10 **Abstract.** The moisture content of vegetation canopies controls various ecosystem processes such as plant productivity, transpiration, mortality and flammability. Leaf moisture content (here defined as the ratio of leaf water mass to leaf dry biomass, or live-fuel moisture content, LFMC) is a vegetation property that is frequently used to estimate flammability and the danger of fire occurrence and spread and is widely measured at field sites around the globe. LFMC can be retrieved from satellite observations in the visible and infrared domain of the electromagnetic spectrum, which is however hampered by  
15 frequent cloud cover or low sun elevation angles. As an alternative, vegetation water content can be estimated from satellite observations in the microwave domain. For example, studies at local and regional scales have demonstrated the link between LFMC and vegetation optical depth (VOD) from passive microwave satellite observations. VOD describes the attenuation of microwaves in the vegetation layer. However, neither were the relations between VOD and LFMC investigated at large or global scales nor has VOD been used to estimate LFMC. Here we aim to estimate LFMC from VOD at large scales, i.e. at  
20 coarse spatial resolution, globally, and at daily time steps over decadal time series. Therefore, our objectives are 1) to investigate the relation between VOD from different frequencies and LFMC derived from optical sensors and a global database of LFMC site measurements; 2) to test different model structures to estimate LFMC from VOD; and 3) to apply the best-performing model to estimate LFMC at global scales. Our results show that VOD is medium to highly correlated with LFMC in areas with medium to high coverage of short vegetation (grasslands, croplands, shrublands). Forested areas show on average  
25 weak correlations but the variability in correlations is high. A logistic regression model that uses VOD and additionally leaf area index as predictor to account for canopy biomass reaches the highest performance. Applying this model to global VOD and LAI observations allows estimating LFMC globally over decadal time series at daily temporal sampling. The derived estimates of LFMC can be used to assess large-scale patterns and temporal changes in vegetation water status and fire dynamics.

## 30 1 Introduction

Changes in water availability and the occurrence and severity of droughts affect various processes in land ecosystems and vegetation (Konings et al., 2021a; Sippel et al., 2018). For example, soil moisture and atmospheric water demand affect plant water uptake, the water potential and water content of vegetation, stomatal conductance and transpiration (Jarvis, 1976; Bonan, 2015). The regulation of plant water content and stomatal conductance controls the exchange of water, carbon and energy  
35 between the ecosystem and atmosphere. Hence soil moisture and atmospheric water demand are strong controls on plant productivity, growth and mortality (Li et al., 2021a; McDowell, 2011; DeSoto et al., 2020). Furthermore, the water content of living or dead vegetation material controls the occurrence and intensity of disturbances such as fires. A low water content of the fuel is associated with higher flammability or a higher risk of fire occurrence and spread (Chuvieco et al., 2010). Hence fuel moisture content (FMC) is a key variable to estimate daily to long-term changes in fire danger (Stocks et al., 1998; Jolly  
40 et al., 2015). FMC is defined as the ratio of the mass of water to the dry biomass of a material and can be directly measured from determining the fresh and dry mass  $m$  of a vegetation sample (Yebra et al., 2013):

$$FMC = \frac{m_{\text{fresh}} - m_{\text{dry}}}{m_{\text{dry}}} \quad (1)$$

FMC is frequently expressed as a percentage number (FMC x 100%). FMC can be determined for living vegetation components such as green grasses and leaves (i.e. live-fuel moisture content, LFMC) or for dead vegetation components such as litter and  
45 woody debris (dead-fuel moisture content, DFMC) (Matthews, 2014; Yebra et al., 2013; Viney, 1991). FMC is measured frequently at various locations in grasslands, shrublands or forest ecosystems in several countries to validate or calibrate satellite retrieval algorithms and ultimately to support fire danger forecasting. LFMC measurements from various countries have been compiled in the Globe-LFMC database which provides observations from 1383 sites over the period 1977 to 2018 but with different length and frequency of observations among different sites (Yebra et al., 2019). Site-level measurements of  
50 LFMC provide an accurate estimate of the plant water status; however, their limited spatial coverage is a constraint for spatial-explicit estimates of the role of fuel moisture for fire danger.

In order to complement site observations of LFMC, satellite observations can be used to estimate LFMC over large areas (Yebra et al., 2013). Thereby, especially satellite observations in the visible and infrared domain of the electromagnetic spectrum have been used to estimate LFMC. For example, spectral information from the short-wave and near-infrared bands  
55 from Landsat are correlated with LFMC (Chuvieco et al., 2002; Bowyer and Danson, 2004). This is because leaf water content has a strong effect on the absorption of near and shortwave infrared radiation. Hence LFMC can be computed by using empirical models or visible-infrared leaf and canopy radiative transfer models by estimating equivalent water thickness (EWT, i.e. leaf water column per unit area) and the leaf dry matter content (Danson and Bowyer, 2004; Riano et al., 2005). Medium and coarse resolution visible-infrared satellite instruments are most commonly used to estimate LFMC as they provide a  
60 frequent temporal coverage (García et al., 2008; Yebra et al., 2008). For example, observations from the Moderate Resolution Imaging Spectroradiometer (MODIS) are the main input for recently developed algorithms to estimate LFMC at continental or global scales (Yebra et al., 2018; Quan et al., 2021; Zhu et al., 2021). Despite the direct biophysical relations between

surface reflectance and LFMC and their implementation in visible-infrared radiative transfer models, the occurrence of cloud cover, smoke or low sun elevation angles hinder the retrieval of LFMC time series with high temporal frequency from visible-  
65 infrared satellite sensors.

