized the rules for multi-purpose
49 water reservoirs with an evolutionary algorithm. A policy fitting approach requires an optimal set of
50 reservoir inflows, storages, and releases and its effectiveness highly depends on the performance of the
51 optimized reservoir operation model; however, the rules derivation is interpretable and intuitive when
52 optimal reservoir decision-making is highly correlated with state variables. In contrast, simulation-
53 optimization-based approaches do not rely on existing optimal reservoir operations and thus it is generally
54 more flexible than fitting-based rules.

55 Most of these approaches are implemented in water resources systems contained within a basin or
56 jurisdiction in which the benefits (e.g. power generation, water supply, and ecosystem function
57 maintenance) can be quantified and evaluated (Reddy and Nagesh Kumar, 2007; Feng et al., 2018; Yang
58 et al., 2016). Reservoir operations are necessarily more complex after considering a wide variety of social,
59 political, economic, and cultural conditions in river basins (Zeitoun and Mirumachi, 2008). Disputes and

60 conflicts are not uncommon between riparian states in river basins when water sharing agreements are
61 non-existent or non-enforceable and claims may be defined based on historical use. For example, the Nile
62 River serves eleven countries, 250 million people (Nile Basin Initiative, 2017), and is vital to agriculture,
63 industry, and hydropower, (Paisley and Henshaw, 2013), yet no mutually agreed upon water sharing
64 policies exist. (The 1959 agreement (Guariso and Whittington, 1987) has been repudiated by upstream
65 riparian states.) Acknowledging significantly divergent interests and a history of conflict and distrust,
66 quantifying the impact of reservoir operation on downstream benefits is challenging, hindering
67 development of water sharing strategies (Link et al., 2016).

68 According to the Transboundary Freshwater Dispute Database (McCracken and Wolf, 2019), the
69 existing 310 international river basins across the world are shared by 150 countries and disputed areas,
70 cover 45% of the Earth's land surface, and contribute to 60% of the world's freshwater resources. As
71 suggested by Sadoff and Grey (2002), it is critical to understand and account for the range of inter-related
72 benefits resulting from the development of international rivers in a cooperative way. Such cooperation of
73 water resources development in international river basins has been widely investigated in recent years (Li
74 et al., 2019; Luchner et al., 2019; Arjoon et al., 2016; Wheeler et al., 2018; Degefu et al., 2016). For example,
75 Arjoon et al. (2016) proposed a benefit-sharing method based on the optimization results from a hydro-
76 economic model and evaluated the value of cooperative water management in the Eastern Nile River basin;
77 Li et al. (2019) analyzed the water benefits of stakeholders from cooperation under different reservoir
78 operation scenarios by using cooperative game theory methods; Luchner et al. (2019) simulated reservoir
79 operations and water allocation in an international river basin in Central Asia and found that international
80 cooperation in the power sector can ease the conflict between upstream hydropower production and
81 downstream irrigated agriculture.

82 Most previous studies focus on illustrating the importance of a cooperative strategy through water
83 system optimization and simulation (Dombrowsky, 2009;Tilmant and Kinzelbach, 2012) and evaluating
84 the benefits of cooperative operation (Goor et al., 2010;Anghileri et al., 2013;Uitto and Duda,
85 2002;Luchner et al., 2019). There is less literature (Wheeler et al., 2016;Li et al., 2019;Degefu et al.,
86 2016;Teasley and McKinney, 2011), however, addressing strategies for reaching an agreement or
87 consensus on water resources development amongst downstream and upstream riparian countries. Also,
88 although cooperation can result in a win-win situation for both downstream and upstream stakeholders,
89 cooperative water use strategies are obstructed by single-sector interests, especially when long-term
90 commitments are involved (Wu and Whittington, 2006). More specifically, it is often difficult to achieve
91 a mutually agreed-on cooperation strategy given divergent solution preferences by stakeholders.

92 Additionally, benefit sharing policies rely heavily on hydro-economic modeling and cost-benefit
93 analysis (Jeuland et al., 2014), which strives to maximize overall aggregated benefits and subsequently
94 allocate benefits in an equitable way. However, (1) the aggregation of benefits can hide important trade-
95 offs and may increase the risk of floods and droughts for maximum economic benefit; (2) there is no
96 standard that regulates how benefits of water use from various sectors (e.g., drinking, agriculture, industry,
97 recreation, and navigation) are quantified and what mechanism should be applied to equitably
98 allocate/share the benefits (Acharya et al., 2020); and (3) there is presently no basin-wide authority to
99 enforce benefit allocations (e.g. payments from one country to another) although institutions such as the
100 Nile Basin Initiative could serve in this role (Arjoon et al., 2016). Thus, water sharing policies considering
101 the trade-off between economic benefits and drought risk, rather than benefit sharing policies based on
102 cooperative operation strategies analysis, are investigated in this study. The policies will be flexible,
103 interpretable, and more importantly drought-focused such that downstream drought mitigation will
104 become an inherent part of the water sharing framework.

105 In this study, a systemic framework is proposed to derive operational reservoir water-sharing policies
106 using multi-objective optimization for water use conflict mitigation. Specifically, (1) optimize reservoir
107 operating rules and establish trade-off between upstream benefits and downstream drought risks, (2)
108 simulate reservoir operation with the candidate (optimal) rules, evaluate performance, and select the most
109 suitable rules for balancing benefits, (3) derive water-sharing policies conditioned on reservoir operations
110 and water availability, and (4) re-optimize reservoir operating rules incorporating derived water-sharing
111 policies to evaluate effectiveness and performance. The drought-focused water-sharing policies are
112 interpretable as they are derived from and evaluated on reservoir operation simulations from existing
113 optimal rules. Further, the policies are considered flexible by offering opportunities for informing
114 upstream-downstream negotiations. The Grand Ethiopian Renaissance Dam (GERD) in Ethiopia is
115 selected to demonstrate the framework and illustrate how operational water-sharing strategies, reflective
116 of upstream and downstream demands and natural hydrologic variability, can promote water-sharing
117 agreements between upstream and downstream countries.

