## Abstract

Accurate spatial-temporal information on evaporation is needed for use in many sectors including hydrology, agriculture and climate studies. This would require a dense observation network, which is practically impossible. Over the past decades, remotely sensed evaporation models to estimate spatially continuous evaporation have been developed. However, deciding which model to use is a challenge as these models vary in complexity and accuracy across the different global ecosystems. It is even more challenging for complex African ecosystems that have very few, or none at all, flux tower observations. In this study, we used the general water balance evaporation ( $E_{wb}$ ) as reference to which we compared six models that determine evaporation, i.e.,  $FLEX - Topo_{WB}$ , TerraClimate ( $TMC_{WB}$ ), GLEAM, MOD16, SSEBop and WaPOR, in the Luangwa Basin, a semi-arid catchment in the Miombo ecosystem in southern Africa.  $FLEX - Topo_{WB}$  and  $TMC_{WB}$  models are calibrated on discharge, while GLEAM, MOD16, SSEBop and WaPOR have been validated on evaporation data from flux tower observations. Key focus is on inter-model performance comparison in the Miombo ecosystem across phenophases and land cover types. Results show that major spatial-temporal discrepancies in model performance occur in the forest and open water body land surfaces during the dormant and green-up phenophases in the dry season. Compared to  $E_{wb}$ , annually WaPOR consistently overestimated evaporation while GLEAM consistently underestimated evaporation. The rest of the models showed biases within the GLEAM and WaPOR boundaries. With reference to annual mean bias SSEBop and WaPOR showed lowest aggregated 2009 -2020 bias in terms of estimating long-term average annual evaporation. It appears that correct understanding of the Miombo vegetation phenology associated moisture feedbacks and incorporating these in model structure is likely to improve evaporation estimates in the Luangwa Basin and Miombo Woodland ecosystem as a whole.

## 35 1.0 Introduction

Miralles et al. (2020) defines evaporation as “the phenomenon by which a substance is converted from its liquid into its vapour phase, independently of where it lies in nature”. Instead of the often-used term 'evapotranspiration', in this paper we use the term evaporation for all forms of terrestrial evaporation, including transpiration by leaves, evaporation from intercepted rainfall by vegetation and forest floor, soil evaporation, and evaporation from stagnant open water and pools (Miralles et al., 2020; Savenije 2004). Estimates indicate that through the evaporation process, the land surface transfers about 60 per cent of precipitation back to the atmosphere (Oki and Kanae, 2006; Van der Ent et al., 2010). Evaporation, through latent heat transfer, also helps in understanding the energy partitioning at the earth's surface (Trenberth et al., 2009; Fisher et al., 2008). Therefore, evaporation is considered a significant factor in the recycling of water available at the land surface (Van der Ent et al. 2010; Oki and Kanae, 2006). As a result, accurate estimation of evaporation is important as this allows for an improved and deepened understanding of water and energy cycles. However, ascertaining evaporation using field observations is a tedious, complex and expensive requiring specific devices and accurate measurements of various physical variables at different time intervals and spatial scales (Jiménez-Rodríguez et al., 2021; Coenders-Gerrits et al., 2020; Gerrits et al., 2007; Dyck, 1972). The field observations, which are normally point-based, are limited in application due to the shortcomings in the temporal and spatial scale. Furthermore, heterogeneity in the land surface and the loss of high accuracy of the measured values when upscaling to larger regions also limits its application (Dyck, 1972). Currently, assessment of evaporation is mainly from site observations at point scale using various approaches including, eddy covariance (Foken, Aubinet, and Leuning, 2012), lysimeters (Trajkovic, 2010) and the Bowen ratio energy balance (Lakhiar et al., 2018; Schilperoort et al., 2018; Spittlehouse and Black, 1980; Bowen, 1926). To bridge these gaps there has been accelerated development and application of satellite-based approaches to estimate evaporation at local, regional and global scales. Thus, evaporation estimates based on satellite data, largely, are bridging the gaps associated with field data collection, i.e., spatial and temporal constraints (McCabe, 2019; Zhang et al., 2016; Kalma et al., 2008; McCabe and Wood, 2006).

Despite availability of several open-source satellite evaporation models (i.e. Martens et al., 2017; Zhang et al., 2016; Miralles et al., 2011; Mu et al., 2011; Savoca et al., 2013; Bastiaanssen et al., 1998) these models differ in the spatial-temporal estimation of evaporation across land surfaces and scales (Weerasinghe et al., 2020; Jiménez et al., 2011; McCabe & Wood, 2006). Additionally, no consensus exists on which of these models is best taking into account each has its advantages and disadvantages depending on application (Zhang et al., 2016). To explore the relative merits of these models some studies have been done at global and African continent scales (i.e., Blatchford et al., 2020; Dile et al., 2020; Weerasinghe et al., 2020; Jiménez et al., 2011; Miralles et al., 2016; Liu et al., 2016). The overall outcome of these studies is that the accuracy of model estimates is land surface or ecosystem dependent and it varies among ecosystems globally. Furthermore, these remote sensing evaporation models are validated only on locations where in-situ observations exists. For the African continent, in-situ observations are extremely sparse and limited temporally. Additionally, African ecosystems are uniquely diverse and thus it is questionable whether performance of evaporation models is valid for these ecosystems.

Evaluation of models in non-Miombo ecosystems in Africa is not representative for evaporation model behaviour in the Miombo Woodland. Furthermore, for Africa, Weerasinghe et al. (2020) recommended that at catchment scale detailed assessment of models performance be conducted taking into account the characteristics of the specific basin. There is a need to evaluate performance of evaporation models specifically for the Miombo

75 Woodland basins. This is because the Miombo Woodland is Africa's largest tropical seasonal woodland and is a  
 dry forest formation that forms a transition zone between tropical rainforest and the African Savannah across 11  
 countries. It is an extremely important ecosystem in the food, water and energy nexus of Southern Africa (Gumbo  
 et al., 2018; Chidumayo & Gumbo, 2010; Frost, 1996). The Miombo Woodland is also a significant carbon sink  
 crucial in climate change mitigation (Pelletier et al. 2018). Also, noteworthy is the plant species diversity that  
 80 defines the Miombo ecosystem across its spatial vastness (Gonçalves et al., 2017; Giliba et al., 2011; Mapaire,  
 2001; Frost, 1996; Chidumayo, 1987). Different plant species have varying biophysical attributes and interacts  
 differently with the hydrological cycle. In the context of the vast Miombo ecosystem, this implies that species  
 composition in a given basin influences the evaporation characteristics of that basin. This means that actual  
 evaporation patterns at regional or basin scale are simply a summation of compartmentalized local forest and sub  
 85 basin actual evaporation patterns. Therefore, understanding the evaporation pattern at various scales in the Miombo  
 ecosystem is essential to understanding the overall characteristic of the evaporation dynamics at the ecosystem  
 level. Both Pelletier et al. (2018) and Tian et al. (2018) postulated that the functional traits of the Miombo  
 Woodlands vegetation species is different from other ecosystems. By implication, the dissimilarities in the  
 Miombo Woodland's ecological processes with other ecosystems in Africa signals the possibility of unique  
 90 evaporation models behaviour in this complex ecosystem. Furthermore, these evaporation models are normally  
 structured for agricultural purposes. However, crop plant moisture feedbacks are different from natural vegetation  
 as they have different physiological attributes and interact differently with changing hydrological regimes. Of the  
 few evaluation studies done in Africa (i.e., Blatchford et al., 2020; Dile et al., 2020; Weerasinghe et al., 2020),  
 those that included a Miombo Woodlands basin used global scale water balance as reference data. Furthermore,  
 95 the studies did not focus on the potential influence of Miombo Woodland phenological dynamics and plant-water  
 interaction influence on models' performance across seasons. However, what is common are the findings of these  
 studies that satellite-based evaporation products have a mixed performance across the African ecosystems, as they  
 tend to either overestimate or underestimate evaporation. They attribute this behaviour mainly to the uncertainties  
 associated with model structure, forcing data, model processes and scaling (Pagán et al., 2019).

100 In the context of the Miombo ecosystem region, making a choice on which open-source evaporation  
 model to use is extremely difficult due to extremely limited ecosystem specific validation studies. This constraint  
 is attributed to very few fluxes observation sites in the region. However, in absence of spatially distributed field  
 evaporation observations, it is still possible to assess model performance at catchment level using the general water  
 balance approach (precipitation minus surface runoff) (i.e., Weerasinghe et al., 2020; Liu et al., 2016).

105 We formulated this study to contribute to bridging the gap in information on satellite-based evaporation  
 models performance in the Miombo ecosystem. Focus was on the Luangwa sub-basin in the larger Zambezi Basin,  
 one of the largest river basins in the Miombo ecosystem. We chose the Luangwa Basin because it is located in a  
 sparsely gauged semi-arid region (Beilfuss, 2012) where management of water resources, based on reliable  
 information, for various competing uses i.e. hydropower, agriculture, wildlife, industrial and domestic (WARMA,  
 110 2022) is essential. The Luangwa Basin also falls within two of the largest Miombo Woodland sub-groups: dry  
 southern Miombo Woodlands and wet central Zambezi Miombo Woodlands. The central Zambezi Miombo  
 is the largest of the four Miombo sub-groups the other three being the Angolan Miombo, Eastern Miombo, and  
 the Southern Miombo (Frost, 1996; White, 1984). It is also located in Zambia, argued to have the highest diversity  
 of Miombo Woodland trees and considered centre of endemism for the Miombo Woodlands *Brachystegia* species

115 (Frost, 1996). These attributes suggest a catchment that is a fair representation of the Miombo Woodlands conditions and an appropriate site for this type of study. Therefore, our aim was twofold:

- 1) Compare performance of six open access and commonly used evaporation models at sub-basin level against the general water balance approach in the Luangwa Basin. Focus was to observe models' performance in relation to phenological transitions and land cover types.
- 120 2) We discuss potential underlying factors that could be contributing to the observed discrepancies in models' behaviour.

## 2.0 Materials and Methods

### 2.1 Study approach

The model performance comparison was done at monthly, seasonal and annual temporal scales. At annual  
 125 scale we compared six evaporation models to the general water balance evaporation ( $E_{wb}$ ) for the period 2009 - 2020. We deemed the 12 year period sufficient to capture long-term seasonal, monthly and annual variations in catchment evaporation. At monthly scale, we intercompared the performance of the six models with focus on the rain and dry seasons and the various phenophases in the Luangwa Basin. The six models included *FLEX - Topo<sub>WB</sub>* (Hulsman et al., 2021; Hulsman et al., 2020; Savenije, 2010), TerraClimate Thornthwaite-Mather Climatic water balance model (*TMC<sub>WB</sub>*) (Abatzoglou et al., 2018) and Global Land Evaporation Amsterdam Model (GLEAM) (Martens et al., 2017; Miralles et al., 2011). The others are the Moderate-resolution Imaging Spectrometer (MODIS) MOD16 (Running et al., 2019; Mu et al., 2011; Mu et al., 2007), Operational Simplified Surface Energy Balance (SSEBop) (Savoca et al., 2013) and the Water Productivity through Open  
 130 access of Remotely sensed derived data (WaPOR)(FAO 2018). In the absence of field observation of evaporation we chose *FLEX - Topo<sub>WB</sub>* and *TMC<sub>WB</sub>* as reference evaporation at monthly scale because they are calibrated on observed discharge and not on Eddy Covariance tower data from locations outside the Miombo region and Luangwa Basin specifically. We selected GLEAM, MOD16, SSEBop and WaPOR because they are open source with both historical and real-time data. Additionally, they have desirable spatial-temporal attributes for monitoring evaporation and are commonly used products globally with WaPOR being a continental product.