Microwaves can largely penetrate clouds and smoke, are largely independent of the illumination by the sun, and hence provide an alternative to derive information about the land surface. Microwave observations from either active Radar instruments or from passive microwave radiometers are sensitive to the moisture content of soil and vegetation (Ulaby et al., 1979; Jackson et al., 1982) and hence also to FMC (Konings et al., 2019). For example, early studies have shown that fuel moisture conditions  
70 are related to the Radar backscatter of C-band (5.3 GHz frequency  $\approx$  5.6 cm wavelength) Synthetic Aperture Radar (SAR) observations from the ERS-1 and RADARSAT-1 satellites (Leblon et al., 2002; Abbott et al., 2007). Also observations from modern C-band SAR satellites such as Sentinel-1 allow to estimate LFMC (Wang et al., 2019; Rao et al., 2020). SAR observations are generally sensitive to the above-ground biomass and moisture content of vegetation, whereby the sensitivity to certain vegetation components such as crown and stem changes with the used microwave wavelength. While short  
75 microwave wavelengths at C-band, X-band ( $\approx$  3 cm wavelength), and Ku-band ( $\approx$  1.6 – 2.5 cm) are mostly sensitive to the top of the canopy, L-band ( $\approx$  23 cm) is sensitive to the crown, and P-band ( $\approx$  70 cm) to the stem (Saatchi and Moghaddam, 2000). Similar relations between the microwave signal and vegetation water content are valid for observations from passive microwave instruments that measure naturally emitted microwaves from the Earth surface. Passive microwaves are emitted by the soil and vegetation and are then attenuated in the vegetation layer (Jackson et al., 1982; Mo et al., 1982). Passive microwave  
80 instruments are commonly used to estimate surface soil moisture (Njoku and Entekhabi, 1996; Njoku et al., 2003; Wigneron et al., 1998; Dorigo et al., 2017; Wigneron et al., 2021). Recently, surface soil moisture datasets from passive microwave sensors have also been used as a proxy to estimate LFMC (Jia et al., 2019; Lu and Wei, 2021). However, passive microwaves are also directly related to LFMC. The attenuation of the passive microwave signal in the vegetation layer is commonly described by the opacity or optical thickness of the vegetation (VOD, vegetation optical depth) (Jackson and Schmugge, 1991;  
85 Frappart et al., 2020). VOD is proportional to vegetation water content (VWC, i.e. mass of water per unit area) and hence to the dry biomass ( $m_{dry}$ ) and LFMC (Konings et al., 2019):

$$VOD = b \times VWC = b \times m_{dry} \times LFMC \quad (2)$$

where  $b$  is a parameter that depends on vegetation type and wavelength. Using this relation, VWC can be estimated from passive microwave observations of VOD (Jackson and Schmugge, 1991; Sawada et al., 2016, 2017). However, those studies  
90 were mainly based on measurements of VWC and VOD in grasslands and for different crop types and only few observations for the relation between VOD and vegetation water are available for forests (Holtzman et al., 2021; Momen et al., 2017). Thereby, the observed relationship between VOD and above-ground biomass (Rodríguez-Fernández et al., 2018; Mialon et al., 2020; Frappart et al., 2020) suggests that the relationship in equation 2 is also valid for forest ecosystems but is modulated by wavelength (Holtzman et al., 2021). The parameter  $b$  exponentially declines with increasing wavelength, which implies  
95 that longer wavelengths have a lower VOD and are less attenuated by the vegetation layer than shorter wavelengths (Jackson and Schmugge, 1991). As longer microwave wavelengths can penetrate deeper in the vegetation layer, VOD from L-band

instruments (L-VOD) is more related to the biomass and water content of woody components than VOD from instruments with shorter wavelengths (e.g. Ku-, X- and C-VOD) which are more related to leaf cover (Tian et al., 2016; Chaparro et al., 2019; Li et al., 2021b). Hence we assume that Ku-, X- and C-VOD show a stronger relation with LFMC than L-VOD which should be more sensitive to changes in the moisture content of woody components (Konings et al., 2021b). Fan et al. (2018) compared LFMC from site measurements with passive and active microwave satellite datasets of VOD, soil moisture and Radar backscatter ratios, and spectral indices from visible-infrared sensors over France. They showed that X-VOD showed the highest correlation (median  $r = 0.43$  across sites) with LFMC among all microwave-derived properties but that spectral indices from the visible-infrared domain were higher correlated with LFMC than all microwave-derived properties (Fan et al., 2018). However, the relation in equation 2 (Jackson and Schmugge, 1991) and the results from Fan et al. (2018) and Sawada et al. (2016) suggest that LFMC can be directly estimated from passive-microwave VOD.

Despite this direct theoretical relationship between LFMC and VOD, which has been established from field observations, there is currently no study that verified this relationship at large (i.e. continental to global) scale. This implies that no method is existing that would allow to estimate LFMC from VOD at large scales. However, the use of novel VOD datasets with almost daily temporal coverage and data available partly since 1987 (Moesinger et al., 2020; Wang et al., 2021) offers the opportunity to estimate LFMC globally with high temporal resolution and over decadal time scales. In comparison to visible-infrared satellite observations, the main disadvantage of using VOD to estimate LFMC is the coarser spatial resolution of passive microwave data (usually  $0.25^\circ \times 0.25^\circ$ ). However, the same disadvantage applies for soil moisture datasets from passive microwave satellites, which nevertheless experience a wide use for the investigation of land surface processes or to constrain land surface models at large scale (Dorigo et al., 2017; Wigneron et al., 2021; Scholze et al., 2017).