118 **2. Study Area and Data**

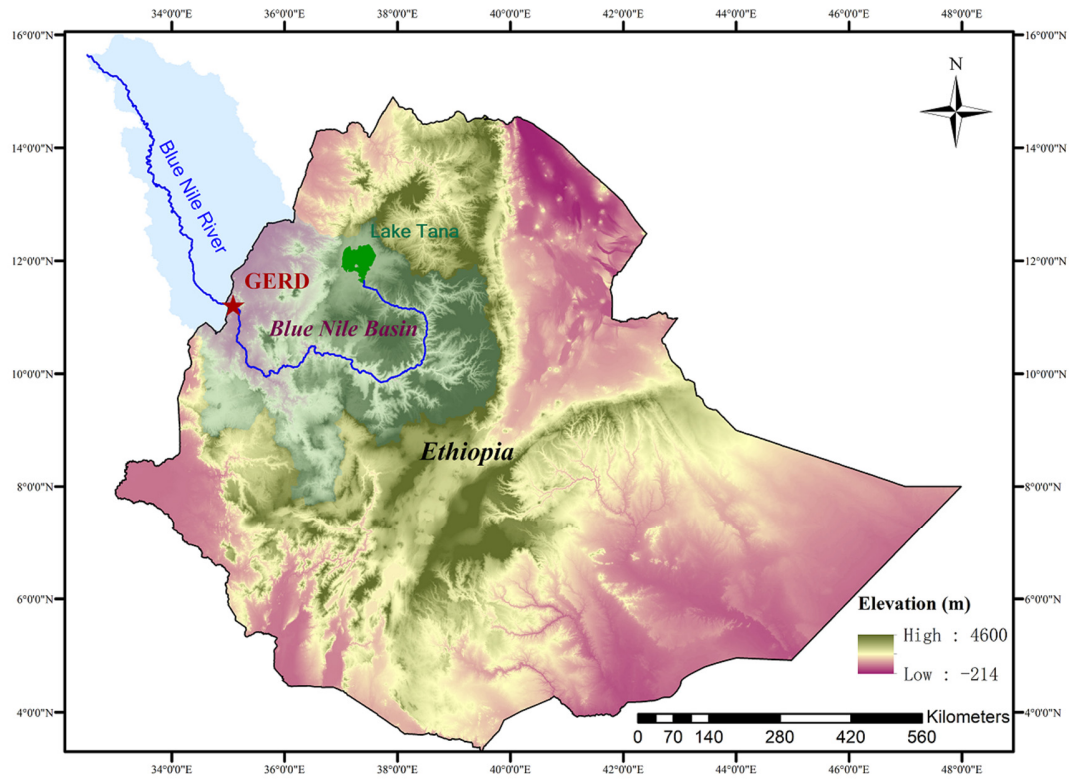

119 **2.1. The Blue Nile Basin and the Grand Ethiopian Renaissance Dam**

120 The Blue Nile River, the largest tributary of the Nile River, originates at Tana Lake in Ethiopia and
121 merges with the White Nile River in Khartoum, Sudan. Average annual rainfall in the upper part of the
122 basin varies between 1200 and 1800 mm (Conway, 2000), with a dominant rainy season in June–
123 September contributing approximately 70% of mean annual precipitation. During this season, the Blue
124 Nile contributes nearly 80% of the total Nile River streamflow (Swain, 2011) and the average annual
125 runoff of the Blue Nile at Roseries, near the Ethiopia–Sudan border, is approximately 49 km³ (Wheeler et
126 al., 2016), thus it plays a significant role in livelihood and development in Ethiopia, Sudan and Egypt.

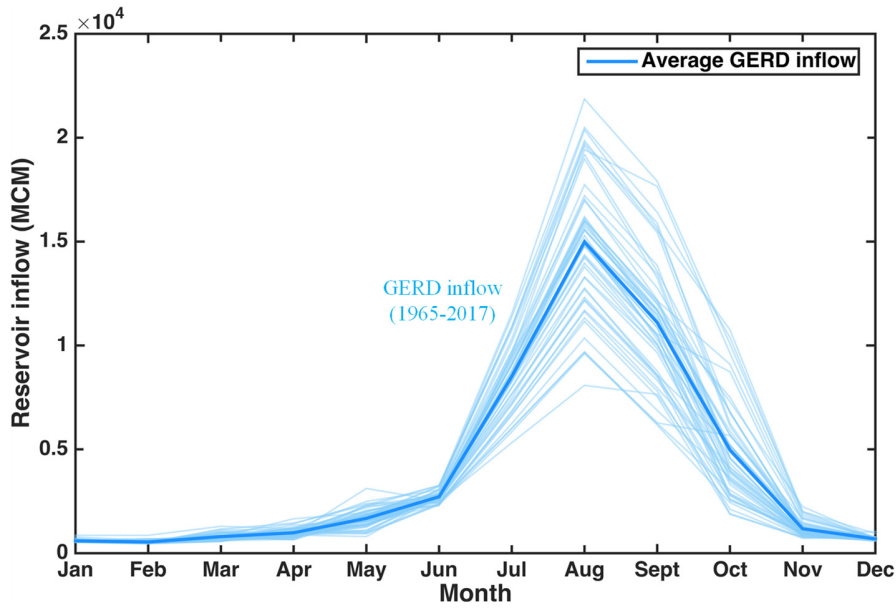

127 Ethiopia started constructing the Grand Ethiopian Renaissance Dam (GERD) across the Blue Nile
128 River in 2011, approximately 15 km upstream of the Sudanese border (Fig. 1). When completed, the
129 GERD will become the largest hydroelectric dam (installed capacity more than 5,000 MW) in Africa
130 (Government of Ethiopia, 2020) and will have a total reservoir capacity of 74 billion cubic meters. The
131 GERD is expected to produce an average of 15,130 GWh of electricity annually (with mean output of
132 1727 MW) (Tan et al., 2017; Tesfa, 2013), which will contribute to Ethiopia's national energy grid and
133 feed the East African power pool (Nile Basin Initiative, 2012). There is uncertainty in media reports
134 regarding the total installed capacity for GERD which ranges from 5,150 MW (Ezega News, 2019b) to
135 6,000 MW (Ezega News, 2019a; Zelalem, 2020). A value of 6,000 MW, which was applied both in the
136 annual electricity production estimation and previous publicly available scientific studies (Tesfa,
137 2013; Yang et al., 2021), is opted for this study. It is worth noting that re-running the simulations with an
138 installed capacity of 5,150 MW instead of 6,000 MW does not change principal conclusions. Although the
139 GERD is primarily designed for hydropower, and thus non-consumptive, operating to maximize power
140 generation may result in a water release schedule significantly different from the natural annual cycle,
141 particularly considering drought periods, with implications to Sudan and Egypt. This is the crux of the
142 current hydro-political confronting the riparian countries.

143 In this study, GERD reservoir operation rules are developed considering power generation and
144 downstream water release (including turbine outflows and spillage losses) simultaneously to mitigate
145 upstream-downstream water use conflicts, particularly tailored to drought periods. The study investigates
146 water-sharing (drought mitigation) policy derivation procedures (reservoir operation simulation and
147 optimization, power generation and downstream water release analysis, drought mitigation policy
148 extraction and validation) balancing GERD production and downstream flow volumes. Historical monthly

149 inflow at El Diem gauging station (located just downstream of the GERD site) for 1965-2017 (Fig. 2) are
150 applied.