140 Compared to other ecosystems, Pelletier et al. (2018) and Tian et al. (2018) observed that Miombo Woodland species exhibit distinct behaviour during the dry season. In view of Pelletier et al. (2018) and Tian et al. (2018) observations, we ascertained existence of discrepancies in spatial-temporal model performance that reflect the distinct behaviour under changing seasons (i.e., dry (May - October) and wet (October - April) seasons) and phenological stages of the Miombo Woodland and Luangwa Basin in general. We compared model  
 145 performance during seven Miombo Woodland phenophases. We based the phenophases classification on the Collection 6 MODIS Land Cover Dynamics (MCD12Q2) Product (Gray et al., 2019), Zimba et al. (2020), as well as on own field observations of the Miombo phenology in the Luangwa Basin. Figure 1 highlights the phenophases classification. The phenophases include; Green-up, Mid-Green up, Maturity, Peak, Senescence, Green-down, and Mid-green down and dormant. For easy of analysis we merged the phenophases into four groups (Figure 1) based  
 150 on dominant activity in each phase.

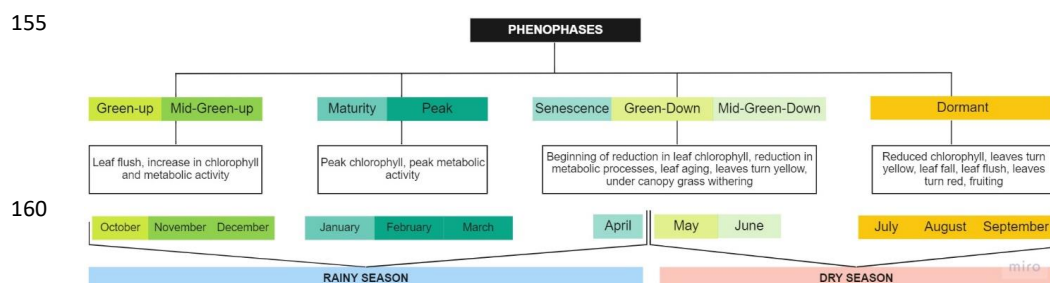

Figure 1. Grouping and description of phenophases in relation to seasonality for the Luangwa Basin used in the study.

The water balance evaporation ( $E_{wb}$ ) has been estimated using equation 1 where we neglect storage change over a year.

$$E_{wb} = P - Q \quad (1)$$

Where,  $P$  is the catchment precipitation in mm/year and  $Q$  is discharge/catchment surface runoff in mm/year. Oki and Kanae (2006) and Zhang et al. (2016) indicated that model inputs are one of the major sources of uncertainties in evaporation model performance. For rainfall and discharge, we made use of the TerraClimate product, which we validated with local observations. In Appendix Figure A1.1, we show the comparison between TerraClimate and observed discharge records. For the simulations the regression between observed and TerraClimate was used to extend the period of observations from 2009 - 2020. For the precipitation we conducted a validation exercise on three precipitation products which included the Climate Hazards Group InfraRed Precipitation with Station data (CHIRPS), Climate Forecast System Reanalysis (CFSR) and TerraClimate precipitation. The assessment was done at monthly and annual scales for years with complete field observations. The field data was obtained from the SASSCAL WeatherNet at Kabwe and Serenje weather stations (<http://www.sasscalweather.net>) and the ZAMSECUR project field observations (Mpika station). Location of the weather stations is shown in Figure 2. The Kabwe and Serenje stations had complete data sets for the period 2014-2016 and Mpika 2020 -2021. The TerraClimate precipitation product appeared to have the least bias for the  $E_{wb}$  reference evaporation. After validating precipitation, we assessed monotonic trends in long-term (2009 – 2020) mean monthly and annual evaporation datasets (i.e., Weerasinghe et al., 2020; Liu et al., 2016).

Different land surfaces, i.e., forests, grassland, open water body give different evaporation feedbacks (Granger and Hedstrom, 2010; Moors, 2012; Makkink, 1957). To this extent, we compared model performances based on six major land cover types; dense forest, mixed open forest and grassland, shrub-land, cropland, open water body and build up area. We used monthly evaporation averages for the period 2009 – 2020. The six land cover classes were purposively selected based on verified field observations of the land cover done between 2018 and 2021 in the Luangwa Basin. We selected areas with minimal potential for land cover class transitioning into other classes overtime. For instance, the dense forest land cover was based on a protected natural forest in a conservancy region, irrigated crop land cover was based on known established active commercial farmlands that have been in existent for over ten years. Rain-fed cropland was selected from areas with established rural

195 settlements and cropland. Build up area/settlement was based on an old and expanding urban settlement. Shrub-  
 land was selected from a game reserve area. To augment the correct selection of the land-cover types we used high  
 resolution google earth platform. We compared the field based land cover data points with the Copernicus 2019  
 land cover classification for the Luangwa Basin. The Copernicus land cover product uses high spatial-resolution  
 (10 m) Sentinel data for classification with more detail than other products. Special focus was on the comparison  
 200 of models in the dense forest across the phenophases.

To observe changes in canopy display in Miombo forest we installed a Denver digital camera on a tower  
 above the canopy of a known Miombo forest in Mpika (Figure 2). This was done to obtain field imagery to compare  
 with the pattern of satellite-based normalised difference vegetation index (NDVI) and evaporation model  
 behaviour at different stages of the canopy display pattern. The observations were done for the period January –  
 205 December 2021.

To establish relationships among variables and assessing accuracy of models we used various statistical  
 models. We checked for monotonic trends and coupled magnitude in evaporation time series using non-parametric  
 Mann-Kendall (Helsel et al., 2020) trends test (equation A1-A6 in section A1.1 in the appendices). We tested for  
 trends at monthly and annual temporal scales for the period 2009 - 2020. To establish correlation among the models  
 210 the Kendall correlation test (Helsel et al., 2020; Kendall, 1975) (equations A7 in section A1.2 in the appendices)  
 was used. Correlation was assessed at monthly and annual scales. Model performance assessment was done using  
 the coefficient of determination ( $R^2$ ) (Helsel et al., 2020) (equation A8 in section A1.3 in the appendices), root  
 mean square error (RMSE) (Helsel et al., 2020) (equation A9 in section A1.3 in the appendices) and the mean bias  
 (Helsel et al., 2020) (equation 2).

215 The mean Bias is the measure of the extent to which modelled values deviate from observed values. It  
 indicates whether there is under or overestimation of values by the model. The interpretation is that the smaller the  
 mean Bias value (positive or negative) the less the deviation of the predicted values from the observed values.

$$\text{Mean Bias} = \sum(X - \hat{Y})/N \quad (2)$$

220 Where  $N$  = number of observations,  $Y$  = actual observations time series and  $X$  is the modelled time series.  
 Statistical analyses were done for the annual scale, rain and dry seasons and for phenophases.

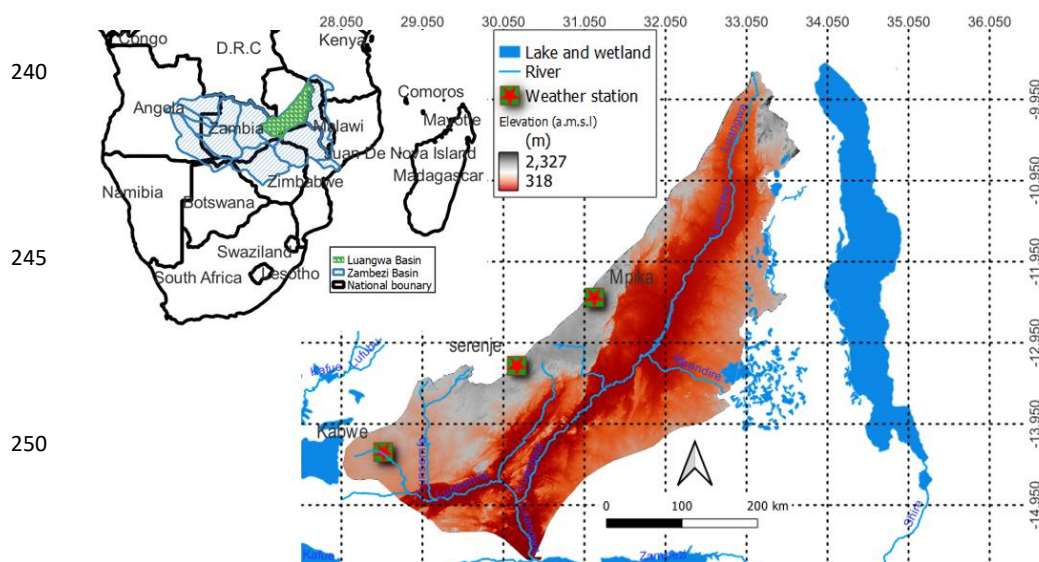

## 2.2 Study site

The Luangwa is a sub-basin in the larger Zambezi Basin in sub-Saharan Africa in Zambia (Figure 2). It  
 is about 159,000 km<sup>2</sup> in spatial extent and is largely covered with deciduous forests, herbaceous wetlands, shrubs  
 225 and herbaceous vegetation/savanna (Figure 2; Phiri et al. (2019)). Elevation ranges between 318 – 2327 m above  
 mean sea level with the central part generally a valley (Figure 2). The Luangwa River, 770 km long, and its  
 tributaries drain the basin (Beilfuss 2012). The Luangwa Basin is scarcely gauged and with paucity of data on  
 various hydrological aspects. The basin is located in a semi-arid environment characterised by a well-delineated  
 wet season, from October to April and a dry season, May to October. Furthermore, the dry season is split into the  
 230 cool-dry (May to August) and hot dry (August to October) seasons. The movements of the inter-tropical  
 convergence zone (ITCZ) over Zambia between October and April dominate the rainfall activity in the basin. The  
 basin has a mean annual precipitation of about 970 mm.yr<sup>-1</sup>, potential evaporation of about 1560 mm.  
 yr<sup>-1</sup>, and river runoff reaches about 100 mm.yr<sup>-1</sup> (Beilfuss, 2012; World Bank, 2010). The key character of

the deciduous forests is that they shed off old leaves and acquire new ones during the period May to October in  
 235 the dry season. Frost (1996) revealed that depending on the amounts of rainfall received in the preceding rain  
 season the leaf fall and leaf flush processes may start early (i.e., in case of low rainfall received) or late (in case of  
 high rainfall received) and may go up to November (i.e., in the case of high rainfall received).

255 Figure 2. Location of the Luangwa Basin in the Zambezi Basin in Zambia and spatial distribution of elevation with  
 ASTER digital elevation model.