Here we aim to estimate LFMC from VOD at large scales, i.e. globally at coarse spatial resolution and at decadal time scales. Therefore, we will use VOD from short wavelengths from the VOD Climate Archive (VODCA) dataset, which provides consistent time series of Ku-VOD, X-VOD and C-VOD harmonized from VOD retrievals from different passive microwave satellites (Moesinger et al., 2020). We first investigate the relation between VOD and LFMC by comparing VOD with a LFMC dataset from MODIS (Yebra et al., 2018) and with the Globe-LFMC database of site observations (Yebra et al., 2019). In the second step, we develop different model structures in order to compute LFMC from VOD and we calibrate each model against site-level observations from the Globe-LFMC database. Finally, we apply the best-performing model globally to estimate LFMC at large scales.

## 2 Data and methods

An overview of the properties of all used datasets is provided in Table 1.

**Table 1: Properties of the used datasets.**

Dataset	Variable	Spatial resolution and coverage	Temporal resolution and coverage	Reference
VODCA v01.0	Ku-VOD X-VOD C-VOD	0.25 x 0.25° Global	Daily Ku-VOD: 1987-2017 X-VOD: 1997-2018 C-VOD: 2002-2018	(Moesinger et al., 2020)
MODIS-LFMC	LFMC (%)	500 x 500 m Australia, Europe including the EU, the UK and Turkey	8-daily (Europe) 4-daily (Australia) 2000-2019	(Yebra et al., 2018)
Globe-LFMC	LFMC (%)	Site measurements (1383 sites) Globally distributed	Irregular sampling, some stations since 1980s	(Yebra et al., 2019)
MOD15A2H v006	LAI	500 x 500 m Global	8-daily 2000-2019	(Myneni et al., 2015)
AVHRR tree and short vegetation cover	Tree cover (%) Short vegetation cover (%)	1 x 1 km Global	Annual 1982-2016	(Song et al., 2018)
ESA CCI Land cover V2.0.7	Land cover classes converted into fractional coverage	300 x 300 m Global	Annual 1992-2015	(Li et al., 2016)
Worldclim 2.5 bioclimatic variables	Mean annual temperature, annual total precipitation	10' x 10' Global	Average for the period 1970-2000	(Fick and Hijmans, 2017)
CGIAR CSI SRTM	Digital elevation model	90 x 90 m Global	2000	(Jarvis et al., 2008)

### 2.1 Vegetation Optical Depth Climate Archive (VODCA) dataset

VOD was taken from the VODCA dataset (Moesinger et al., 2020). VODCA provides VOD at 0.25° x 0.25° spatial resolution in three separate wavelength bands with different temporal coverage, namely Ku-VOD (1987-2017), X-VOD (1997-2018) and C-VOD (2002-2018). The dataset is a merge of VOD retrievals from several passive microwave instruments that were derived with the Land Parameter Retrieval Model (LPRM) (Owe et al., 2001; van der Schalie et al., 2017). The merging uses a

130

cumulative distribution function matching of the individual VOD retrievals into a joint long-term time series. Thereby VOD retrieved from the AMSR-E sensor is used as scaling reference (Moesinger et al., 2020).

135 The VODCA dataset has a daily temporal sampling but observations are not available for each day dependent on time period and latitude. The VODCA dataset was masked for artefacts because of Radio Frequency Interference (RFI), for land surface temperature  $< 0^{\circ}\text{C}$ , and for negative VOD values and, therefore, has mainly gaps in the winter months in northern latitudes. We did not perform any gap-filling or other further processing of the VODCA dataset. However, we excluded grid cells from further analysis that were either not vegetated or that have a higher coverage of ocean or inland water bodies (see section 2.5). Spatial patterns, seasonal dynamics, and long-term trends in the VODCA dataset have been intensively compared with datasets  
140 of leaf area index, gross primary production and vegetation cover and show that VODCA reflects common patterns of large-scale vegetation changes (Moesinger et al., 2020; Li et al., 2021b; Wild et al., 2022).

## 2.2 Live Fuel Moisture Content datasets

LFMC was taken from two datasets, namely from the Globe-LFMC database of site observations (Yebra et al., 2019) and from LFMC data retrieved from MODIS satellite observations by applying the methodology of Yebra et al. (2018) (in the following  
145 MODIS-LFMC). The Globe-LFMC measurements are the primarily dataset for the comparison with VOD and to develop and calibrate the models to estimate LFMC from VOD. However, as there is severe scale mismatch between site measurements of LFMC and the coarse spatial resolution of VOD ( $0.25^{\circ} \times 0.25^{\circ}$ ), we additionally used LFMC retrievals from MODIS to make comparisons at the same spatial scale and to assess if the obtained results are comparable.

Globe-LFMC provides LFMC field measurements from 1383 sites in 11 countries, mainly in the USA (963 sites), China (229  
150 sites), Spain (76 sites) and Australia (42 sites). Each site has a different temporal coverage and sampling frequency of measurements and different plant species are sampled (Yebra et al., 2019). At some sites, only one plant species is sampled throughout the time but at other sites, several plant species are sampled. LFMC values vary at many sites between species. In order to simplify the comparison of LFMC measurements from different species with VOD, we grouped each species according to their genus into a typical growth form. We considered the following growth forms: broad-leaved trees (TreeB), needle-  
155 leaved trees (TreeN), shrubs, grass (i.e. herbaceous graminoid), and forbs (i.e. herbaceous non-graminoid). As some plant genera can grow as tree or shrub, we decided for one or the other based on the land cover type (forest or shrubland) at the site and based on the site photos that come with the Globe-LFMC database.