151

153

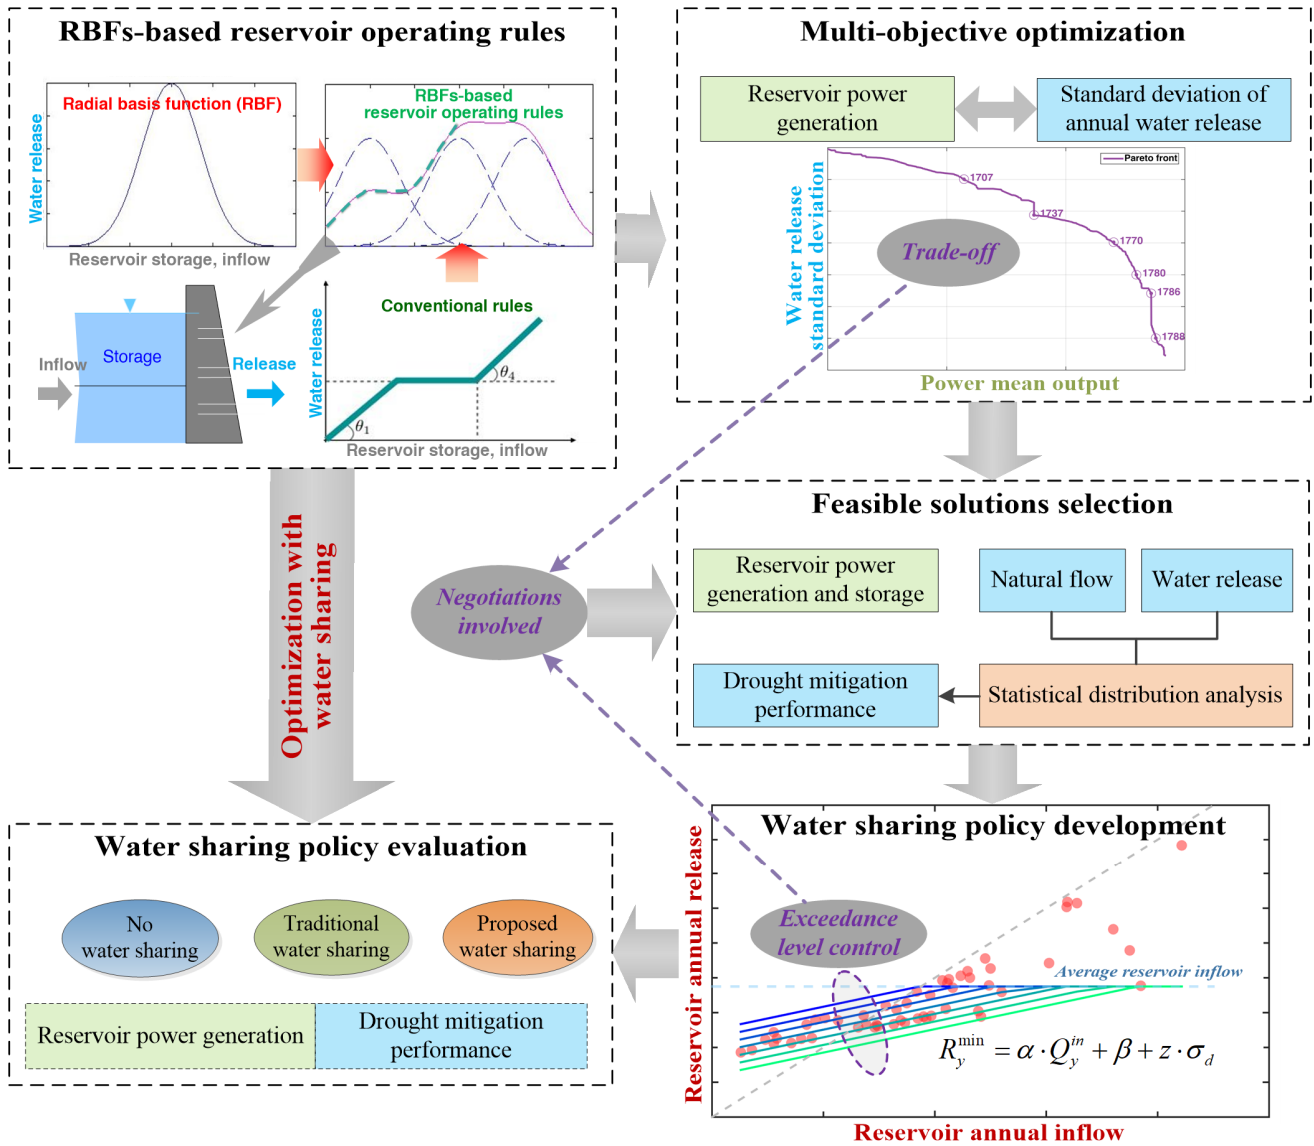

154 Fig. 2 Monthly inflow into the GERD reservoir during 1965-2017.

155 **3. Models and Methods**

156 The procedure for water sharing policy derivation and evaluation including large-scale reservoir
 157 operations is introduced in this section (Fig. 3). In summary, the process is as follows:

- 158 • First: optimize the reservoir operating rules approximated with Radial Basis Functions (RBFs)
 159 and obtain the Pareto front for upstream and downstream benefits trade-off.
- 160 • Second: select feasible solutions on the Pareto front according to the requirements of power
 161 generation and drought mitigation; specifically, for a given power generation level, the
 162 distribution of annual water release is analyzed with special attention to low flow years.
- 163 • Third: define the relationship between annual reservoir inflow and releases based on the selected
 164 feasible solutions; the policy can be further framed as a function of reservoir annual inflow
 165 predictions.
- 166 • Fourth: incorporate the policy into general RBFs-based rules to evaluate policy effectiveness and

robustness.

169 Fig. 3 Procedure of drought mitigation policy derivation and evaluation for reservoir operation.

170 3.1. Reservoir operation model

171 The primary purpose of the GERD reservoir is hydropower production; this objective function can
 172 be described as follows:

173
$$Max \quad E = \sum_{t=1}^T P_t \cdot \Delta t, \quad P_t = \eta \cdot g \cdot \rho \cdot Q_t^p \cdot H_t^p / 1000 \quad (1)$$

174 where E is hydroelectricity generation (kW h) during total number of operational periods T ; P_t is the
 175 power generation output (kW) during time period t and Δt is the time (h) of a single period; η , g , and ρ
 176 refer to the dimensionless hydropower generation efficiency of the turbines (set as 0.9 in this study),
 177 gravitational acceleration (9.8 m/s²), and water density (1000 kg/m³), respectively; and Q_t^p and H_t^p are
 178 reservoir release for power generation (m³/s) and average power head (m) in period t , respectively.

179 In lieu of modeling specific water requirements downstream of the GERD, minimizing annual water
 180 release variance is applied. This approach favors reliable releases yet also reflects natural hydrologic
 181 variability, and can be described as below.

182
$$Min \quad Std(Q_y^{out}) = \sqrt{\frac{\sum_{y=1}^Y (Q_y^{out} - \bar{Q}_y^{out})^2}{Y}} \quad (2)$$

183 where Q_y^{out} is the reservoir water release (which includes turbine outflows and spillage losses) in year y
 184 and \bar{Q}_y^{out} and $Std(Q_y^{out})$ are the mean value and standard deviation of reservoir annual water release across
 185 all operational years Y , respectively.

186 Physical and operational reservoir constraints are listed as below.

187 (a) Water balance:

188
$$S_{t+1} = S_t + (Q_t^{in} - Q_t^{out}) \cdot \Delta t - EP_t \quad (3)$$

189 where S_t and S_{t+1} are reservoir storage (m^3) in period t and $t+1$, respectively, Q_t^{in} represents reservoir
 190 inflow (m^3/s) in period t , Q_t^{out} is reservoir release (m^3/s) in period t , and EP_t is the sum of evaporation and
 191 seepage from the reservoir (m^3) in period t .

192 (b) Reservoir capacity limits (Jameel, 2014):

193 The reservoir structural and operational constraints can be expressed as:

$$194 \quad S^{\min} \leq S_t \leq S^{\max} \quad (4)$$

195 where S^{\min} and S^{\max} are the minimum (14.8 billion m^3) and maximum (74 billion m^3) allowable reservoir
 196 storage.

197 Additionally, S^{begin} and S^{end} represent the initial and final reservoir storage (m^3) for simulations
 198 (both of them are set as 65.1 billion m^3), respectively, and are prescribed as:

$$199 \quad S_t = \begin{cases} S^{begin} & t = 1 \\ S^{end} & t = T \end{cases} \quad (5)$$

200 (c) Reservoir release limits:

201 The reservoir release constraints are expressed as:

$$202 \quad QL_t \leq Q_t^{out} \leq QU_t \quad (6)$$

203 where QL_t and QU_t are the minimum and maximum release (m^3/s) in period t , respectively. The
 204 expected guidelines for GERD reservoir water release are not explicitly available, thus releases are set

205 higher than zero and lower than the maximum reservoir inflow (21.9 billion m³/month) during the high-
 206 flow season to reduce or eliminate downstream floods.

207 (d) Power generation limits (Tesfa, 2013):

$$208 \quad PL_t \leq P_t \leq PU_t \quad (7)$$

209 where PL_t and PU_t are the minimum (0 MW) and maximum (6000 MW) power limits in period t ,
 210 respectively.

211 3.2. Reservoir operating rules

212 In this study, reservoir water releases are conditioned on radial basis functions (RBFs), a non-linear
 213 function approximating method (Buşoniu et al., 2011) which can provide universal approximation (Tikk
 214 et al., 2003) and ensure a flexible reservoir operating rules structure. For more applications of RBF models
 215 in reservoir operation see Giuliani et al. (2015a). The reservoir operating rules are defined as below.

$$216 \quad Q_t^{out} = \sum_{u=1}^U \omega_u \varphi_u(X_t) \quad t=1, \dots, T \quad 0 \leq \omega_u \leq 1 \quad (8)$$

$$217 \quad \varphi_u(X_t) = \exp \left[- \sum_{j=1}^M \frac{((X_t)_j - c_{j,u})^2}{b_u^2} \right] \quad c_{j,u} \in [-1, 1], b_u \in (0, 1] \quad (9)$$

218 where U is the number of RBFs, $\varphi(\cdot)$ and ω_u are the weights of the u^{th} RBF, M is the number of input
 219 variables X_t , and \mathbf{c}_u and b_u are the M -dimensional center and radius vectors of the u^{th} RBF, respectively.