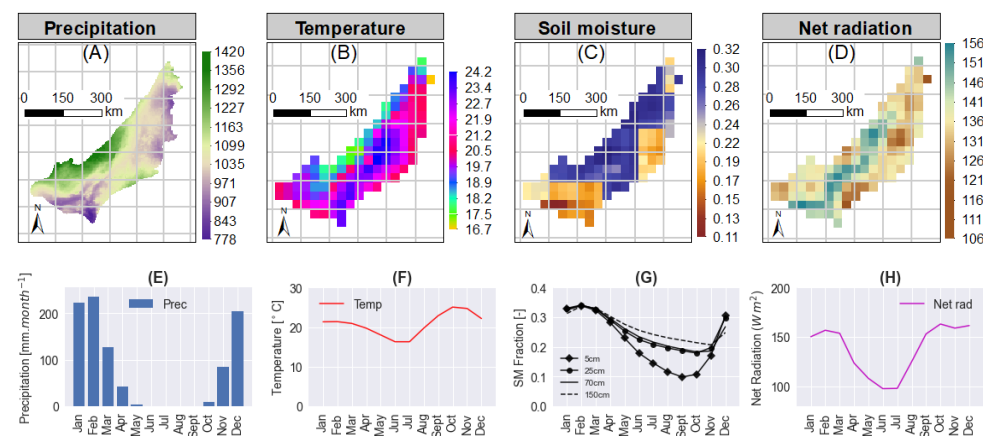

According to Phiri et al. (2019), the basin is largely covered by primary and secondary deciduous forests.  
 Primary forests are parcels of forests without anthropogenic disturbances while secondary forests are  
 260 characteristically regenerated forests after anthropogenic disturbances. The larger component of the forest in the  
 basin seems to fall under the secondary forest. This is indicative of increased anthropogenic activities such as  
 commercial and small-holder agriculture in the basin. Another anthropogenic activity that affects Miombo forest  
 and the general Luangwa Basin landscape are the wide spread annual wild fires, which result in large areas getting  
 burnt. The fires normally occur between May and November in the dry season (Phiri et al., 2019; Frost, 1996). The  
 265 Luangwa Basin also hosts hydro-power stations located on tributaries (i.e., Lunsemfwa River) to the Luangwa  
 River (Phiri et al., 2019).

### 2.3 Meteorological conditions during study period

Figure 3 shows the spatial (A-D) and temporal (E-H) distribution of average precipitation, temperature, soil  
 270 moisture and net radiation for the study area during the period 2009 – 2020. From Figure 3A we see that the  
 highlands receive more rainfall than the low lands. In terms of the temporal distribution (Figure 3E), much of the  
 precipitation is between December and April. Across the basin, spatial distribution of temperature (Figure 3 B&F)  
 varied with lower temperatures observed in high soil moisture content (Figure 3 C & G), high rainfall temperature

environments. Like with the air temperature, monthly net radiation (Figure 3 D & H) spatially varies across the basin ranging between 100 - 200  $\text{W.m}^{-2}$ . High net radiation, of above 150  $\text{W.m}^{-2}$ , is observed for period September - February. Net radiation is lowest during the cool dry season, May - August.

**Figure 3.** (A-D) Spatial distribution of long-term (2009 -2020) TerraClimate precipitation (mm/year) and CFSR soil moisture ( $\text{m}^3.\text{m}^{-3}$ ), air temperature ( $^{\circ}\text{C}$ ) and net radiation ( $\text{W.m}^{-2}$ ) in the Luangwa Basin. (E-H) Long-term (2009 – 2020) averages showing the monthly temporal distribution of precipitation, soil moisture, air temperature and net radiation for the Luangwa Basin.

## 2.4 Data sets

Apart from the  $E_{wb}$ , we used six evaporation products that included two water balance evaporation models (WBM) FLEX-Topo<sub>WB</sub> and  $TMC_{WB}$  and four energy balance evaporation models (EBM) GLEAM, MOD16, SSEBop and WaPOR (Table 1).

We used the FLEX-Topo<sub>WB</sub> because it was structured specifically for the Luangwa Basin landscape and was calibrated on field observations-based discharge of the basin at a daily temporal scale (Hulsman et al., 2021). We forced FLEX-Topo<sub>WB</sub> model with spatially distributed CHIRPS precipitation and GLEAM potential evaporation. Each cell has been discretised into functionally distinct hydrological response units (HRU) based on the topography. The model uses a single ground water system within a grid cell to which all HRU are connected. It is composed of several storage components representing the interception storage, unsaturated root-zone storage, as well as fast and slow responding storages. Furthermore, each storage component has been structured as a reservoir with matching water balance equations. In terms of performance, with respect to observed discharge, calibrated for the period 2004 -2009, the model performed relatively well with the following Nash-Sutcliffe metric;  $NS_Q = 0.66$  (using discharge time-series),  $NS_{\log}(Q) = 0.82$  (using logarithmic discharge time-series),  $NS_{FDC} = 0.91$  (using flow duration curve) and  $NS_{\log}(FDC) = 0.97$  (using logarithmic flow duration curve). However, the limitation with the FLEX-Topo<sub>WB</sub> was the 27.7 km spatial resolution. Compared to FLEX-Topo<sub>WB</sub>,  $TMC_{WB}$  is a relatively high spatial resolution water balance product. Like FLEX-Topo<sub>WB</sub>, it is also calibrated with field observations based on the Global Runoff Data Centre (GRDC) data set (Abatzoglou et al., 2018). It has shown good results in ecosystems where it has been validated and compared relatively well with other evaporation

310 products (Abatzoglou et al., 2018). In our study, calibration with basin discharge, the 4 km spatial resolution and monthly temporal resolution were desirable attributes for use as reference evaporation.

As evaporation products, GLEAM, MOD16, SSEBop and WaPOR were selected for use in this study because they are open -source products with wide usage across Africa and the globe in the case of GLEAM, MOD16 and SSEBop. Except GLEAM (with spatial resolution of 27.7 km), these products have high spatial  
315 resolution (i.e., 500m, 1000m and 250 m for MOD16, SSEBop and WaPOR respectively) and temporal resolution (daily, 8-day and decadal respectively) which are attributes suitable for our application. GLEAM and WaPOR account for interception and vegetation interaction with the root zone storage. These are important aspects in the evaporation processes and potentially significant components in the Miombo ecosystem evaporation. Since different land cover surfaces have different moisture feedbacks, the use of land cover products in GLEAM,  
320 MOD16 and WaPOR are likely to give better representation of spatial distribution of moisture feedbacks in the Miombo ecosystem. It is an established fact that different land surfaces have specific land surface temperature feedbacks (i.e., Rocha et al., 2020; Sun et al., 2016) a principal utilised by SSEBop model to estimate evaporation. Since the Miombo ecosystem and the Luangwa Basin in particular is a water limited semi-arid environment the use of the land surface temperature feedbacks to estimate evaporation could prove a more reliable approach in this  
325 ecosystem. In general, we selected these evaporation products based on the potential of the structure and processes to capture moisture feedbacks in a unique ecosystem in a semi-arid environment.

Table 1. Characteristics of data used in this study

Variable	Product name	Time Period	Spatial coverage/location	Temporal resolution	Spatial resolution	Reference	Source of data

### 3.0 Results

#### 3.1 Sensitivity of precipitation products and trends analysis of evaporation products

Figure A1 in the appendices shows the validation results of the precipitation products. Overall, the TerraClimate precipitation showed the least bias and was thus used in the general water balance evaporation estimates. Figure A2 in the appendices shows the results of the comparison of TerraClimate runoff data with field observations and regression results. The regression results are close to field observations hence the use of the approach to extend runoff estimates for the period 2009-2020. Table 2 and Table A2 (in the appendices) shows annual and monthly descriptive and Mann-Kendall trends analysis statics for the various evaporation products used in the study. At both monthly and annual scales, except for the SSEBop with a significant monthly seasonal downward trend (Table A1 in the appendices), all other evaporation products showed no significant trend in evaporation as the computed Z-test statistics were  $-1.96 < Z(c) < 1.96$  and the  $p$ -values were greater than the alpha level 0.05. The non-existent of significant trend in long-term basin evaporation fulfilled the condition for use of the general water balance to estimate basin-scale reference evaporation for comparison across different times. At annual scale, except for the  $E_{wb}$  (14 percent), the rest of the evaporation products showed less than 10 percent annual variation in evaporation estimates. However, seasonal monthly evaporation showed variations of up to 60 percent (i.e.,  $TMC_{WB}$  and MOD16) (Table A1 in the appendices). The large variability when a wet year follows a dry year, or vice-versa (as we see between 2014 and 2017 in Figure 4), is due to over-year storage that the water balance methods neglects at annual scale.

Table 2. Descriptive and Mann-Kendall trends statics for each model for the period 2009 - 2020

Statistic	No	Min	Max	Mean	SD	VC	Z-test	$\beta$	p-value	Alpha	Decision
$TMC_{WB}$	12	694.87	940.68	808.26	79.01	0.09	0.07	1.37	0.95	0.05	No trend
FLEX-Topo <sub>WB</sub>	12	741.57	870.14	801.77	40.79	0.05	-1.44	-7.70	0.15	0.05	No trend
WaPOR	12	854.61	1039.35	970.78	50.40	0.05	-1.30	-4.46	0.19	0.05	No trend
SSEBop	12	766.94	919.14	836.91	46.40	0.05	-0.75	-5.70	0.45	0.05	No trend

MOD16	12	756.16	861.79	806.96	31.55	0.04	0.34	0.68	0.73	0.05	No trend
$E_{wb}$	12	644.19	1070.70	821.01	122.72	0.14	0.21	5.10	0.84	0.05	No trend

Interpretation: No. = number of observation, Min = minimum, Max = maximum, SD = standard deviation, VC = variation coefficient

#### 3.2 Temporal variability in evaporation and model performance at annual scale

Figure 4A shows the annual evaporation and TerraClimate precipitation while Figure 4B gives the annual Bias for each model with reference to  $E_{wb}$  for the period 2009 – 2020. Figure A3 in the appendices shows performance statics of the models at annual scale. As mentioned above, the peak and dip in the bias in the period 2014 – 2017 is an artefact of the general water balance method that neglects over-year storage. Across the examined period, annual estimates of evaporation varied from model to model with the WaPOR and GLEAM at the upper and lower end respectively. It appeared, that except for  $TMC_{WB}$ , the rest of the models did not consistently respond appropriately to changes in annual precipitation. With reference to  $E_{wb}$ , compared to other EBM the WaPOR consistently overestimated annual evaporation and GLEAM consistently underestimated annual evaporation. Between 2009 and 2014, FLEX – Topo<sub>WB</sub>,  $TMC_{WB}$ , MOD16 and SSEBop evaporation pattern aligned relatively well with low biases. However, between 2015 and 2020  $TMC_{WB}$  showed higher evaporation estimates than the FLEX – Topo<sub>WB</sub>, MOD16 and SSEBop but followed  $E_{wb}$  pattern (Figure 4).