MODIS-LFMC is based on an inversion (using look-up tables) of different radiative transfer models for grass/shrubs (PROSAILH) and trees (PROGeoSAIL) to estimate LFMC from surface reflectance observations of MODIS (Yebra et al.,  
160 2018). The method and dataset were initially developed for Australia. Additionally, we used retrievals for Europe based on the same method. The dataset provides LFMC at 500 m spatial resolution for the period 2000 to 2019 at 4-daily (Australia) and 8-daily (Europe) time steps. The dataset comes in tiles based on the original sinusoidal grid of MODIS observations. We first merged all tiles within Europe or Australia and then reprojected the data to a longitude/latitude projection (WGS84) using

165 nearest neighbour resampling in GDAL. We then aggregated the dataset to  $0.25^\circ \times 0.25^\circ$  spatial resolution of the VODCA dataset using spatial averaging.

### 2.3 Leaf area index – MODIS

As the relationship between VOD and LFMC also depends on leaf or canopy biomass, we additionally used leaf area index (LAI) retrievals from MODIS as a proxy for total leaf biomass. The MOD15A2H collection 6 product provides LAI globally on 500 m spatial resolution and 8-daily time steps (Myneni et al., 2015). We only used retrievals that were flagged as good  
170 quality in the dataset. Like the MODIS-LFMC data, the LAI data was projected to geographical coordinates and then aggregated to  $0.25^\circ \times 0.25^\circ$  spatial resolution by spatial averaging. The 8-daily MODIS LAI data obtains a clear temporal variability within months which despite the use of good quality observations might be still related to atmospheric effects or possibly other changes in leaf and canopy properties (e.g. water content) that were not considered during the retrieval of LAI. As we here intend to use LAI only as a proxy for the temporal changes in canopy biomass, we averaged the 8-daily LAI values  
175 to monthly values to suppress the intra-monthly variability.

### 2.4 Vegetation cover and ancillary data

The cover of trees and short vegetation was used to stratify the comparison between LFMC and VOD with land cover information and to account for land cover in the models to calculate LFMC from VOD. For this purpose, we used the dataset from Song et al. (2018), which provides the percentage of tree cover, short vegetation and bare ground within grid cells of 1  
180 km x 1 km resolution. The dataset was estimated based on observations from AVHRR and provides annual maps for the years 1982 to 2016.

We additionally used information about ocean and inland water cover from the ESA CCI land cover map (version 2.0.7) (Li et al., 2016). We aggregated the land cover information from the original spatial resolution to the fractional coverage of different plant functional types at  $0.25^\circ \times 0.25^\circ$  by using the cross-walking approach (Poulter et al., 2015). We then used the  
185 fractional cover of water (> 50%) in grid cells to mask VOD data in global analyses (see section 2.5).

Global maps of mean annual temperature and annual precipitation from the Worldclim 2.5 dataset (Fick and Hijmans, 2017) and the CGIAR SRTM digital elevation model (Jarvis et al., 2008) were used to stratify analyses with ancillary information (Figure A 3).

### 2.5 Combination and comparisons of VOD and LFMC data

190 We combined the VOD and LFMC data in four different data combinations for our comparisons. Each combination of VOD and LFMC data had a different purpose and used a different masking or temporal sampling of data. The four combinations enable to 1) compare satellite retrievals from MODIS-LFMC with the different bands of VOD; 2) compare site measurements of LFMC from Globe-LFMC with VOD; 3) calibrate and test models to estimate LFMC from VOD using LFMC site measurements; and 4) to apply the best performing model to global VOD data to estimate LFMC globally.

195 The first data combination (D1) uses MODIS-LFMC for Australia and Europe to compare the temporal dynamic of LFMC  
with Ku-, X- and C-VOD. In order to make a comparison of VOD and LFMC time series per grid cell and to assess the  
differences between the different VOD wavelengths, we only used observations from dates that occur in all four datasets (i.e.  
MODIS-LFMC, Ku-VOD, X-VOD and C-VOD). These are for Australia 1,390 time steps between 2002-06-22 and 2017-07-  
28 and for Europe 900 time steps between 2002-06-26 and 2017-07-31. We then computed the Spearman rank correlation  
200 between LFMC and the different VOD bands per grid cell and stratified the result for tree and short vegetation cover.

The second data combination (D2) is used to compare site measurements from Globe-LFMC with VOD. For this comparison,  
we used VOD data from the same days when LFMC measurements were available. As each site has a different temporal  
sampling of LFMC, the number of joint pairs of LFMC and VOD observations is on average per site 80, 72 and 42 for Ku-,  
X- and C-VOD, respectively, whereby the differences between the number of observations for each band are caused by the  
205 longer temporal coverage of Ku-VOD than for X- or C-VOD. Single sites have up to 827 pairs of Ku-VOD/LFMC  
observations. For this comparison we only matched LFMC with the dates of each individual VOD band but did not match  
additionally the dates of the three VOD bands because this would decrease the availability of LFMC/VOD pairs further. We  
then computed the Spearman rank-correlation between VOD and all LFMC measurements for each site (regardless of the  
sampled plant species) and also for each individual species at a site. We calculated the correlation for all sites/site-species with  
210 at least 10 pairs of LFMC/VOD observations. Based on this criterion, correlations were computed for 910 sites. We then  
assessed how a difference in the land cover distribution at the site and at the corresponding  $0.25^\circ \times 0.25^\circ$  grid cell affects the  
correlation between LFMC and VOD. Therefore, we extracted for the coordinate of each site the percentage of tree and short  
vegetation cover from the original resolution ( $1 \times 1$  km) and the aggregated resolution ( $0.25^\circ \times 0.25^\circ$ ) of the vegetation cover  
dataset. The use of both resolutions allows assessing if the local land cover distribution at the site is comparable with the land  
215 cover distribution of the  $0.25^\circ \times 0.25^\circ$  grid cell of the VOD data. The difference in land cover between the 1 km spatial  
resolution at the local site and the coarse  $0.25^\circ$  resolution of the corresponding grid cell was computed based on the Euclidean  
distance:

$$D = \sqrt{(TC_{25} - TC_1)^2 + (SV_{25} - SV_1)^2} \quad (3)$$

whereby TC and SV are tree cover and short vegetation, respectively and the subscripts 1 and 25 denote the 1 km and  $0.25^\circ$   
220 spatial resolution. As TC and SV are percentages, the difference D is in percent.