220 Because water release generally depends on the reservoir state (Revelle et al., 1969) and inflow, with
221 intra- and inter-annual variability, reservoir storage S_t , inflow Q_t^m , and seasonal information τ_t (where τ_t
222 refers to the position of the current period (month) t within a water year) are selected as input variables
223 and $X_t = (S_t, Q_t^m, \tau_t)$.

224 In this study, the number of RBFs is set to four (as in Giuliani et al. (2015b)), thus $U=4$ and $M=3$ (three
225 input variables) in equation (8)-(9) resulting in 20 parameters in the RBFs-based rules. The parameters in
226 RBFs-based rules are optimized with a simulation-optimization model (Rani and Moreira, 2010), using
227 the Pareto-Archived Dynamically Dimensioned Search (PA-DDS) evolutionary algorithm which has been
228 successfully applied to reservoir operating rules optimization (Yang et al., 2020). The procedure of the
229 PA-DDS algorithm has been described in detail by Asadzadeh and Tolson (2013).

230 3.3. Drought-focused water sharing policy

231 To ensure downstream water supply, the GERD reservoir will need to be operated under minimum annual
232 water release constraints. Apart from the RBFs-based rules determining the reservoir water release in each
233 time step (months), a drought mitigation policy is also adopted to address dry periods. The policy is based
234 on annual time steps and represented as a linear regression between annual reservoir inflow and water
235 release. More specifically, the minimum annual reservoir water release can be determined by the following
236 equation:

$$237 \quad R_y^{\min} = \alpha \cdot Q_y^{\text{in}} + \beta + z \cdot \sigma_d \quad (10)$$

238 where Q_y^{in} and R_y^{\min} refer to reservoir inflow and minimum reservoir water release during year y ,
239 respectively; α and β are regression parameters estimated from simulations containing reservoir

240 inflow values below the historical average (approximately 49 BCM). An exceedance parameter z is
 241 multiplied by the standard deviation of the regression residuals σ_d to vary how conservative the drought
 242 mitigation policy is (see Fig. 4 for a visualization of exceedance parameters). This policy design favors
 243 downstream releases under drought conditions by supplementing what would occur under natural flow
 244 conditions, however as a trade-off, the minimum reservoir release in any year will not exceed the historical
 245 average reservoir inflow (see the horizontal line in Fig. 4).

246 The drought policy is conditioned on reservoir inflows and releases for a transparent, interpretable, and
 247 intuitive process, which is important especially when negotiations are involved. The gradient of the policy
 248 line is highly correlated with variability in reservoir releases, in general, as the slope increases, so does
 249 the variability in releases. Thus, the parameter α can be estimated from the trade-off between reservoir
 250 power generation and downstream water release variability. The exceedance parameter z further controls
 251 the degree of drought mitigation; larger z values indicate higher drought thresholds (see the intersection
 252 between the policy line and 1:1 dash line in Fig. 4). In the drought policy design, these two parameters can
 253 be estimated separately to isolate their impact on drought mitigation performance. This case study mainly
 254 focuses on the impact of the first parameter as the exceedance parameter z is eventually set as 0%.

255 In this study, the drought mitigation policy is designed with annual streamflow data, however reservoir
 256 operating rules are derived for monthly operation. With reservoir storage in current month S_m , reservoir
 257 inflow in current month Q_m^{in} , and the predicted reservoir inflow during the rest of the year $Q_{m+1}^{in}, \dots, Q_{12}^{in}$,
 258 the reservoir water release in current month Q_m^{out} and the rest of year $Q_{m+1}^{out}, \dots, Q_{12}^{out}$ can be obtained from
 259 equations (8) and (9), thus the annual reservoir inflow and water release can be estimated as below.

$$260 \quad Q_y^{in} = \sum_1^m Q_m^{in} + \sum_{m+1}^{12} Q_m^{in} \quad (11)$$

261
$$Q_y^{out} = \sum_1^m Q_m^{out} + \sum_{m+1}^{12} Q_m^{out} \quad (12)$$

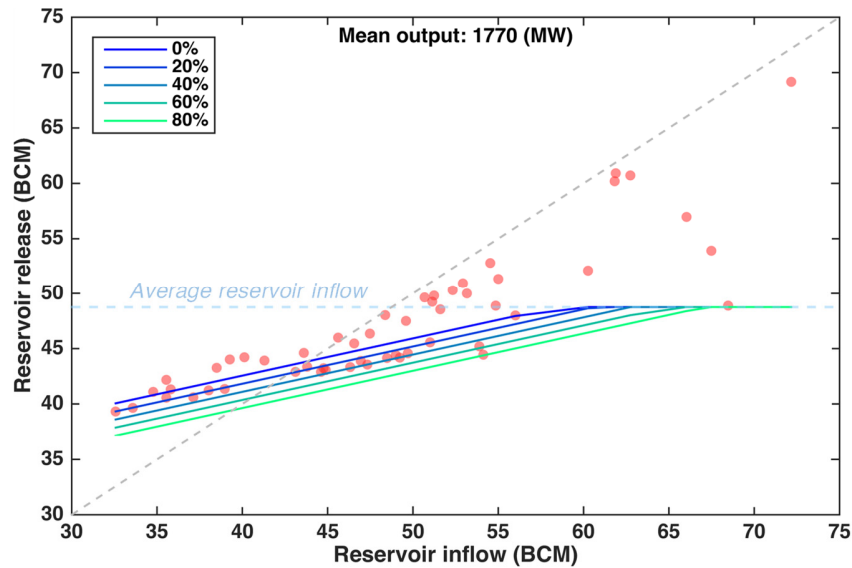

262 The minimum reservoir water release in year y can be estimated from equation (10) as R_y^{\min} . To ensure
 263 the minimum annual water release obligation is met, if the estimated annual reservoir water release Q_y^{out}
 264 is lower than R_y^{\min} , the release in current month Q_m^{out} will be corrected according to the following:

265
$$Q_m^{out} = Q_m^{out} + (R_y^{\min} - Q_y^{out}) \times \frac{Q_m^{in}}{\sum_m^{12} Q_m^{in}} \quad (13)$$

266 The estimated variables R_y^{\min} , Q_y^{out} , and $\sum_m^{12} Q_m^{in}$ are updated in each time step. In the last month of each
 267 year, the annual reservoir inflow estimation Q_y^{in} will be equal to actual annual inflow $\sum_1^{12} Q_m^{in}$ and the
 268 estimated minimum annual release R_y^{\min} will be R_y^{\min} . If $Q_y^{out} < R_y^{\min}$, the reservoir water release in the last
 269 month Q_{12}^{out} will be corrected as $Q_{12}^{out} + (R_y^{\min} - Q_y^{out})$ and the Q_y^{out} will be equal to R_y^{\min} . Thus annual
 270 reservoir release Q_y^{out} will always be greater than or equal to the specified minimum reservoir water release
 271 R_y^{\min} and it can be inferred that the minimum annual release R_y^{\min} is mainly determined by the policy
 272 parameters α , β , and z , rather than forecast accuracy.

273 As illustrated in equation (10) and Fig. 4, the minimum annual reservoir release can be estimated from the
 274 annual reservoir inflow after the drought policy line is determined. Considering actual annual reservoir
 275 inflow will not be available until the last month of each year, the annual reservoir inflow forecast is used
 276 instead. In this study, both a climatology inflow forecast (Q_t^{in} set as the long-term average streamflow for
 277 that month) and a perfect inflow forecast (Q_t^{in} set to observed reservoir inflow Q_t^{in}) are used to evaluate

278 the performance of the drought mitigation policy. To avoid adverse downstream and upstream flood
 279 caused by spillage, both the monthly and annual water release will be less than the maximum reservoir
 280 inflow in flood seasons and wet years.