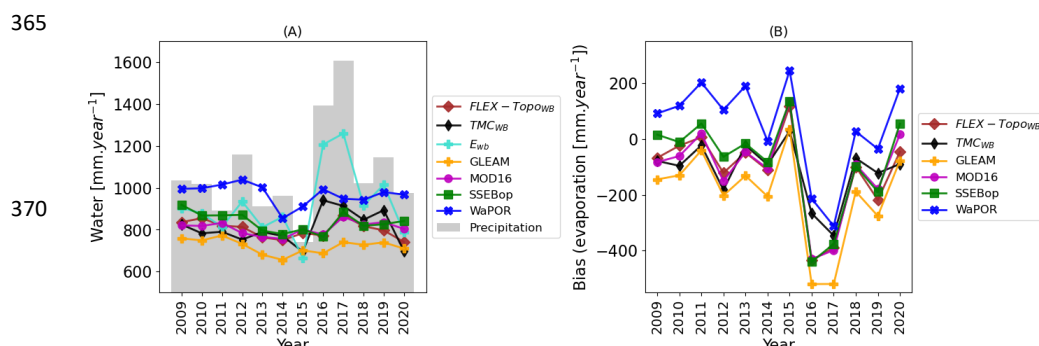

Figure 4. (A) EBM and WBM temporal pattern of average annual evaporation and (B) annual bias evaporation of models with reference to the general water balance ( $E_{wb}$ ) for the period 2009 – 2020 in the Luangwa Basin.

There is weak correlation ( $r < 0.4$ ) between  $FLEX - Topo_{WB}$  and  $TMC_{WB}$  (Table A2 in the appendices). Except with the WaPOR,  $FLEX - Topo_{WB}$  exhibited strong ( $r > 0.7$ ) annual correlation with GLEAM, MOD16 and SSEBop.  $E_{wb}$  and  $TMC_{WB}$  showed weak ( $r < 0.4$ ) correlation with all EBM (Table A2 in the appendices). With reference to the  $E_{wb}$  (Figure 4B), except for the years 2016, 2017 and 2019 WaPOR overestimated evaporation and showed a bias range of -311 to 245.34 mm.year<sup>-1</sup>. The rest of the models generally underestimated annual evaporation with bias ranges of -434.05 to 117.7 mm.year<sup>-1</sup> for  $FLEX - Topo_{WB}$ , -346 to 28.70 mm.year<sup>-1</sup> for  $TMC_{WB}$ , -519.59 to 35.34 mm.year<sup>-1</sup> for GLEAM, -430.05 to 16.86 mm.year<sup>-1</sup> for MOD16 and -430 to 135 mm.year<sup>-1</sup> for SSEBop (Figure 4B and Figure A3 in the appendices). Generally, with reference to  $E_{wb}$ , the SSEBop, MOD16 and  $FLEX - Topo_{WB}$  appeared to have relatively lower annual biases compared to other models especially for the period 2009 – 2015. During the 2016 – 2020 period, the WaPOR appeared similar with other models and showed relatively lower bias (Figure 4B). For the entire 12 year period (2009 – 2020) the WaPOR showed the least aggregated mean bias of about 50 mm.year<sup>-1</sup> (overestimation) followed by the SSEBop with about -84 mm.year<sup>-1</sup> (underestimation). GLEAM showed the largest aggregated bias of about -200 mm.year<sup>-1</sup> (underestimation) (Figure A4 in the appendices).

### 3.3 Temporal distribution of mean monthly evaporation, correlation and model performance

Figure 5A shows inter-annual variability in EBM and WBM monthly evaporation. Across the 2009 – 2020 period, the general pattern in the temporal distribution of evaporation for each model appeared consistent. Major discrepancies in temporal pattern appear to be seasonal with a clear distinction between the rain and dry seasons. Figure 5 B shows long-term (2009 – 2020) aggregated temporal distribution of mean monthly evaporation for EBM and WBM. The WBM and EBM models behaviour appear to agree better during the high moisture and high canopy cover period in the rainy season between November and April. Model behaviour begins to differ at the wet (October – December) and dry (March – May) season boundaries. Significant differences in model behaviour is exhibited during the dry period of the year between May and October.

**Figure 5.** Comparison of models temporal distribution of mean monthly evaporation: (A) inter-annual temporal variations in mean monthly evaporation (B) Aggregated mean monthly evaporation for the rain and dry seasons in the Luangwa Basin (2009 – 2020).

Overall, during the rainy season the TMC<sub>WB</sub> model generally exhibit slightly higher values of evaporation compared to the other models. Reference to the FLEX-Topo<sub>WB</sub>, EBMs, with an exception of the WaPOR and SSEBop, exhibits relatively lower evaporation estimates during the drier part of the year and the patterns also differ. Though WaPOR shows a similar temporal distribution pattern with FLEX-Topo<sub>WB</sub>, its evaporation estimates are higher.

Subjecting the 2009 – 2020 monthly time series to a normality test showed the data was not normally distributed which necessitated the use of the non-parametric Kendall correlation test. FLEX-Topo<sub>WB</sub> and TMC<sub>WB</sub> showed similar correlation coefficients with EBM with Kendall  $\tau > 0.54 \leq 0.80$  (Figure A5 and Table A3 in the appendices). FLEX-Topo<sub>WB</sub> had strongest correlation with GLEAM ( $\tau = 0.77$ ), followed by MOD16 ( $\tau = 0.75$ ), WaPOR ( $\tau = 0.66$ ) and SSEBop ( $\tau = 0.54$ ). TMC<sub>WB</sub> had strongest correlation with GLEAM ( $\tau = 0.73$ ), followed by WaPOR ( $\tau = 0.62$ ), MOD16 ( $\tau = 0.61$ ) and SSEBop ( $\tau = 0.54$ ). Intercomparison among EBM showed highest correlation ( $\tau = 0.80$ ) was between GLEAM and MOD16 while lowest correlation ( $\tau = 0.56$ ) was between SSEBop and WaPOR. Figure 6 shows EBM performance statistics with reference to FLEX-Topo<sub>WB</sub> and TMC<sub>WB</sub>. With reference to FLEX-Topo<sub>WB</sub> strongest agreement with all EBMs was at the end of rain season during

senescence, green-down and Mid-green-down phenophases with  $R^2$  range of 0.77 – 0.98 and Bias range 6.13 – 13.41 mm.month<sup>-1</sup>. The most disagreement of the EBM's with FLEX-Topo<sub>WB</sub> was during the dormancy phenophase in the dry season with  $R^2$  range 0.001 – 0.54 and Bias 8.59 – 26.75 mm.month<sup>-1</sup>. GLEAM, except during Green-up and Mid-green-up, generally underestimated evaporation while WaPOR generally overestimated evaporation across phenophases. MOD16 and SSEBop showed mixed performance with general underestimation of evaporation during senescence, green-down, Mid-green down and dormant phenophases (Figure 6). With reference to TMC<sub>WB</sub>, like with FLEX-Topo<sub>WB</sub>, strongest agreement with all EBM's was during senescence and Mid-green-down phenophases with  $R^2$  range 0.61 – 0.85 and Bias range 1.67– 22.75 mm.month<sup>-1</sup>. The most disagreements, contrary to the observations with FLEX-Topo<sub>WB</sub>, were during Green-up/ mid-Green-up and Maturity/Peak phenophases in the rainy season with  $R^2$  range of 0.32 – 0.77; 0.06 – 0.58 respectively. In terms of Bias, with an exception of MOD16 all EBM's generally underestimated evaporation during Maturity and Peak phenophases.

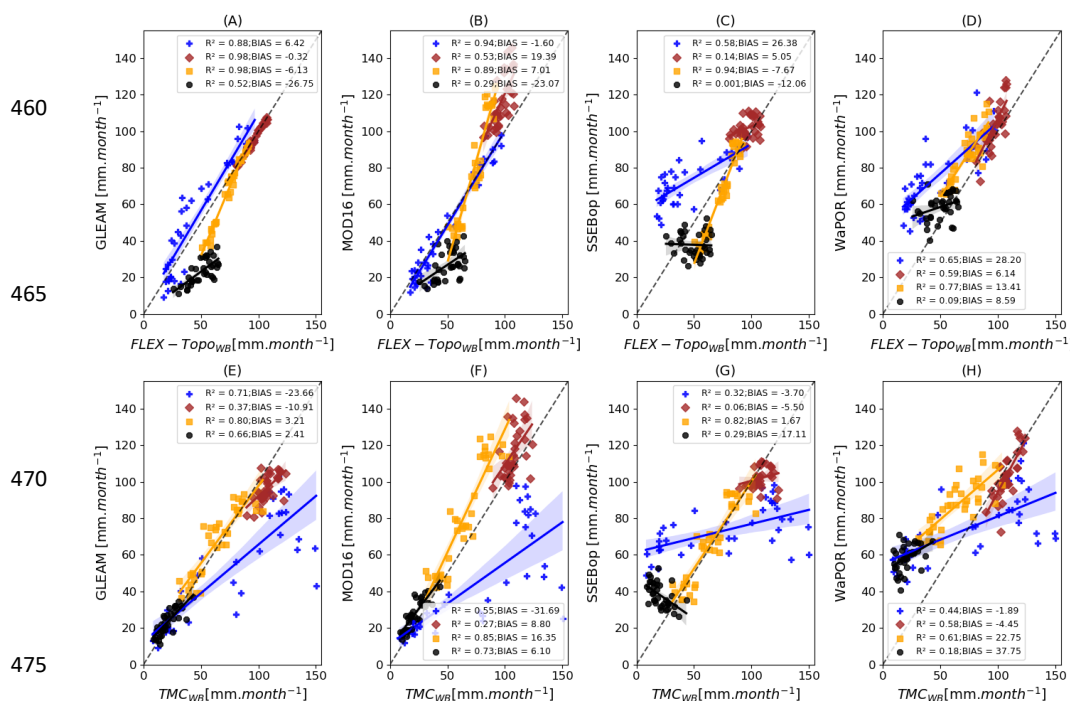

Figure 6 A. Basin scale comparison of mean monthly (2009-2020) EBM with WBM. (A-D) EBM comparison with FLEX-Topo<sub>WB</sub> and (E-H) comparison with TMC<sub>WB</sub>. Colour code: BLUE= Green-up/Mid-Green-up; BROWN = Maturity/Peak; ORANGE = Senescence/Green-down/Mid-Green-down and BLACK = Dormant phenophase.

With reference to Bias, MOD16 underestimated evaporation during Green-up and Mid-Green-up phenophases but overestimated during the rest of the phenophases with Bias range 6.10 – 31.69 mm.month<sup>-1</sup>. GLEAM, SSEBop and WaPOR showed mixed performance underestimating during Green-up/ mid-Green-up and Maturity/Peak phenophases and overestimating evaporation during senescence, Mid-green down and dormant

phenophases with Bias range of  $1.89 - 37.75 \text{ mm.month}^{-1}$  (Figure 6). With reference to both FLEX-Topo<sub>WB</sub> and TMC<sub>WB</sub> model performance varied depending on season, i.e., rainy or dry season, and phenophase.