The third data combination (D3) used Globe-LFMC site measurements to calibrate and evaluate models to estimate LFMC  
from VOD. We found from data combination D2 that the correlation between site measurements of LFMC and VOD decreases  
if the land cover distribution at  $1 \times 1$  km around the site increasingly differs from the land cover distribution at the  $0.25^\circ \times$   
 $0.25^\circ$  grid cell of the VOD data (see results in section 3.1). Therefore, we aimed to select only sites for the calibration and  
225 evaluation of models that are homogenous and representative for the coarse resolution of the VOD data. The Globe-LFMC  
database provides for each site a spatial coefficient of variation of the normalised difference vegetation index to quantify the  
homogeneity of vegetation cover at each site (Yebara et al., 2019). We used sites with a low coefficient of variation ( $CV <$   
 $0.26$ ). Additionally, we used the land cover difference D (equation 3) to quantify the representativeness of the land cover at

the site for the coarse spatial resolution of the VOD data. We selected only sites with  $D < 10\%$ , i.e. with a similar land cover  
230 distribution at 1 km and  $0.25^\circ$  spatial resolution. We further selected sites for model calibration that have at least 15 pairs of  
VOD and LFMC observations and that showed a positive correlation ( $r > 0.2$ ) between VOD and LFMC. These selection  
criteria were leaving 216 sites to calibrate and test models (Figure A 3).

The fourth data combination (D4) uses daily-sampled VODCA Ku-VOD and monthly-averaged MODIS LAI to estimate daily  
LFMC globally with the best performing model for the overlapping period of both datasets (2000-02-01 to 2017-07-31). We  
235 applied the model to all grid cells at  $0.25^\circ \times 0.25^\circ$  spatial resolution that have on average at least 5% vegetation cover ( $TC +$   
 $SV \geq 5\%$ ) and that have less than 50% water cover.

## 2.6 Models to estimate LFMC from VOD

We tested four different models to estimate daily LFMC from daily values of VOD. The models A and B are based on an  
empirical regression between LFMC and VOD. Model A only uses VOD as a predictor. Model B additionally uses monthly-  
240 averaged LAI as predictor to account for seasonal changes in canopies. Model C makes directly use of the VOD-LFMC  
relationship presented in equation 2 (Jackson and Schmugge, 1991; Konings et al., 2019). Thereby, monthly LAI is used as  
proxy for canopy biomass ( $m_{dry}$ ). Model D uses VOD as proxy for canopy biomass and adopts the approach of Sawada et al.  
(2016), which use LAI as proxy for VWC. Each model has up to four model parameters. Prior ranges and values of those  
model parameters were chosen in order to always obtain a positive relationship between VOD and LFMC and to obtain typical  
245 LFMC values (Table 2).

**Model A** assumes that LFMC is directly proportional to VOD and does not account for effects of canopy biomass. Thereby  
we use a logistic regression (S-curve) because LFMC cannot be smaller than 0% and LFMC values higher than 200% are rare  
(the 95-percentile of LFMC is 193%, the maximum is 549% in the Globe-LFMC database). Model A is defined as:

$$LFMC = \frac{LFMC_{max}}{1 + e^{-sl \times (VOD - VOD_0)}} \quad (4)$$

250 Where  $LFMC_{max}$  is the maximum possible LFMC value and  $sl$  is the slope of the curve.  $VOD_0$  is the inflection point of the  
logistic curve, i.e. the VOD value at which half of the LFMC between 0% and  $LFMC_{max}$  is reached. The parameters  $LFMC_{max}$ ,  
 $sl$  and  $VOD_0$  were calibrated for each site.

**Model B** extends model A by additionally accounting for LAI. Thereby, we assume that LFMC can be expressed based on a  
weighted combination  $x$  of VOD and LAI. Like in model A, we use a logistic regression in order to limit LFMC between 0%  
255 and  $LFMC_{max}$ :

$$x = f \times VOD + (1 - f) \times LAI \quad (5)$$

$$LFMC = \frac{LFMC_{max}}{1 + e^{-sl \times (x - x_0)}} \quad (6)$$

Where  $f$  is a fraction between zero and one that regulates if VOD ( $f = 1$ ) or LAI ( $f = 0$ ) contributes more to the calculation of  
 $x$  and hence to LFMC.  $sl$  and  $x_0$  are the slope and inflection point of the logistic curve. Note that we kept the parameter  
260  $LFMC_{max}$  constant at 400% in model B (corresponding to the 99.99%-ile of LFMC in the Globe-LFMC database) throughout

all analyses because the calibration results from model A have shown that any high value for  $LFMC_{max}$  is not sensitive for the performance of the estimated LFMC.