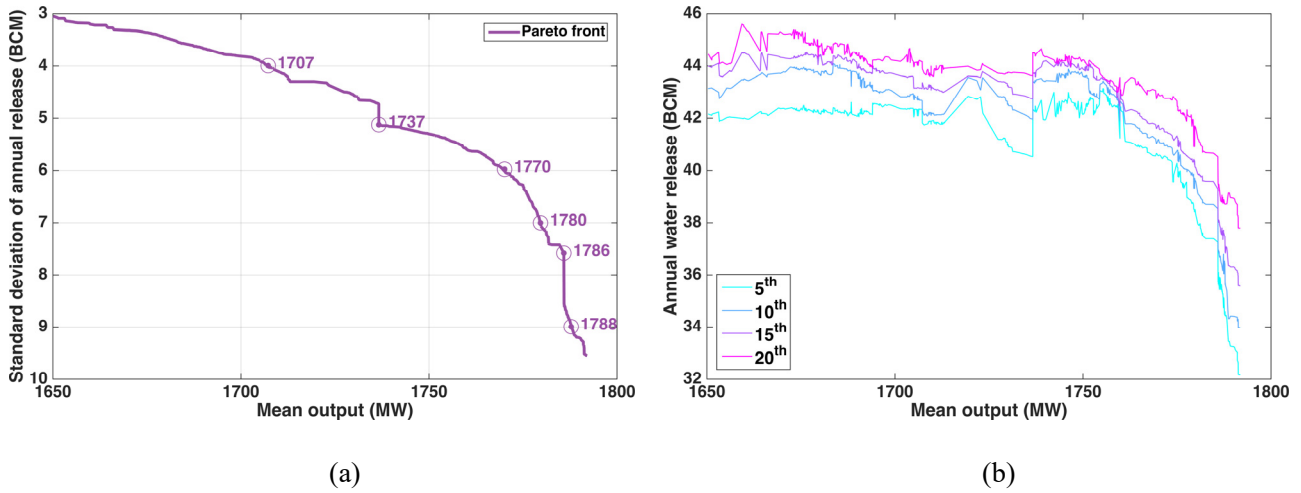

281
 282 Fig. 4 Sample drought mitigation policy with varying exceedance levels ($z=0\%$, 20% , 40% , 60% , and 80%)

283 4. Results and Discussion

284 4.1. Multi-objective reservoir operation with no drought policy

285 Multi-objective optimization of GERD reservoir operating rules illustrates that there is a trade-off between
 286 reservoir power generation and deviation in reservoir annual water releases (Fig. 5 (a)). More specifically,
 287 GERD monthly mean power generation output is estimated at 1788, 1708, 1737, and 1707 MW for annual
 288 release standard deviations of 9, 7, 6, 5, and 4 BCM, respectively. Although the reservoir operating rules
 289 are not optimized for maximum annual water release, less $Std(Q_y^{out})$ typically leads to relatively more
 290 releases in dry conditions (e.g., 5th, 10th, 15th, and 20th percentiles), especially when the mean output is
 291 greater than 1750 MW (Fig. 5 (b)). Thus downstream countries may benefit more from reservoir operating

292 rules favoring smaller $Std(Q_y^{out})$ in drought conditions; this trade-off between power generation and
 293 $Std(Q_y^{out})$ can be used to balance GERD power generation and downstream water use benefits. There also
 294 exists a trade-off between $Std(Q_y^{out})$ and other power indicators such as firm output (see Fig. S1 in
 295 Appendix S1).

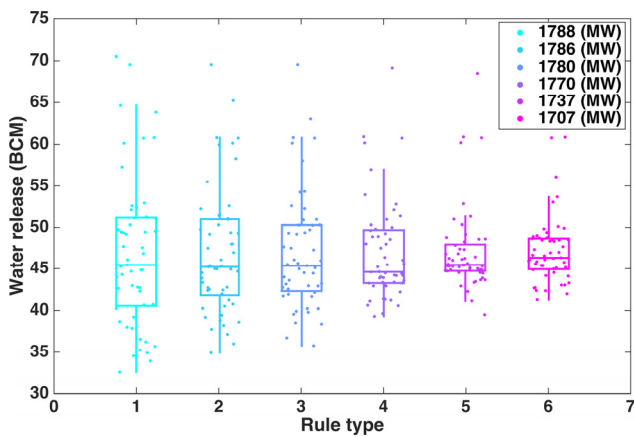

296 Fig. 5 Multi-objective optimization results of reservoir operating rules in terms of (a) Pareto front and (b) the
 297 relationship between power generation and 5th, 10th, 15th, and 20th percentile of annual water release.

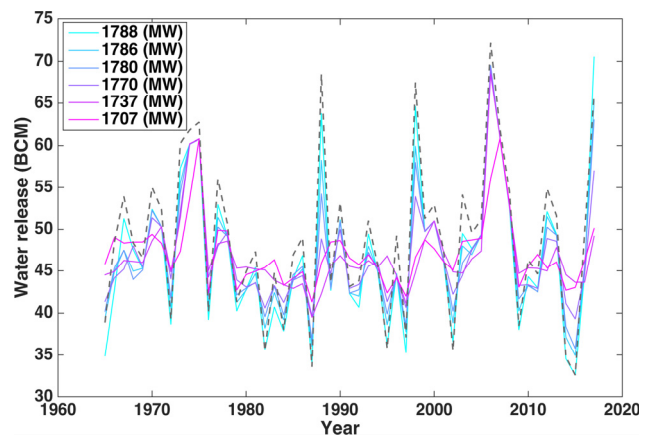

298

299 The reservoir operating rules simulation results under various mean output levels illustrates that the
 300 variance of annual water release shrinks and reservoir storage declines as power output decreases (Fig. 6).
 301 Although the median values of annual water release for all six output levels are approximately the same
 302 (around 45 BCM), the reservoir operating rules with more output generally have lower minimum water
 303 releases (Fig. 6 (a) and (b)), especially in dry periods. In general, greater reservoir storage leads to more
 304 power generation (see equation (1)) and vice versa, thus the reservoir operating rules generating 1788 MW
 305 of mean output produces the highest water level, and 1707 MW the lowest (Fig. 6 (d)). Also, there is a

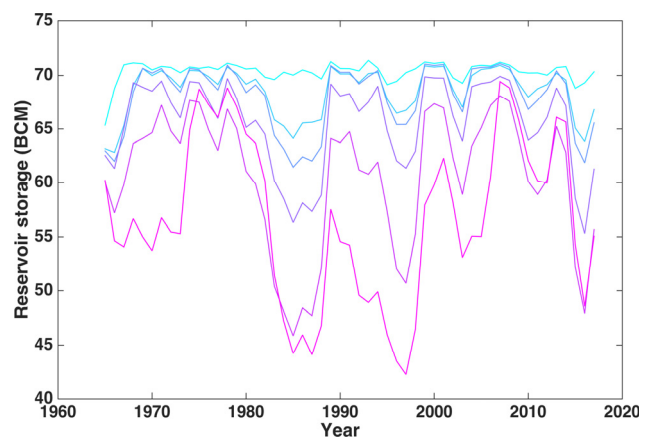

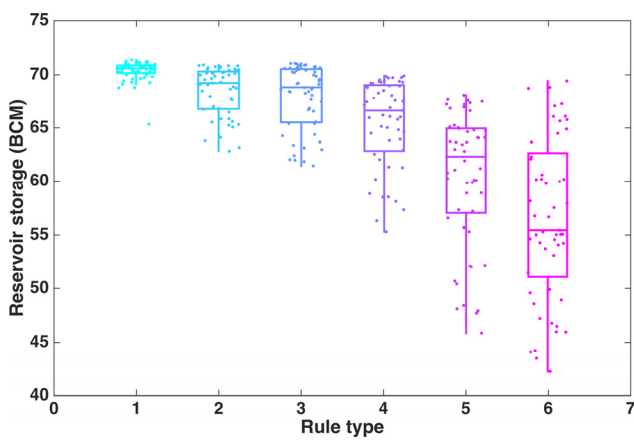

306 clear trade-off between the variance of reservoir storage and water release (Fig. 6 (a) and (c)); smaller
 307 reservoir storage variance ensures higher reservoir levels, greater water release variance, and lower
 308 minimum water releases. It is worth noting that the 75th and 90th percentiles of reservoir storage are much
 309 more sensitive to power output than those of water release. More specifically, the 90th percentile of water
 310 release for rule types 5 and 6 are almost the same, however, the corresponding percentile of reservoir
 311 storage (as well as power output) are notably different (Fig. 6 (a) and (c)). This indicates that rule type 6
 312 may be inferior to rule type 5 despite of the trade-off in Fig. 5 (a). Thus, it is necessary to analyze the
 313 operation results (including water release and power generation) before selecting the reservoir operating
 314 rules based on the Pareto front in Fig. 5 (a).