### 3.3 Spatial-temporal evaporation distribution during phenophases and model performance

Figure 7A shows spatial-temporal distribution of NDVI and evaporation while Figure 7B shows violin plots of evaporation across phenophases in the Luangwa Basin. NDVI was used as indicator of spatial-temporal transitions in vegetation greenness, canopy cover and vegetation water content across phenophases. Spatial and temporal distribution of evaporation varied among models across phenophases (Figure 7A and B). During the maturity/peak period, the MOD16 and TMC showed spatial patterns different from the NDVI and other evaporation models. In terms of distribution of evaporation values, except for MOD16, all models had similar pattern and ranged between  $250 \text{ mm.3-months}^{-1}$  and  $350 \text{ mm.3-months}^{-1}$  (Figure 7A). FLEX-Topo<sub>WB</sub>, GLEAM and TMC<sub>WB</sub> showed very minimal variation in evaporation estimates. MOD16, SSEBop and WaPOR exhibited outliers at both end of the distribution. During the senescence/green-down period, spatial distribution of evaporation was similar among all models and followed NDVI pattern. During dormant phenophase, except for the SSEBop and WaPOR, the rest of the models exhibited similar spatial distribution of evaporation and appeared in tandem with NDVI.

During the maturity/peak phenophases (Figure 7 A), except for the MOD16 and TMC, distribution of evaporation estimates was relatively similar among all the models as indicated by the means, standard deviations and variation coefficient (Table A4 in the appendices). The maturity/peak phenophases occurs during the wettest period of the year i.e., between January and March (Figure 1). In the maturity/peak phenophases, MOD16 exhibited the highest bias of about  $19 \text{ mm.month}^{-1}$  and  $11 \text{ mm/month}$  with reference to the FLEX-Topo<sub>WB</sub> and TMC<sub>WB</sub> respectively (Figure 7 A and Table 3). The rest of the EBM showed lower biases. With reference to the FLEX-Topo<sub>WB</sub> all EBM showed strong correlation with coefficients ( $R^2$ ) of above 0.85 (Table 3). However, the TMC<sub>WB</sub> showed lower correlation coefficients ( $R^2$ ) with EBMs ranging between 0.45 – 0.85 with least (0.45) correlation observed with MOD16 (Table 3). The maturity/peak phenophases exhibited lower biases among models (Table 3). The Senescence/Mid-Green down phenophases occurs during the transition from the rain to the dry season. During this period, evaporation distribution exhibited relatively similar means, standard deviations and variation coefficients among models. Across the basin all models estimated evaporation in the range  $200 - 300 \text{ mm.3-months}^{-1}$  during this period (Figure 7 and Table A4 in the appendices). In terms of magnitude of evaporation, compared to the maturity/peak phenophases the senescence/mid-green-down/greendown phenophases exhibited lower estimates, both maximum and minimum estimates. With reference to FLEX-Topo<sub>WB</sub> and TMC<sub>WB</sub> high correlation coefficients of between 0.75 and 0.99, RMSE of between 1.2 and  $8.8 \text{ mm.month}^{-1}$ , and biases of between  $-7.7$  and  $22.7 \text{ mm.month}^{-1}$  were noted (Figure 7A, Table 3 and Table A5 in the appendices). Compared to the other phenophases, the dormancy phenophase, normally experienced between July and September in the dry season, showed the most variations, in terms of evaporation spatial distribution and magnitude (Figure 7A and B). In addition, this is the period the basin spatially experiences lowest NDVI values (Figure 7A). During dormancy phenophase, all EBM and WBM showed the lowest evaporation, exhibited distinct individual patterns and, with reference to the FLEX-Topo<sub>WB</sub>, showed the largest range of correlation ( $R^2$ ) (0.54 – 0.97) (Figure 7A, Table 3 and Table A6 in the appendices). The green-up and Mid-green up phenophases, normally occur between October and December. The start of greening up is before the start of the rains in October. In all model estimates, evaporation

525 magnitude begins to increase at the start of the green-up phenophase. However, there seem to be significant  
 observable differences in the evaporation pattern, both in terms of distribution and magnitude. With reference to  
 the  $TMC_{WB}$  all EBM exhibited lower maximum values though the means for WaPOR and SSEBop were relatively  
 of similar magnitude. All EBM showed strong correlation with the  $TMC_{WB}$ , correlation coefficient range of 0.75  
 to 0.94, but seem to underestimate evaporation with a bias range of 1.9 to 31.7 mm.month<sup>-1</sup> (Figure 7A, Table 3  
 530 and Table A4 in the appendices).

Generally, reference to the FLEX-Topo<sub>WB</sub> and  $TMC_{WB}$ , and depending on the phenological stage, all EBM  
 showed a mixed performance of underestimating and overestimating evaporation. With reference to the FLEX-  
 Topo<sub>WB</sub>, with an exception of WaPOR, underestimation of evaporation appeared more pronounced in the transition  
 period from the rainy to the dry season (i.e., Senescence/Mid-Green down phenophases) and during the dry season  
 535 (Dormancy phenophase). With reference to the  $TMC_{WB}$ , all EBM, with an exception of MOD16 (during the  
 maturity/peak phenophases), appeared to underestimate evaporation during the green-up/mid-green up and the  
 Maturity/peak phenophases in the rainy season (Figure 7B and Table 3). In terms of distribution of magnitude of  
 evaporation, it appeared to vary with model spatial resolution. Models with relatively finer spatial resolution (i.e.,  
 MOD16, SSEBop and WaPOR) showed a wider spread of evaporation values than those with coarser resolution  
 540 (i.e., FLEX-Topo<sub>WB</sub>, GLEAM and  $TMC_{WB}$  (Figure 7 B).

Figure 7. (A) Spatial-temporal distribution of NDVI and models evaporation (mm.3-months<sup>-1</sup>) across phenophases  
 for the year 2020 and (B) Violin plots showing variations in models' evaporation across phenophases for the year  
 2020 in the Luangwa Basin. Violins represent the distribution of the evaporation with indication of the median  
 555 (white dot), interquartile range (thick line), and 95% interval (thin line).

### 3.4 Land-cover based evaporation and model performance

Figure 8A and Table 3 show the 2019 Copernicus land cover map with locations of the land cover types  
 used in this study. Figure 8B shows Google earth images of the land cover types and the number of pixels used in

the study for each evaporation model. Average monthly values of evaporation for the period 2009 – 2020 for each land cover type were obtained based on pixels in a defined area (i.e., polygons) that covered the land cover of interest.

Figure 9 shows plots of the evaporation across land cover types for each model. The evaporation pattern based on the land cover type is very distinctive but appears to follow the basin energy and water variability cycles (Figure 3). The most notable difference in land-cover based evaporation estimates by the models was observed in the classes' dense forest and open water body. In these two environments, the WaPOR and SSEBop showed a different upward pattern and higher evaporation values compared to the rest of the models especially in the dry season (Figure 9 A and F). In irrigated cropland the *FLEX – Topo<sub>WB</sub>*, SSEBop and WaPOR appears to respond to irrigation activities in August during the dry season. All three models show a decline in evaporation in September with *FLEX – Topo<sub>WB</sub>* continuing to decline to October while SSEBop and WaPOR showed an upward movement after September. However, all models show a similar pattern in the rain-fed cropland in the dry season though WaPOR exhibits relatively higher values (Figure A6 in the appendices).

Tables A6 and A7 in the appendices show the calculated statistics for each land cover. Most notable differences statically were in the class dense forest. In dense forested environment, the WaPOR and the SSEBop showed the least standard deviations (less than 14 mm.month<sup>-1</sup>) and coefficients of variation (less than 13%) (Tables A4 and A5 in the appendices). The rest of the models showed relatively higher standard deviations and coefficients of variations of above 40 percent but not exceeding 65 percent (Table A5 in the appendices). With regard to the mixed open forest and grassland area the overall pattern for all models was similar and exhibited high correlations exceeding Kendall correlation coefficient of 0.8 among all models (Figure 9 B and Table A5 (ii) in the appendices).

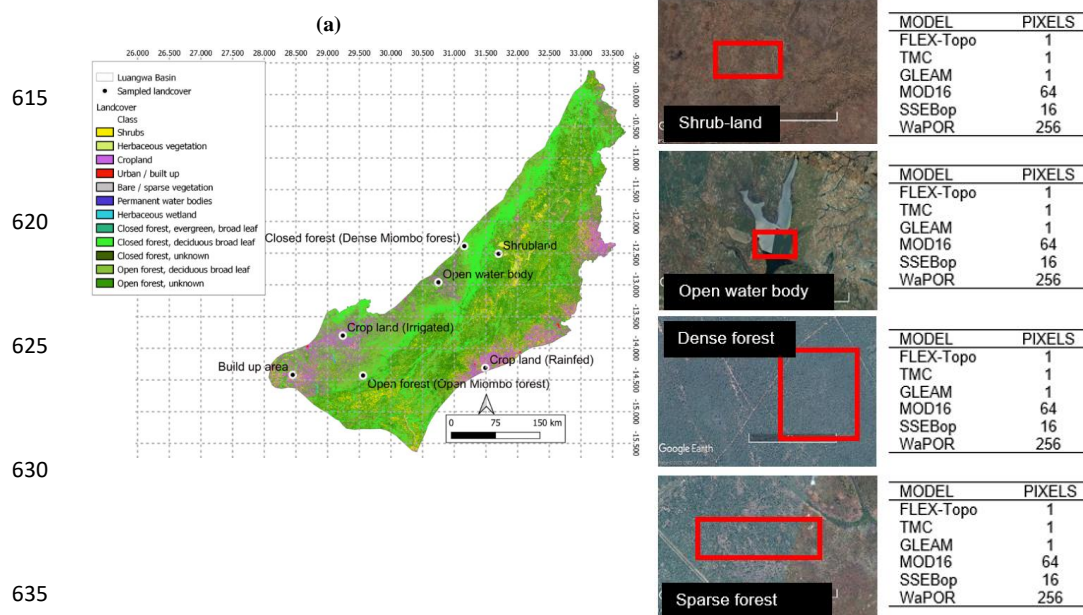

Overall, the WaPOR and SSEBop appeared to have similar patterns of evaporation across the land cover types with strong Kendall correlation coefficients of above 0.5 across land-cover types (Tables A5 and A6 in the appendices).

Since the dense forest class showed the most notable difference in vegetated land cover classes, we statistically analysed the observed differences for each phenophase. Figure 10 shows regression plots and statistics for each phenophase. When compared to both *FLEX – Topo<sub>WB</sub>* and *TMC<sub>WB</sub>*, GLEAM showed the highest correlation range ( $R^2 = 0.26 - 0.92$ ) and least bias (Bias range = 0 – 11.31 mm.month<sup>-1</sup>) (Figure 10 A) across phenophases while SSEBop and WaPOR showed the least correlation ( $R^2 = 0 - 0.58$ ) and highest bias (Bias range = 1.79 – 56.01 mm.month<sup>-1</sup>) (Figure 10 C, D, G, H). MOD16 compared well with *FLEX – Topo<sub>WB</sub>* across phenophases ( $R^2 = 0.41 - 0.81$ ; Bias = 6.23 – 26.93 mm.month<sup>-1</sup>) but not so much with *TMC<sub>WB</sub>* ( $R^2 = 0.38 - 0.76$ ; Bias range = 4.82 -38 mm.month<sup>-1</sup>) (Figure 10 B and F). Generally, most model disagreements were observed during green-up/mid-green-up and dormant phenophases.