**Model C** uses the relationship between VOD and LFMC from equation 2 by solving for LFMC:

$$LFMC = \frac{VOD}{b \times m_{dry}} \times 100\% \quad (7)$$

265 Thereby we express the dry biomass of the canopy based on a linear relation with LAI:

$$m_{dry} = a \times LAI + c \quad (8)$$

For the parameter  $b$ , a prior value of 1.5 with a range between 0.1 and 4 was taken based on the values presented in Jackson and Schmugge (1991). The parameter  $a$  was varied between 0.01 and 100 as dry canopy biomass should positively scale with LAI. The parameter  $c$  is the intercept of this linear regression and was chosen around zero (between -10 and 10). Note that the parameters  $a$  and  $b$  are directly positively correlated in model C and could indeed be represented by a combined product. However, as we have both prior information on the values of  $b$  (i.e. VOD-VWC relation) and  $a$  (i.e. the relation between leaf mass and leaf area) but not on their combined product, we decided to keep the two factors separated.

270 **Model D** uses the basic definition of FMC (equation 1) and follows the approach by Sawada et al. (2016) who use LAI as a proxy for VWC in order to model VOD. In model D, LFMC is directly computed from the ratio of VWC and dry biomass:

$$275 \quad LFMC = \frac{VWC}{m_{dry}} \times 100\% \quad (9)$$

VWC is computed based on an exponential relationship with LAI (Paloscia and Pampaloni, 1988; Sawada et al., 2016):

$$VWC = e^{\frac{LAI}{k}} - 1 \quad (10)$$

Where the parameter  $k$  defines the shape of the exponential relationship. As we have no prior information about the value of  $k$ , we sampled  $k$  over a large range (0.1 - 100). Dry biomass is computed based on a linear relation with VOD which is based on the assumption that VOD at short wavelengths is proportional to canopy biomass (Frappart et al., 2020):

$$280 \quad m_{dry} = a \times VOD + c \quad (11)$$

The parameters  $a$  and  $c$  define like in model C the relation with dry biomass.

**Table 2: Overview about prior parameter values and results after site-level calibration for the four models.**

Model	Parameter	Prior parameter (prior, minimum and maximum)	Parameter after site-level calibration (median and percentiles 5% and 95% across all sites with the same growth form)			
			Forb or Grass	Shrub	Broad-leaved tree	Needle-leaved tree
Model A (equation 4)	LFMC <sub>max</sub> (%)	360 [315, 600]	375 [315, 592]	420 [315, 554]	476 [343, 599]	389 [315, 579]
	sl	10 [3, 50]	10.34 [4.2, 23.8]	4.9 [3.2, 8.6]	5.6 [3, 12]	3.9 [3, 6]
	VOD <sub>0</sub>	0.8 [0.1, 1.4]	0.78 [0.62, 1.1]	1 [0.76, 1.2]	0.95 [0.79, 1.14]	1.02 [0.84, 1.22]
	LFMC <sub>max</sub> (%)	fixed at 400	--	--	--	--

285

## 2.7 Site-level calibration and evaluation

The parameters of the models A to D were calibrated separately for each species at each site from the data combination D3. For the calibration, we used a genetic optimization algorithm together with a cost function that is sensitive to the statistical distribution of LFMC and the temporal correlation. We initially tested several common model performance measures as cost functions like the root-mean squared error (RMSE), modelling efficiency and the Kling-Gupta efficiency (KGE) (Gupta et al., 2009) to calibrate the model parameters but we found that based on those cost functions the variance of the observed LFMC was underestimated in most cases. As an alternative, we developed a cost function that aims to fit the observed variance by minimizing the differences in the percentiles of the statistical distribution of LFMC. The used cost function  $J$  adopts the basic definition of the Euclidean distance like in the Kling-Gupta efficiency and is here defined as the Euclidean distance in a multivariate space of performance measures based on the Pearson correlation  $r$  between estimated and observed LFMC and the ratios of the 5%, 50% and 95% percentiles  $p$ :

290

295

$$J = \sqrt{3 \times (r - 1)^2 + \left(\frac{S_{p=5}}{O_{p=5}} - 1\right)^2 + \left(\frac{S_{p=50}}{O_{p=50}} - 1\right)^2 + \left(\frac{S_{p=95}}{O_{p=95}} - 1\right)^2} \quad (12)$$

Where  $S$  and  $O$  are the percentiles of simulated and observed LFMC, respectively. The individual terms in the cost function are zero in case of a perfect model-data agreement and can go to infinite. The correlation-related term was multiplied with 3 to give the temporal correlation the same weight like the three distribution-based ratios.

300

The cost function was minimized for each model and for each plant species at each site by using the Genetic Optimization using Derivatives (GENOUD) algorithm (R package rgenoud, version 5.8-3) (Mebane and Sekhon, 2011). GENOUD is a global optimization algorithm that additionally uses a local search algorithm. We used GENOUD with 100 parameter sets per generation and computed it for ten generations. The local search algorithm was used only after the third generation to avoid a too fast convergence of the algorithm to a local minimum. Prior ranges of each parameter (Table 2) were provided as search domains to the optimization algorithm. As a measure for parameter uncertainty, we then selected the best-performing parameter sets from the optimization results, which have a cost  $J$  less than or equal to the 25%-ile of all parameter sets in an optimization

305

run. As a result, we obtained for each species at each site a sample of best-performing parameters for each model. The median and the percentiles 5% and 95% of each parameter from the best-performing parameter sets are listed for different growth forms in Table 2.

310 Additionally to the used cost function, we used the Pearson correlation coefficient  $r$ , the RMSE and the KGE performance measures to evaluate the optimization results. The KGE allows associating the lack of model performance to a mismatch between observed and estimated mean values (bias component), to a mismatch between observed and estimated variance (variance component) and to a lack of correlation (correlation component) (Gupta et al., 2009). We used the KGE and its three 315 components to diagnose the model performance.