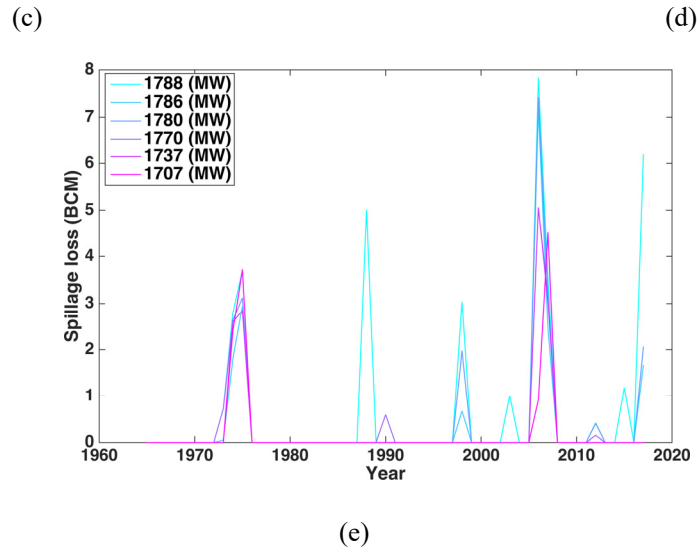

(a)

(b)

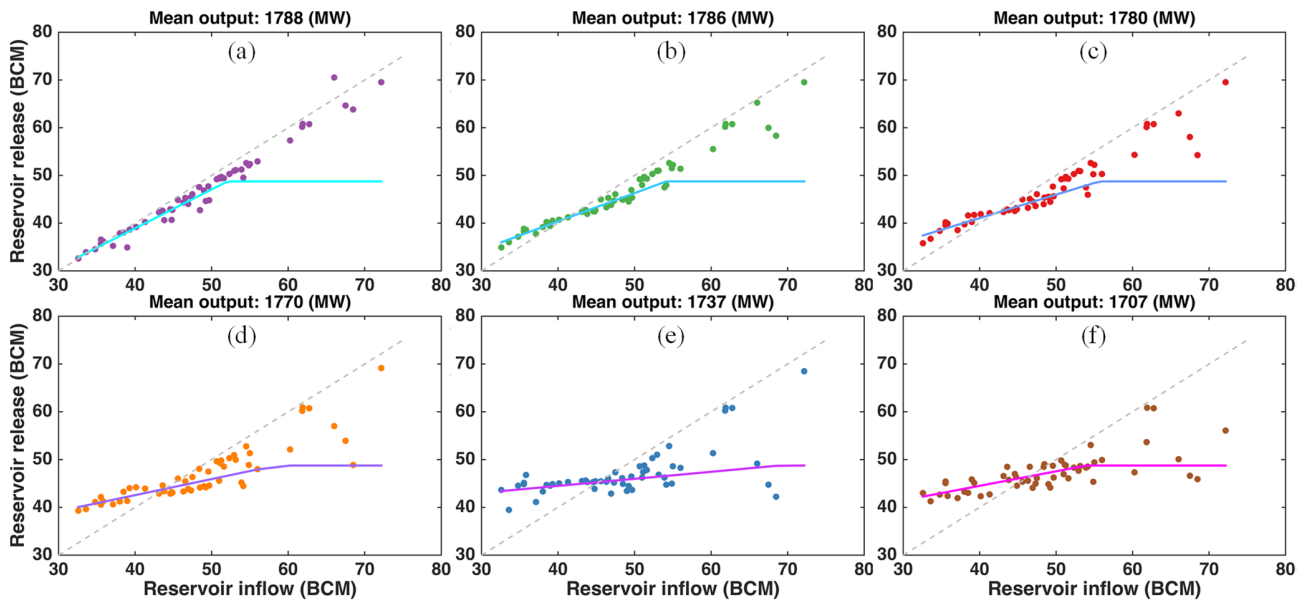

315 Fig. 6 Boxplots and values of annual reservoir (a)(b) water releases, (c)(d) storages, and (e) spillages for various
 316 reservoir operating rules; dashed line in (b) refers to reservoir inflow.

317 Comparing across rule types, rules with high mean output generate more hydropower mainly in wet years.
 318 In particular, rule type 1 (1788 MW) can generate approximately 670, 760, and 670 MW more than rule
 319 6 (1707 MW) in years 1988, 1998, and 2017, respectively. In these years, the annual reservoir inflow is
 320 greater than 65 BCM (Fig. 6 (b)). It is worth noting that the annual reservoir inflow in the previous one or
 321 two years (i.e., year 1987, 1997, and 2015) is less than 38 BCM (Fig. 6 (b)) and the reservoir storage of
 322 rule type 1 is much higher than in other rule types (Fig. 6 (d)). Thus, it can be inferred that rule types with
 323 larger power generation can increase the mean output by releasing less water during dry years to maintain
 324 relatively higher reservoir water levels. In this way, more water will be available and higher head (H_t^p
 325 in equation (1)) can be achieved for future wet years, leading to much more power generation.

326 However, releasing less water in dry years is not a strategy preferred by downstream countries. Although
 327 downstream releases are always greater than the minimum natural GERD inflow (which occurs in 2015),
 328 releases may clearly be less than natural flow in some dry years (e.g., 1965 & 1997, see Fig. 6 (b)), which

329 may aggravate drought conditions. According to the relationship between annual reservoir inflow and
 330 water release simulated from rule type 1, water release is less than reservoir inflow in most cases (Fig. 7
 331 (a)). In comparison, rule type 3 (1780 MW) releases more water than reservoir inflow in dry years. As
 332 power generation decreases further the number of years with reservoir water releases exceeding inflow
 333 increases. Applying a linear regression between annual reservoir inflow and water release (see the lines
 334 in Fig. 7), a drought mitigation policy (equation (10)) can be extracted to constraint annual water release
 335 in reservoir operation. Rule types favoring more power generation generally produce a steeper gradient in
 336 the drought mitigation policy.

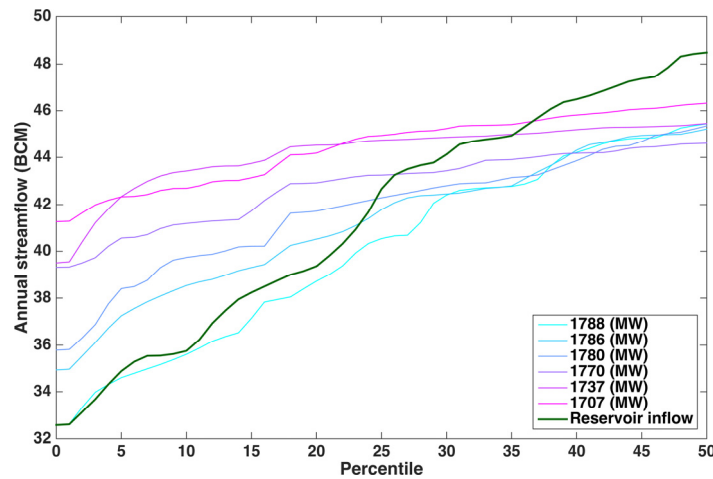

337
 338 Fig. 7 Relationship between annual reservoir inflow and water release (points) and the corresponding drought
 339 mitigation policy (lines) for various power generation levels.