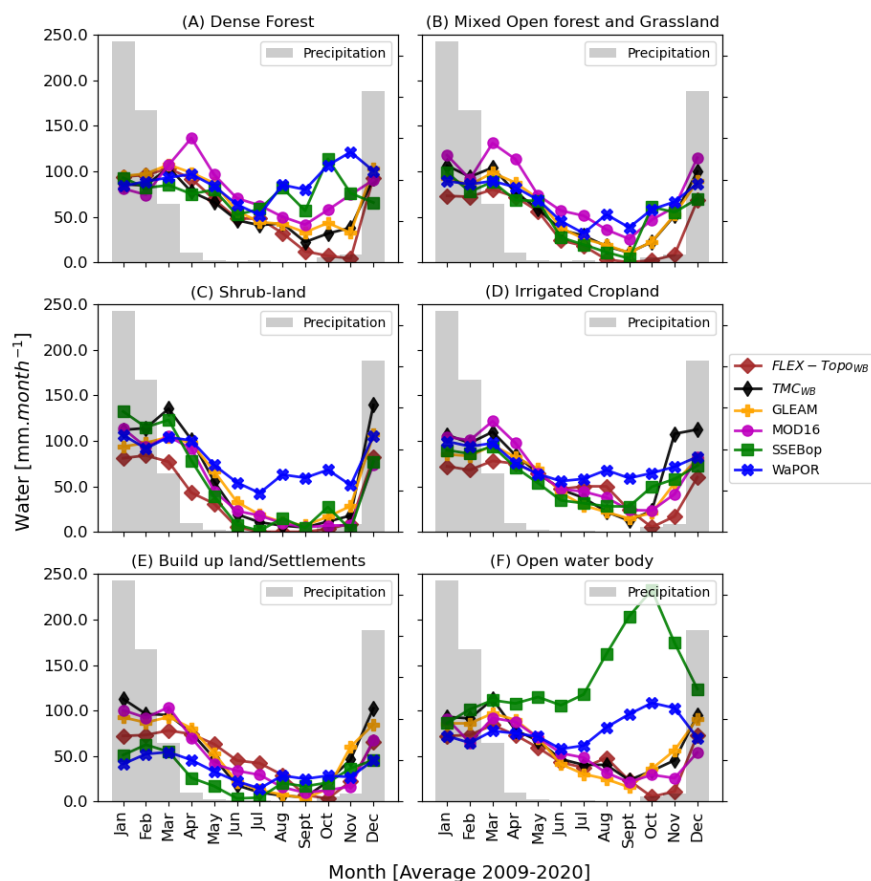

**Table 3.** Location of field verified land cover types

Land cover type	Latitude	Longitude
Build up area	-14.42	28.45
Cropland (Rain-fed)	-14.31	31.49
Cropland (Irrigated)	-13.80	29.24
Dense forest (Miombo forest)	-12.39	31.16
Open water body	-12.96	30.75
Shrubland	-12.51	31.70
Sparse forest (Open Miombo/grassland)	-14.43	29.51

**Figure 8.** Verified locations (Table 3) of land cover types on the Copernicus 2019 land cover map (A) for the Luangwa Basin. © Google earth (B) was used to generate polygons based on the field verified locations for extraction of evaporation values for each model.

**Figure 9.** Land cover type dependent temporal distribution of long-term (2009-2020) mean monthly evaporation in the Luangwa Basin. Major differences, in evaporation temporal pattern and magnitude between WBM and EBM as well as among EBM, seem to occur in natural vegetation i.e., Dense Miombo Woodland in the dry season (May – October).

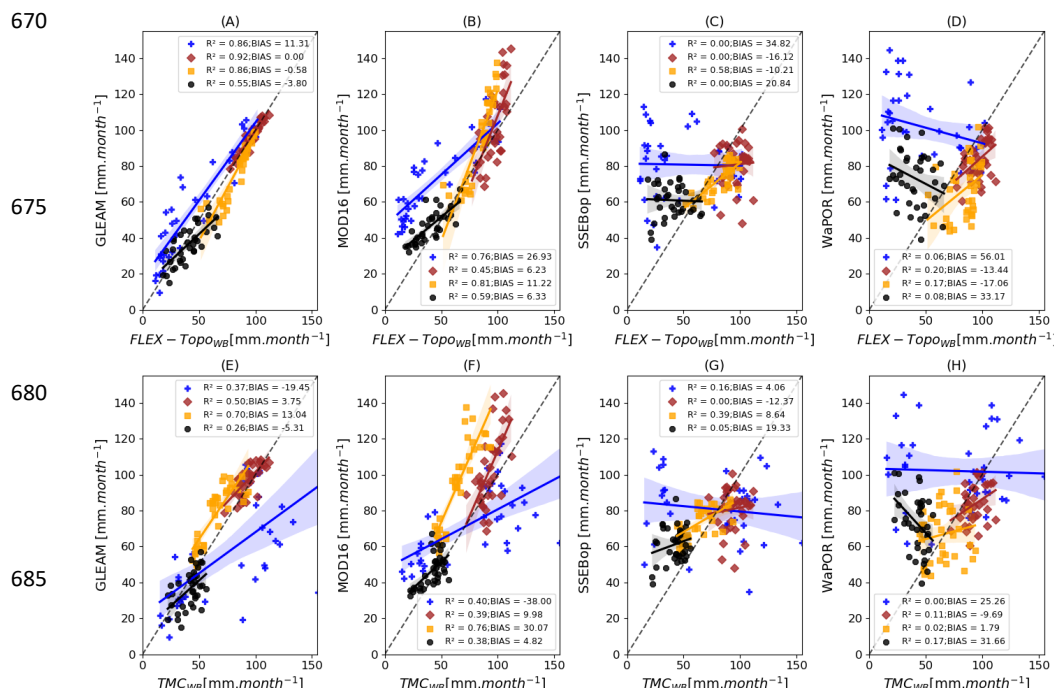

Figure 10. Relationship of EBM and WBM mean monthly (2009-2020) evaporation across seasons and phenophases in dense Miombo Woodland in the Luangwa Basin. (A-D) EBM comparison with FLEX-TopoWB and (E-H) comparison with TMCWB. Colour code: BLUE= Green-up/Mid-Green-up; BROWN = Maturity/Peak; ORANGE = Senescence/Green-down/Mid-Green-down and BLACK = Dormant phenophase.

#### 4.0 Discussion

The objectives of this study were to evaluate evaporation models performance in the Luangwa Basin and to discuss the potential underlying factors to the observations. We discuss differences in spatial and temporal model performance and highlight potential underlying factors to the observed discrepancies.

##### 4.1 Observations in model's performance in terms of spatial-temporal distribution of evaporation

Across seasons and phenophases, we have observed discrepancies in spatial-temporal models' performance. Precipitation and forest cover have been shown to be the main determinants of water availability at catchment level through actual evaporation rather than the potential evaporation (Zhang et al., 2001). For instance, forested areas tend to have higher evaporation than non-forested or grassland areas and this is dependent on the age and health of the trees (Teuling, 2018). In agreement with Teuling (2018) and Zhang et al. (2001) results of this study show significant land cover dependent differences in the spatial and temporal distribution of evaporation. Forested areas showed the most discrepancies in the spatial-temporal distribution pattern of evaporation in all models with the WaPOR and SSEBop exhibiting visibly distinct patterns from the other models in the dry season. Furthermore, in periods with high soil moisture and high canopy cover (i.e., maturity/peak and senescence/Green-down/mid-green down) all models performed similar. However, significant diversion in model behaviour was more pronounced during periods of limited soil moisture and low canopy cover (i.e., dormancy and green-up/mid-

green up phenophases). Documented coefficient of variation in Miombo Woodland canopy cover (i.e., as proxied by the leaf area index and normalised difference vegetation index) is about 30 percent (Zimba et al., 2020; Frost, 1996). Furthermore, Miombo species leaf colour transitions and leaf fall does not occur at the same time but varies among species (i.e., Figure 11) and also depends on the amount of rainfall received in the preceding season (Frost, 1996). The field observations we made in 2021 at Mpika (Figures 2 and 11) confirmed and illustrates the differences in leaf fall/flush, leaf colour transitions and green-up at Miombo local forest level.

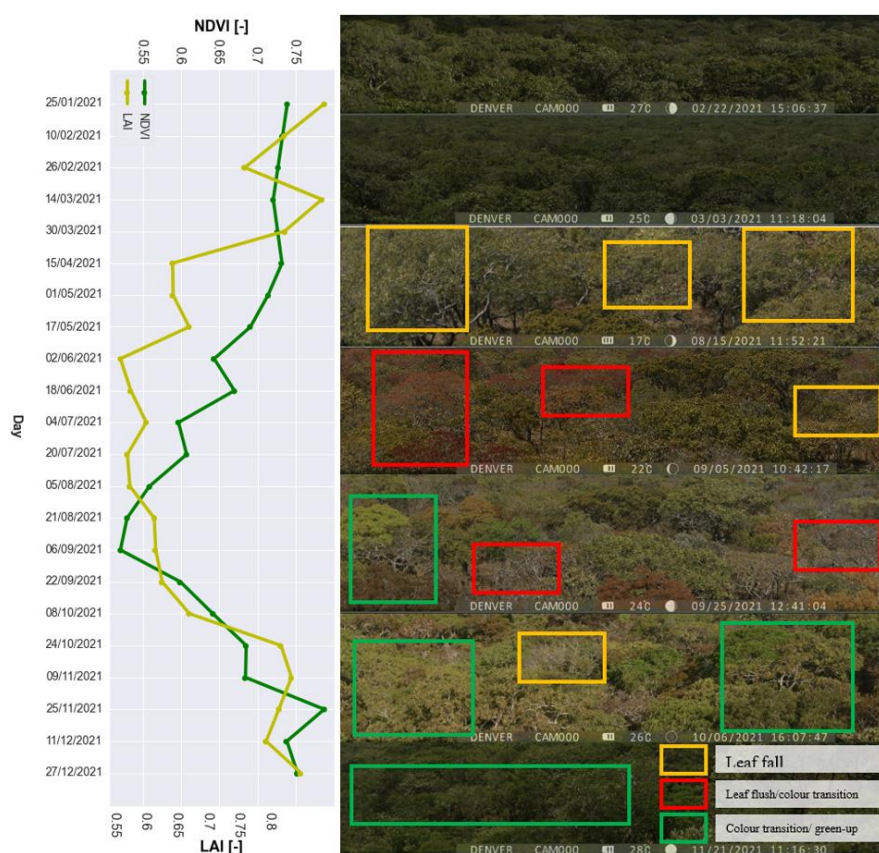

Figure 11. MODIS LAI, NDVI, and the Miombo Forest canopy display pattern for the year 2021 at Mpika station.