Please note that we did not perform for the site-level calibrations any evaluation with independent test data. We used at each site all available pairs of LFMC/VOD observations for model calibration because a split of the available LFMC observations would further reduce the available data and sites for model calibration as many sites have few observations. However, we built a random forest model to predict the parameters of the best performing model in space and we applied spatial cross validation 320 to evaluate the performance of the predicted LFMC (section 2.8).

## 2.8 Spatial model application, evaluation and uncertainty assessment

The calibration of model parameters was performed for each species at each site and allows evaluating and comparing the performance of the four models at site level. However, in order to apply the best-performing model globally, the model parameters need to be estimated for each grid cell of the global  $0.25^\circ \times 0.25^\circ$  raster. We therefore tested different regression 325 approaches to predict single model parameters from percentage tree cover or from other model parameters. We initially tested different regression approaches to estimate the model parameters, namely linear regression, 2<sup>nd</sup>- and 3<sup>rd</sup>-order polynomials, generalized additive models (GAM), and random forest (RF). While 3<sup>rd</sup>-order polynomials, GAM and RF resulted in similar performance in training, only RF had plausible results in cross validation. Hence, we decided to use RF to estimate the parameters of model B in space. Thereby we followed a step-wise application of RF: In the first RF model, we predicted the 330 parameter  $x_0$  of model B from percentage tree cover. In the second RF model, we then predicted the parameter  $sl$  from tree cover and the parameter  $x_0$ . In the third RF model, we predicted the parameter  $f$  from tree cover, and the parameters  $x_0$  and  $sl$ . The parameter  $\text{LFMC}_{\max}$  was held constant at 400%. We applied RF in the same way for the parameters of the other models by first always predicting the parameter that had the highest correlation with tree cover. We used the randomForest package version 4.6-14 (Liaw and Wiener, 2002) in R with 200 decision trees per RF and a node size of 15. A higher number of decision 335 trees did not result in better performance. The node size describes the number of samples in the terminal nodes of each decision trees that are averaged to provide the regression result. Note that we here used based on our experience with RF a higher node size of 15 than the default value of 5 in order to reduce the risk of overfitting when using RF with only one to three predictors and only 216 sites. In summary, to predict the parameters of model B for one grid cell, a nested set of three RF models is needed (one RF for each parameter).

340 In order to train and evaluate the set of three RF models, we applied a 20-fold spatial cross validation procedure. Therefore,  
we spatially clustered all Globe-LFMC sites from the data collection D4 based on their coordinates using a k-means clustering  
with 20 clusters. We then used the optimized model parameters from all sites within 19 clusters to train the set of three RF  
models and applied the trained set of RF to the 20<sup>th</sup> cluster to predict and evaluate the parameters of model B. Model B was  
then applied with the predicted parameters to estimate LFMC and to cross-validate LFMC. The procedure was repeated 20  
345 times so that each spatial cluster was once not included in the training of the RF models but used for cross-validation.  
During this spatial training and cross-validation procedure, we also attempted to propagate the uncertainty of the optimized  
model parameters. Therefore, we randomly sampled from each Globe-LFMC site in the training set five out of the best-  
performing parameter sets from the site-level calibration. Hence, in each of the 20 folds a different combination of best-  
performing parameter sets was used to train the set of RF models.

350 The spatial training and cross-validation resulted in 20 sets of RF models that allow estimating model B parameters for any  
grid cell based on percentage tree cover. Each of the 20 sets of RF models varies based on the spatial distribution of the used  
Globe-LFMC sites in training and based on the uncertainty of the best-performing model parameters after site-level calibration.  
To estimate LFMC globally, we applied all 20 sets of RF models to all global vegetated grid cells. Therefore, we excluded  
grid cells with less than 5% vegetation cover (tree cover + short vegetation cover) and grid cells with more than 50% water  
355 cover. For each grid cell we then obtained the model parameters from the set of RF models and used model B to predict 20  
realisations of LFMC. We then computed from the predicted LFMC values the median, minimum and maximum values as  
measures of the uncertainty. In the results, we display this uncertainty estimate as relative uncertainty (i.e. (maximum LFMC  
– minimum LFMC) / median LFMC).