340 4.2. Drought policy selection and analysis

341 To select the most suitable drought mitigation policy, both the corresponding power generation and reservoir release
 342 benefits in drought years may be evaluated. In this study, annual reservoir release amount and the deviation of annual
 343 releases are used as proxies for downstream benefits. For example, if annual releases during drought years is greater than

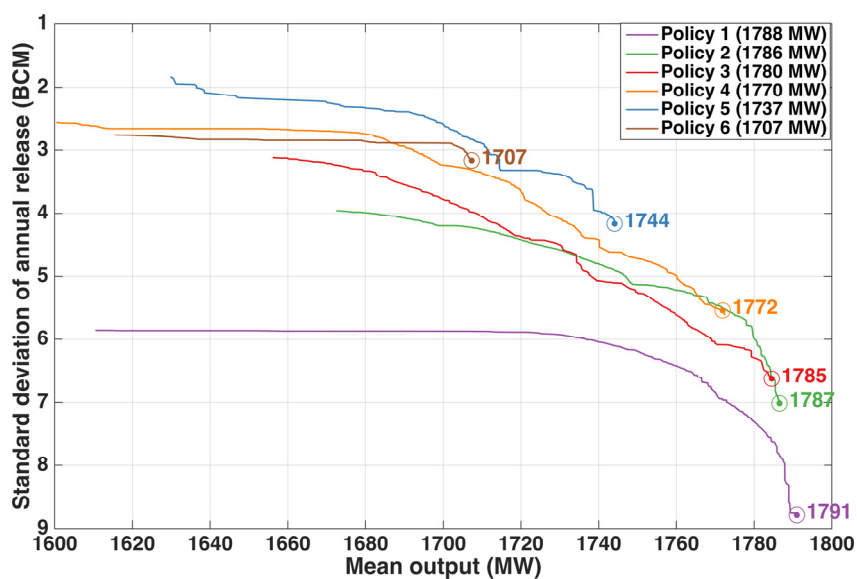

344 annual reservoir inflow (or natural flow), downstream droughts are partially mitigated. In general, the statistical
 345 distributions of annual reservoir inflow and releases are significantly different when reservoir operations are tailored to
 346 drought mitigation. This difference is more pronounced for lower power generation levels (see Fig. S2 in Appendix S1).
 347 Considering low flows, the 10th percentile of water releases increases as hydropower generation decreases, from 35.6
 348 BCM for rule type 1 (1788 MW) to 42.7 BCM for rule type 6 (1707 MW). Except for rule type 1, all rule types ensure
 349 that the 10th percentile of releases is greater than the 10th percentile of annual reservoir inflow (35.8 BCM). This equates
 350 to supplementing downstream flows to address drought conditions when the 10% exceedance value of annual reservoir
 351 inflow is used as the drought threshold. Further, even when reservoir inflow is less than its 20th percentile value, water
 352 releases are greater than annual reservoir inflow except for rule type 1 (Fig. 8). However, when the threshold exceeds the
 353 25th percentile, only solutions based on rule type 3-6 contain annual releases surpassing inflow. These distributions (Fig.
 354 8) can provide critical insights during riparian negotiations regarding trade-offs between power generation and
 355 supplementing downstream flows during drought conditions. Although only six candidate solutions are illustrated here,
 356 more representative solutions may be analyzed in practice.

357
 358 Fig. 8 Percentiles of annual reservoir inflow and water release under various power generation levels.

359 Incorporating these drought policies (Fig. 7), reservoir operating rules are optimized again for maximum
 360 power generation and minimum deviation of annual release volumes, illustrating varying trade-offs for
 361 drought policies 1-6 (Fig. 9). Drought policies produce similar but not exact hydropower generation as the

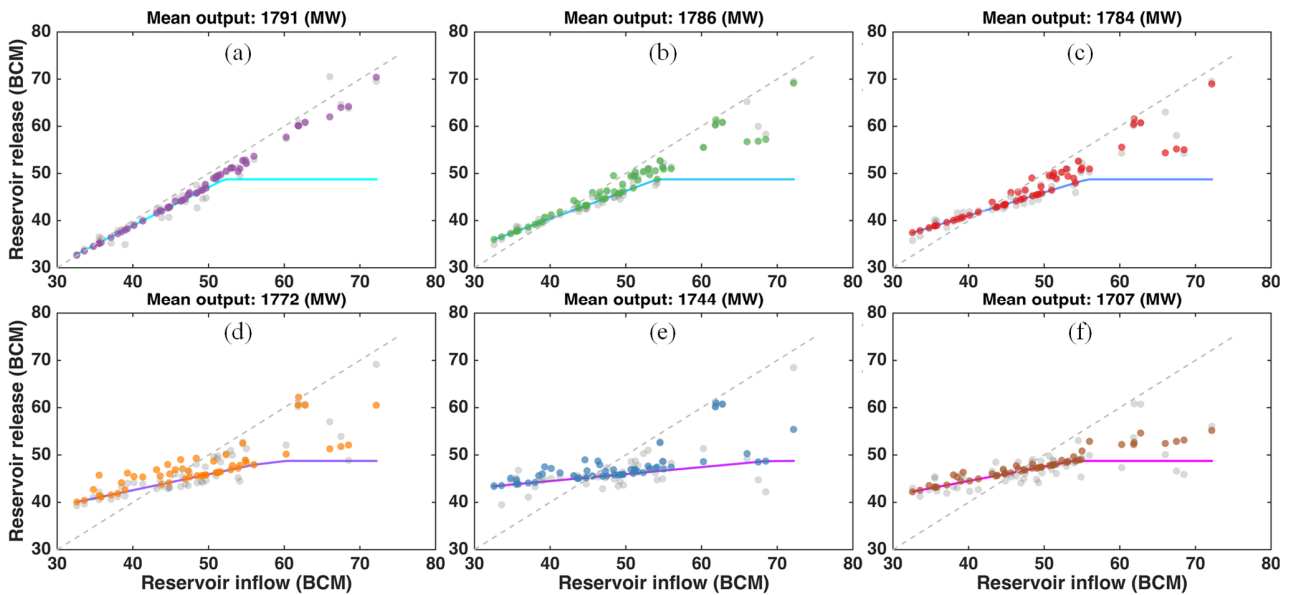

362 original operating rules (e.g. policy 1 original = 1788MW, drought = 1791MW); the standard deviation
 363 of annual releases also does not change significantly. Comparing drought policies producing a high level
 364 of hydropower production (e.g. moving from policy 1 to 2), a small trade-off in production (~4MW) leads
 365 to approximately a 2 BCM decrease in the standard deviation of annual releases. For lesser hydropower
 366 production policies (e.g. moving from policy 5 to 6), a larger difference of 37MW leads to a smaller (~1
 367 BCM) change in the standard deviation of annual releases.