The field observations of Miombo canopy display dynamics agreed with the MODIS based LAI and NDVI pattern for the year 2021 (Figure 11). LAI and NDVI differed at the start of rise with LAI starting early in August indicating increase in leaf flush activity. Unlike the LAI, NDVI begins to rise in September indicating a delay resulting from the leaf colour transitions as exhibited in Figure 11. Implication of the leaf colour transitions, variations in the time for leaf fall and the variation coefficient in canopy display is that during the dry season the Miombo Woodland, at forest/catchment level, is not completely leafless as it returns 70 percent of the canopy display (i.e., Figure 11). Tian et al. (2018) showed that while transpiration co-varies with canopy cover (i.e., leaf area index (LAI)) in the Miombo Woodland the water storage in the root zone and the body of the vegetation tends

to increase towards the end of the rain season remaining relatively constant during the dry season until the LAI  
 750 begins to increase again. Further, Tian et al. (2018) observed that the Miombo Plants tend to rely on the deep root  
 zone water during the dry period of the year. Vinya et al. (2018) showed that the stem water storage dynamics  
 strongly influence canopy display. Pelletier et al. (2018) and Tian et al. (2018), using different approaches, deduced  
 how different the Miombo Woodlands species traits are from other ecosystems; how they store water and their  
 interaction with the root zone storage during the dry season. Their findings, largely, could possibly explain the  
 755 differences we observed in the model's spatial temporal distribution of evaporation during the dry season. Forest  
 cover strongly influences catchment evaporation during the dry season ( Zhang et al., 2001; Teuling, 2018). The  
 Luangwa Basin is largely covered by the Miombo Woodland (*Sustainable Management of Miombo Woodlands*,  
 2018; Frost, 1996 ). Miombo Woodland species unique attributes, i.e., stem water storage, canopy display  
 behaviour and interaction with root zone storage (Pelletier et al., 2018; Tian et al., 2018; Vinya et al., 2018)  
 760 probably accounts for the observed spatial-temporal evaporation distribution patterns by the different models in  
 this study.

A key underlying factor for the observed discrepancies in spatial distribution of evaporation by models is  
 the difference in the land cover products used. For instance, MOD16 heavily relies on a global land-cover product  
 (Gray et al., 2019b; Running et al., 2019) known to misclassify certain land cover types and showing low user  
 765 accuracy in certain regions (i.e., Leroux et al., 2014). WaPOR uses the Copernicus land cover product but adds  
 the distinction between irrigated and rain-fed areas (FAO, 2018). For vegetation fraction, GLEAM uses the  
 MODIS MOD44B product (Martens et al., 2017; Miralles et al., 2011). Dissimilarities in the land cover products  
 possibly reflect in differences in the models spatial distribution of evaporation.

#### 770 4.2 Potential underlying factors in model performance in the Luangwa Basin

In this section, we look at model architecture and observed evaporation estimates in relation to Miombo  
 Woodland attributes and how this potentially explains models' performance in the Luangwa Basin.

In this study, although GLEAM consistently underestimated annual evaporation for the period 2009 –  
 2020, it agreed well with the  $FLEX - Topo_{WB}$  and  $TMC_{WB}$  during the rain season. This suggests that the  
 775 underestimation observed at annual scale could be because of GLEAM behaviour during the dry season. Firstly,  
 GLEAM assumes a maximum root-zone soil moisture depth of 250 cm for tall vegetation i.e., the Miombo forest.  
 However, Miombo species in deep soils have been shown to have tap roots exceeding 5 m depth and lateral roots  
 covering between 15 – 25 m (Frost, 1996). Different ecosystems and land-cover types have different root zone  
 storage capacities to buffer drought periods (Wang-Erlandsson et al., 2016). Pelletier et al. (2018) and Tian et al.  
 780 (2018) showed that Miombo Woodland species potentially access ground water for various physiological activities  
 during the dry season. Vinya et al. (2018) showed linkage between changes in canopy display and Miombo plants  
 stem water storage in the dry season. The Miombo Forest largely retains its canopy cover during the dry season  
 (i.e., Figure 11; Zimba et al., 2020; Frost 1996). Therefore, with capacity to tap into ground water reservoirs and  
 stem water storage mechanisms, depending on the species, it is likely that Miombo plants continues transpiring  
 785 throughout the dry season. Additionally, use of the net precipitation for the running water balance to determine  
 root zone soil moisture implies that GLEAM evaporation is sensitive to precipitation regimes. This, in our study,  
 is augmented by observations in the temporal pattern of GLEAM (Figure 5) as it showed relatively, i.e., compared  
 to  $FLEX - Topo_{WB}$ , and MOD16, higher evaporation at the commencement of the rainy season during the green-

up and Mid-green-up phenophases. It also means that the quality of the rainfall product used to parameterise root-zone soil moisture affects evaporation estimates. Luangwa Basin is in a sparsely gauged semi-arid environment in Africa for which some precipitation products show large bias (Oki and Kanae, 2006). Therefore, it is likely that GLEAM does not effectively capture the Miombo Woodland evaporation in the dry season.

With reference  $E_{wb}$ , MOD16 showed relatively low annual bias. In addition, MOD16 showed low bias and high correlation with the  $FLEX - Topo_{WB}$  and  $TMC_{WB}$  at monthly scale for the period 2009 -2020. MOD16 showed mixed performance across phenophases depending on the water balance model compared with. With  $FLEX - Topo_{WB}$  the MOD16 showed underestimation in the dry season and overestimation in the rainy season. With the  $TMC_{WB}$  the MOD16 showed overestimation in the dry and underestimation in the rainy season. Like with the other models the major discrepancy was in dry season during the dormant and green-up phenophases, most significantly in the dense forest-land cover. During the rainy season potential sources of overestimation/underestimation, with  $FLEX - Topo_{WB}$  and  $TMC_{WB}$ , could be that the precipitation product used in MOD16 either overestimates or underestimates precipitation (Oki and Kanae, 2006) in the Luangwa Basin. For the MOD16 performance in the dry season, especially in forested areas, potential underlying factors for this behaviour could be attributed to model phenophases characterisation and stomatal conductance thresholds. It is possible the stomatal conductance thresholds are not correctly adjusted (i.e., low or higher than actual threshold value) for the Miombo ecosystem. In addition, arid and semi-arid ecosystems, like the Miombo ecosystem in the Luangwa Basin, are driven by moisture in the soil (Verstraeten et al., 2008; Makkeasorn et al., 2006). MOD16 does not couple canopy transpiration with soil moisture which is a potential source of underestimation especially in view of the already discussed Miombo species interaction with root zone soil moisture during the dry season. Discrepancy in spatial distribution of MOD16 with other models could be a result of the classification accuracy of the land cover product used that may or may not correctly characterise the land cover in the Luangwa Basin. Generally, other than the model structure, sources of error in MOD16 are likely also to be from model inputs like the LAI, accuracy of the land cover map used, especially with regard to classification of forest cover in the Miombo region, and meteorological data.

At annual scale, with reference to  $E_{wb}$ , the SSEBop showed relatively low bias (Figure 4B). SSEBop major spatial and temporal digression from other models was in the dry season in between the senescence and the green-up phenophases. In contrast to other models, SSEBop showed an upward movement in evaporation starting from August in the dormant phenophase in the dry season. The rest of the models showed a start of increase in evaporation at the commencement of the green-up phenophase (Figure 5). In addition, with an exception of WaPOR, the SSEBop had the second highest evaporation during the driest part of the dry season (September-October). Three observations, in relation to model structure, that aid explanation for SSEBop spatial-temporal behaviour (Figures 5B, 7, 9 and 12 A) in the Luangwa Basin include the model's land-cover based (i.e., Dense Forest and Open water body) performance, spatial-temporal pattern of LST (Figure 12 B) and the area burnt by fire (Figure 12 C). SSEBop depends on LST to distinguish hot and cold pixels for estimation of evaporation (Savoca et al., 2013). Under water limited conditions, compared to non-evaporating surfaces evaporating land surfaces tend to have lower LST (Rocha et al., 2020; Akinyemi, Ikanyeng, and Muro, 2019; Sun et al., 2016). The start of rise in LST in August is preceded by a cool dry season with low net radiation (Figure 3) to aid evaporation in both open water body and dense forested areas. The start of increase in SSEBop evaporation and LST in August (i.e., Figure 12 D) corresponds to start in rise in both air temperature and radiation. This provides energy for

evaporation (Heck et al. 2020) from open water bodies and dense forests as demonstrated in Figure 9A & F. Dry  
 land surfaces such as dry grassland, burnt area and built up surfaces tend to have high LST which the SSEBop  
 classify as non-evaporating hot pixels.

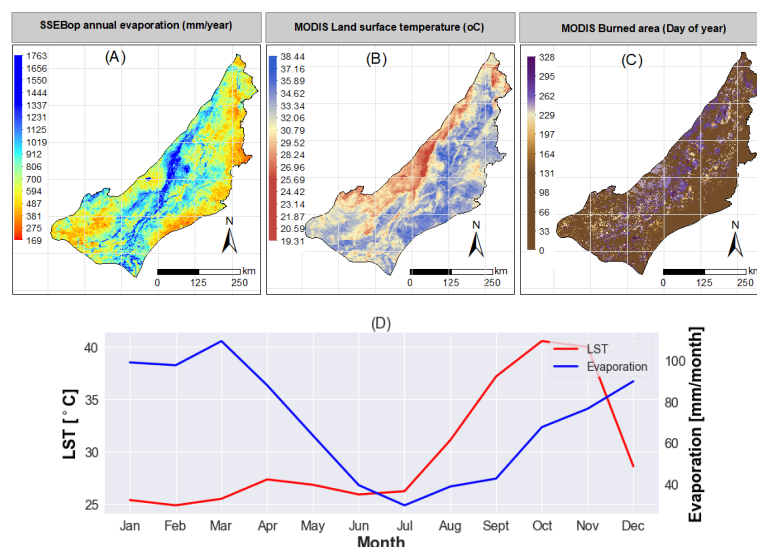

Figure 12. (A) 2020 annual SSEBop evaporation distribution, (B) annual MODIS 2020 spatial land surface  
 temperature distribution, (C) MODIS burned area distribution and (D) monthly temporal distribution pattern of  
 SSEBop evaporation and MODIS LST for the year 2020 in the Luangwa Basin.

This explains the spatial pattern of SSEBop evaporation during the dormant phenophases (Figure 7A)  
 with dense forest areas and open water bodies showing high evaporation values while dry croplands, dry grassland  
 and burnt areas show low or no evaporation (Figure 9). LST is also used as indicator of plant water condition and  
 soil water condition (Sun et al., 2019; Zhang et al., 2014). The SSEBop temporal behaviour in the dry season  
 seems to confirm that Miombo plants have a water storage mechanism and interacts with ground water systems  
 that facilitate the observed evaporation pattern.