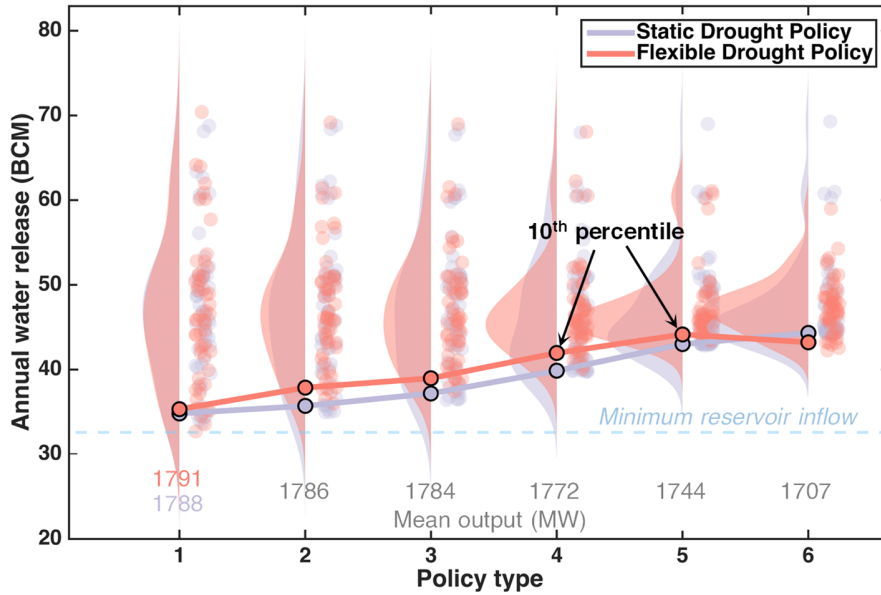

368
 369 Fig. 9 Multi-objective optimization of reservoir operating rules with drought mitigation policies.

370 After re-optimization with the drought policy information included, greater power generation and smaller
 371 values of the standard deviation of annual water releases are produced. More importantly, the re-optimized
 372 rules can fully ensure minimum annual releases under different reservoir inflow levels (Fig. 10). The
 373 reservoir operation results of the proposed drought policy are compared with those of conventional
 374 drought/water sharing policies. A conventional water sharing policy here refers to a “guaranteed quantity”
 375 or “minimum flow” strategy, i.e., GERD will guarantee a fixed volume of water release each year.
 376 Compacts adopting this strategy in whole or in part include the Colorado River Compact, Arkansas River
 377 Basin Compact, and Sabine River Compact, 68 Stat. 690 (1953) (McCormick, 1994; Draper, 2006). A

378 comparison (Fig. 11) indicates that the flexible drought policy proposed here can generate more power
 379 than a conventional (static) drought policy with a similar statistical distribution of water releases. In
 380 addition, flexible policies can better mitigate drought conditions (see the kernel distribution as well as 10th
 381 percentile of water releases in Fig. 11) than static policies for similar power output levels. This is because
 382 the flexible policy is derived from optimal reservoir operation results, which tends to generate more power.
 383 In contrast, the static policy (which is presented as a horizontal line instead of sloped lines in Fig. 10)
 384 transfers the risk of water shortages (or hydrologic variability) completely to the upstream GERD, which
 385 will limit GERD's ability to produce more power.

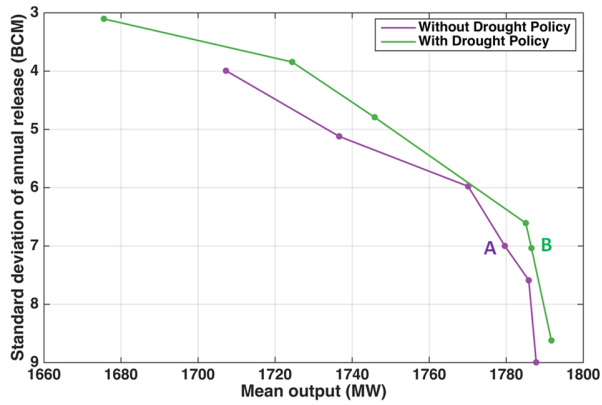

386
 387 Fig. 10 Relationship between annual reservoir inflow and releases using re-optimized reservoir operating rules;
 388 drought policies represented by lines; gray points refer to the inflow and release relationship from which drought
 389 policies are derived.

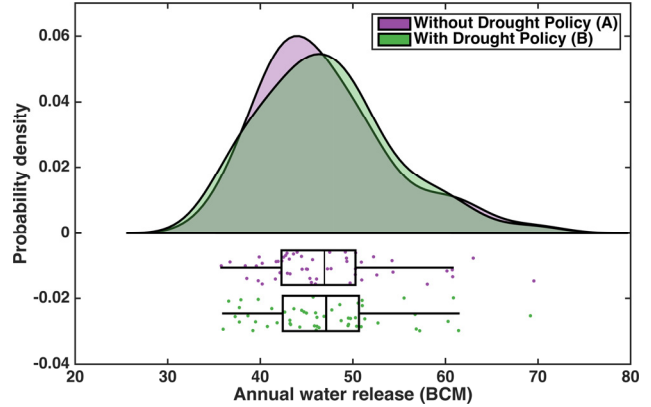

390

391 Fig. 11 Comparison of reservoir operations using flexible and static drought policies based on power generation
 392 output and water release distribution analysis. Policy type 1 refers to the comparison with a similar statistical
 393 distribution of water releases; Policy type 2-6 refer to comparisons with similar power generation outputs.

394 These re-optimized rules produce slightly more power than the original rules for equivalent standard
 395 deviation of annual release values (Fig. 12(a)) even though they are re-optimized constrained on annual
 396 water releases for drought conditions). Performance of the re-optimized rules, however, mainly depends
 397 on the exceedance parameter z in equation (10); more conservative drought mitigation policies (with larger
 398 z values) can generate more power. Because the trade-off between power generation and the standard
 399 deviation of annual releases is similar between the original rules and drought policy rules (Fig. 12(b)), it
 400 is feasible to base negotiations on the original rules in this case, as the expected drought policy outcomes
 401 are superior.

(a)

(b)

402 Fig. 12 (a) Pareto fronts of reservoir operation with and without drought policy; (b) boxplot of reservoir storage for
 403 solution A and B in the Pareto fronts and kernel distribution of annual reservoir water releases with and without the
 404 drought policies.

405 5. Conclusions

406 Reservoir operations in river basins will become more complex after considering diverse and potentially
 407 conflicting objectives between upstream and downstream stakeholders. With the water-sharing policy
 408 framework proposed here for the Grand Ethiopian Renaissance Dam on the Blue Nile River, a relationship
 409 between downstream and upstream water availability is established, water-sharing policies are derived
 410 from multi-objective optimization results of reservoir operating rules, and the effectiveness of these
 411 policies during drought periods is analyzed. It is demonstrated that a framework incorporating RBF-based
 412 rules and a drought-focused water sharing policy can lead to robust reservoir decision-making. There is a
 413 clear trade-off between power generation and the standard deviation of reservoir releases; however,
 414 effective policies are available to balance this trade-off, even considering drought periods.

415 It is worth noting that there are limited drought periods in the historical streamflow time series, which
 416 may lead to greater uncertainty in water sharing during severe droughts and may result in underestimating

417 the impact of hydrologic variability on GERD operations. To address this, the GERD inflow record could
418 be extended by relating it to other long-term gauging stations in the Nile basin to capture more historical
419 droughts and better characterize hydrologic conditions for enhanced policy design. In addition, the trade-
420 off in objectives may be affected by land use or climate changes, and if significant, the drought policy
421 may need to be adjusted accordingly in the future. However, there will always exist a trade-off between
422 reservoir power generation and water release variability, which can be used to inform drought policy
423 design, and the linear feature of the drought policy makes it relatively easy to adjust. It is very important
424 to connect the characteristics of a water sharing policy with the trade-off between reservoir storage and
425 releases. In this study, greater variability in releases leads to a steeper gradient of the drought policy line.
426 These types of drought policy characteristics can provide guidance for stakeholders to effectively adjust
427 the water sharing policy. Thus, the interpretable drought policy proposed here can enhance the
428 understanding of water sharing and promote multilateral negotiations between upstream and downstream
429 countries.

430 This framework here is based on annual flows, however seasonal and monthly scale operations could be
431 of primary importance in smaller basins or for smaller-capacity reservoirs. Also, many other objectives
432 and constraints including firm power output, agricultural water supply reliability, and ecosystem functions
433 could be considered. Future research could explore drought-focused water sharing policies guiding
434 reservoir operations across multiple time scales simultaneously and the application of seasonal-to-sub-
435 seasonal inflow forecasts.