With reference to  $E_{wb}$ , the WaPOR consistently overestimated annual evaporation from 2009 to 2020  
 with exception of 2016, 2017 and 2019 (Figure 4B). Analysis at seasonal level showed that the observed  
 overestimation at annual scale was due to the distinct model behaviour during the dry season. During the rainy  
 season, i.e., December to March in the Mid-green-up, maturity and peak phenophases, the WaPOR was  
 consistently similar with other models and relatively underestimated evaporation (compared to MOD16  
 and  $TMC_{WB}$ ) (Figure 5). Overestimation started at the commencement of the downward movement in soil moisture  
 at the end of the rainy season. This behaviour remained consistent throughout the dry season across the different  
 Luangwa Basin phenophases and land-cover types. Spatial-temporal patterns (Figures 5, 7 and 9) showed WaPOR  
 performed distinctly differently from other models especially in dense forest areas and open water bodies. The  
 Luangwa Basin is largely forested (Phiri et al., 2019; Figures 8 and 13) with a diverse plant species composition  
 but largely Miombo Woodland species (Frost 1996; White 1984). The 2019 Copernicus land cover classification,

80 percent user accuracy and forest classification accuracy of about 75% (Buchhorn et al., 2020; Martins et al., 2020), showed that 77 % of the Luangwa Basin's 159,000 km<sup>2</sup> total basin area is forest (dense and open forest). The deep plant rooting depth of up to about 25 m in some Miombo species (Frost 1996) evidences the capacity of the plants to access ground water resources in deep soils in the dry season. Retention of about 70 percent of canopy cover and the variations in time for leaf fall, leaf flush and leaf colour transitions among the Miombo species in the dry season (Zimba et al., 2020; Vinya et al., 2018, Frost, 1996) implies availability of an evaporative surface (i.e., leaves for transpiration). Forest cover is therefore a major influence on the basins hydrological feedbacks. Use of land-cover and phenology data sets and coupling of canopy transpiration with soil moisture in the root zone potentially explains the behaviour of the model in the dry season. By incorporating these aspects in its structure, the WaPOR is able to track the Miombo vegetation canopy display and phenological transitions as well as dynamic vegetation interaction with the root-zone soil moisture. The WaPOR's Miombo Woodland evaporation spatial-temporal pattern could be a correct representation of the ecosystem's moisture feedbacks. However, the question is whether the quantities estimated are correct.

Figure 13. Copernicus 2019 land cover composition (%) in the Luangwa Basin.

Generally, there is a need to obtain land-cover specific field measurements of evaporation and associated model inputs such as precipitation, relative humidity, leaf area index, net radiation, air temperature, land surface temperature and validation of land cover maps in the Miombo ecosystem. Models performance and satellite-based model inputs can be benchmarked against the field measurements after which influence of models architecture and inputs can effectively be evaluated.

## 5.0 Conclusions

This study aimed at comparing performance of open-source evaporation products in the Luangwa Basin, a semi-arid largely Miombo ecosystem, across phenological phases. Selecting an evaporation product for use in Miombo Woodland river basins, especially at local catchment level, is difficult due to limited validation studies

- in the region albeit with an increasingly large pool of models from which to pick. This study contributes to availability of information on performance of evaporation products in the Miombo Woodland. With the data sets used in this study, major conclusions drawn are that:
- (i) Model performance varies across seasons and phenophases with significant discrepancy in evaporation model performance occurring during water limited dormant and green-up phenophases. The characteristics of the phenological phases of vegetation, such as the reduction in chlorophyll, reduction in metabolic activities, leaf fall, leaf flush and leaf colour transitions coupled with vegetation interaction with the root-zone storage during these two phenophases appear to influence model performance.
  - (ii) With reference to land-cover types and evaporation estimates, it appears the forest cover, in this case Miombo forest, plays a significant role manifested in the differences in model performance in dense Miombo forest compared to the performance in other land cover types during the dormant and green-up phenophases. It is clear that the Miombo Woodland plant-water dynamics influences model performance.
  - (iii) Model structure and forcing data appear to influence the spatial-temporal pattern of evaporation estimates especially during the dormant and green-up phenophases. This is clearly demonstrated by the differences in the quantities of evaporation estimates, the start of rise/increase in evaporation and the spatial pattern that appear to reflect model input behaviour especially in the dry season.
  - (iv) Since moisture feedbacks are land surface dependent a conclusive understanding of the underlying factors for the discrepancies in model behaviour is only possible with field measurements of evaporation on various specific land cover types in the Luangwa Basin in particular and the Miombo ecosystem in general.
  - (v) In general, our study agrees with previous studies in other African ecosystems that performance of evaporation products varies. Since evaporation products used in this study were not the same as those in the studies done in the larger Zambezi Basin, our model performance assessment is not comparable. Our study based on aggregated annual mean bias, with reference to the annual general water balance, showed the SSEBop and the WaPOR to have relatively lower aggregated bias compared to other models. However, with the uncertainties in the water balance forcing data such as underestimation and overestimation of precipitation, there is a clear need for field measurements of evaporation in the Miombo ecosystem to compare with the different evaporation products. The water balance approach likely underestimated evaporation especially in the dry season, due to storage effects. Based on individual model structure and the observed performance it is highly likely that SSEBop and WaPOR captures more correctly the Miombo vegetation moisture feedbacks than the other products in the dormant and green-up phenophases. However, these assumptions need verification with field measurements of evaporation, especially in the Miombo forest.

#### Data availability

950 Precipitation field data at Mpika station is available on <https://doi.org/10.4121/19372352.v2>

#### Code availability

Code for FLEX-Topo model can be requested from the authors

## 6.0 Appendices

970

### A1.0 Statistical approaches used in this study

#### A1.1 Analysis of trends catchment evaporation time series

975 The Mann-Kendall trends test (Helsel et al. 2020) (equations A1 –A6) is a commonly used non-parametric test that ascertains monotonic trends in time series data. The advantage is that it does not require the data to be normally distributed and is not responsive to abrupt changes in the time series. The null hypothesis is that there is no trend in the series while the alternative hypothesis is that there is a trend in the series.

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^n \text{Sgn}(x_j - x_i) \quad (\text{A1})$$

980

Where  $n$  is the number of observations,  $x_j$  and  $x_i$  are the  $j$ th and  $i$ th observations respectively, and  $j > i$ . Equation 3 defines the sign function  $\text{Sgn}$  between consecutive  $x$  values:

$$\text{Sgn}(x_j - x_i) = \begin{cases} +1; & x_j > x_i \\ 0; & x_j = x_i \\ -1; & x_j < x_i \end{cases} \quad (\text{A2})$$

985 The variance is expressed by equation 4:

$$Var(S) = \frac{n(n-1)(2n+5) - \sum_{i=1}^n t_i i(i-1)(2i+5)}{18} \quad (A3)$$

The modified variance ( $Var^*(S)$ ) expressed as equation 5:

$$990 \quad Var^*(S) = Var(S) \cdot \frac{n}{n^*} \quad (A4)$$

Where  $\frac{n}{n^*}$  is the correction factor.

The test statistic  $Z(c)$  is computed by equation 6:

$$Z(c) = \begin{cases} \frac{S-1}{\sqrt{Var^*(S)}}, & S > 0 \\ 0, & S = 0 \\ \frac{S+1}{\sqrt{Var^*(S)}}, & S < 0 \end{cases} \quad (A4)$$

995

If  $Z > 0$ , it indicates an increasing trend, and vice versa. Given a significant level of  $\alpha = 0.05$ , the null hypothesis of a non-existent trend is accepted if  $-1.96 < Z(c) < 1.96$ , for a two-tailed test.

The magnitude of each model time series trend was evaluated by a simple non-parametric procedure developed by Sen (Sen 1968; Theil 1950).

1000

$$\beta = Median\left(\frac{x_j - x_i}{j - i}\right), j > i \quad (A6)$$

Where  $\beta$  is Sen's slope estimate.  $\beta > 0$  indicates upward trend in a time series and  $\beta < 0$  indicates downward trend during the period.

#### A1.2 Analysis of correlation in evaporation time series

1005

Hydrological data is known to be non-normal in distribution (Helsel et al. 2020) thus assessing correlation among hydrological variables is normally done using non-parametric test. In this study, we used the Kendall correlation statistic (Helsel et al. 2020; Kendall, 1975) to assess relationships among the various evaporation products at monthly and annual scales. Kendall's Tau is a correlation parameter that measures the strength of the relationship between variables. Kendall's Tau is performed on the ranks of the data. This implies that for each specific variable the values are put in order and numbered for instance, 1 for the lowest value, 2 for the next lowest until the  $n$ th value is numbered. As is the case with other measures of correlation, Kendall's Tau takes values between -1 and +1, in which a positive correlation indicates that the ranks of both variables increase together while a negative correlation denotes opposite directions in the ranks of the variables (rank of one variable increases, the other decreases). In essence, Kendall's Tau represents a difference between the probability that the observed data are in the same order versus the probability that the observed data are not in the same order. Kendall Tau statistic is given by equation A7.

1015

$$\tau = \frac{n_c - n_d}{n(n-1)/2} \quad (A7)$$

where  $n_c$  denotes concordant pairs and  $n_d$  are discordant pairs. When the rank of the second variable is greater than the rank of the former variable the pair is said to be concordant. When the rank of the second variable is equal to or less than the rank of the first variable, the pair is considered discordant (Hirsch and Helsel, 2002). There were no tied values in the evaporation time series.

### A1.3 Assessment of model performance

To assess how close to the reference data the EBM evaporation were we used three statistical parameters; the coefficient of determination ( $R^2$ ), the root mean square error (RMSE) and the bias.

The coefficient of determination ( $R^2$ ) is the proportion of the difference in the modelled data that is predictable from the observed data. It is a statistical measure of how well the modelled estimates approximate the observed data. The closer to 1 the  $R^2$  is the better the performance of the mode.  $R^2$  is estimated using equation A8.

$$R^2 = 1 - \frac{\sum_{i=1}^N (X_i - Y_i)^2}{\sum_{i=1}^N (\bar{Y} - Y_i)^2} \quad (A8)$$

Where,  $X_i$  is the predicted  $i$ th value, and the  $Y_i$  element is the actual  $i$ th value.

The RMSE is the square root of the summation of the square of the difference(s) between the observed and modelled values over the total number of observations (Equation 10). The RMSE quantifies the deviation of the predicted values from the observed values. The closer to zero the RMSE value is the better the model prediction(s). RMSE is estimated using equation A9.

$$RMSE = \sqrt{\frac{\sum_{i=1}^N (Y_i - \bar{X}_i)^2}{N}} \quad (A9)$$

Where  $i$  = variable  $i$ ,  $N$  = number of observations,  $Y$  = actual observations time series and  $X$  is the modelled time series.

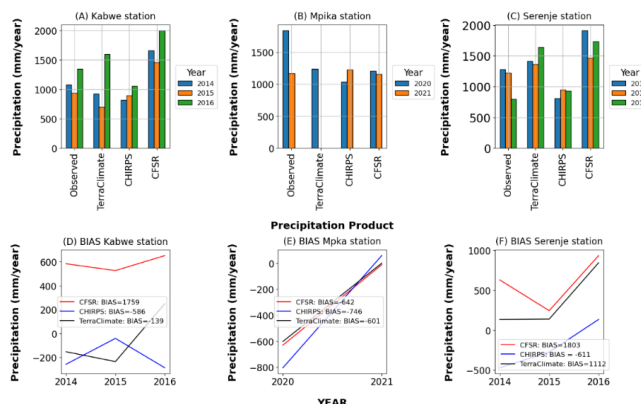

Figure A1. Comparison of observed precipitation with satellite precipitation products TerraClimate, CHIRPS and CFSR at (A) Kabwe weather station, (B) Mpika weather station and (c) Serenje weather station in the Luangwa Basin. D- F shows the aggregated annual bias for each model.