### 3 Results and discussion

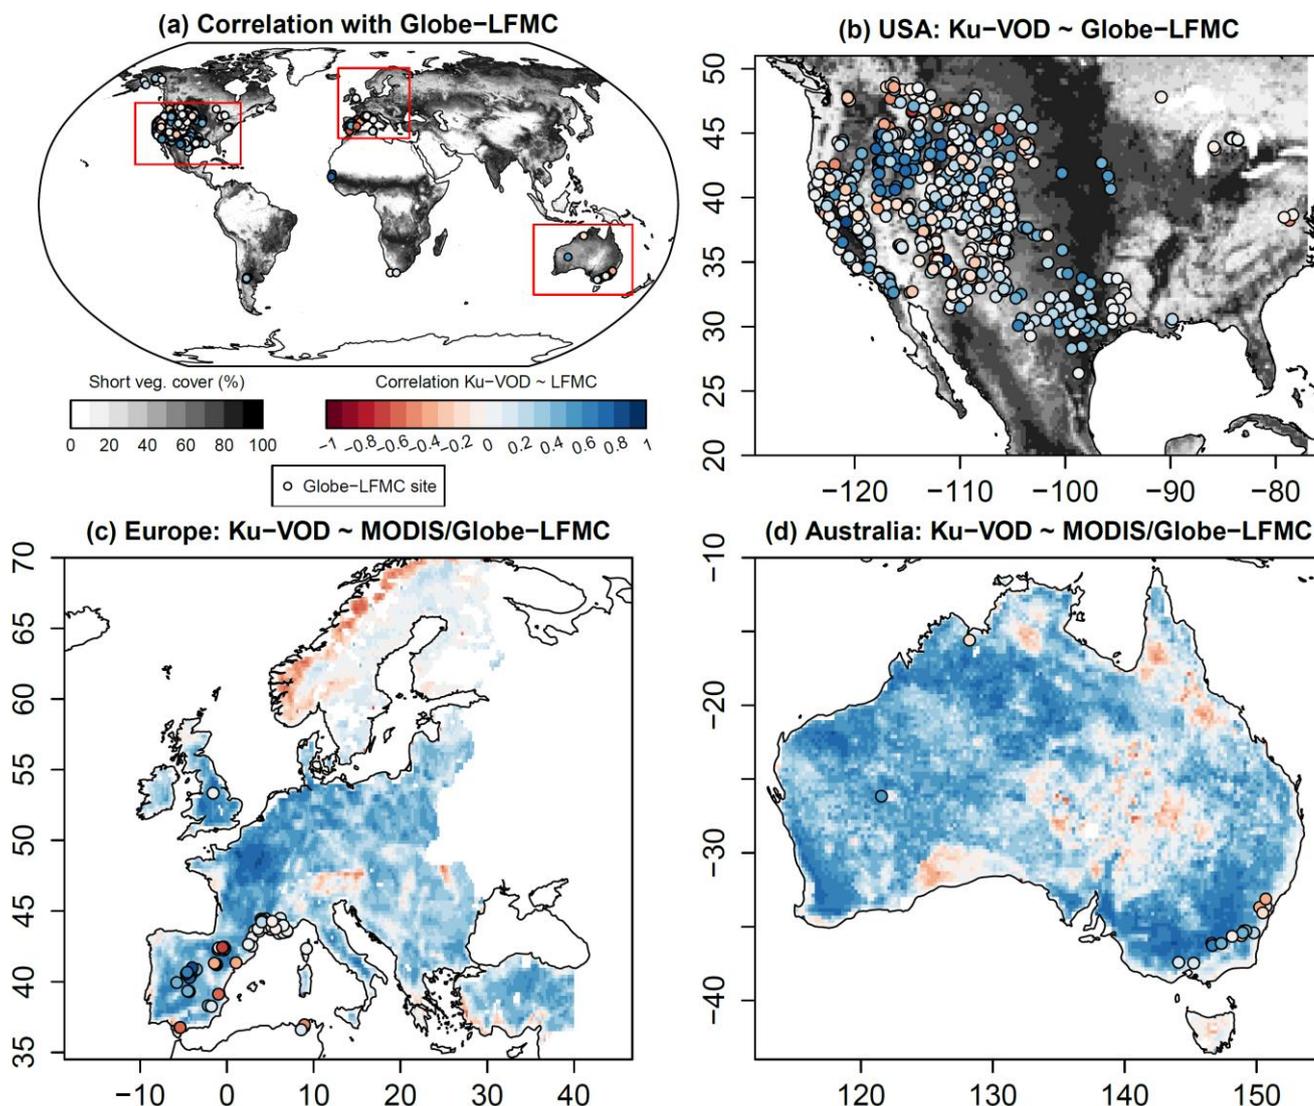

#### 360 3.1 Correlation between VOD and LFMC

##### 3.1.1 Temporal and spatial correlations

The comparison of VOD and LFMC time series from ground measurements and MODIS retrievals shows widespread positive  
temporal correlations (Figure 1). Across the 910 Globe-LFMC sites with  $\geq 10$  pairs of VOD/LFMC observations, the median  
temporal correlation between LFMC and VOD is 0.10 for Ku- and X-VOD, and 0.06 for C-VOD. The maximum correlation  
365 is 0.88 for Ku-VOD, 0.79 for X-VOD, and 0.80 for C-VOD. Globally, 633 sites show positive correlations and 277 sites show  
negative correlations with Ku-VOD. For X- and C-VOD, 632 and 395 sites show positive correlations, respectively. The  
comparison with MODIS-LFMC shows median correlations of 0.30 for Ku-VOD, 0.26 for X-VOD and 0.28 for C-VOD in  
Europe and 0.39 for Ku-VOD, 0.37 for X-VOD and 0.35 for C-VOD in Australia. These results show that correlations between  
VOD and LFMC from site measurements and MODIS retrievals are in the majority of sites or grid cells positive and similar  
370 for the different VOD bands but that Ku-VOD shows slightly higher correlations.

The spatial pattern of temporal correlations between LFMC and Ku-VOD indicate spatial clusters with medium to high positive correlation and clusters with low or negative correlation (Figure 1). In the USA, sites with low correlation ( $r < 0.1$ ) are in many cases distributed along the mountain ranges of the Rocky Mountains, Coast Range or Sierra Nevada (Figure 1 b). This association of low correlations with mountain ranges is also confirmed by the comparison with MODIS-LFMC in Europe, where positive correlations between LFMC and Ku-VOD are widespread but negative correlations occur in the Alps, the Carpathians and the Scandinavian mountains (Figure 1 c). Additionally, the flatter areas of central and eastern Scandinavia show generally very low correlations between Ku-VOD and MODIS-LFMC. In Australia, positive correlations between LFMC and Ku-VOD dominate but negative correlations occur in parts of the northern Great Dividing Range, and in parts of the Simpson Desert and the Nullabor Plain (Figure 1 d). These spatial patterns of correlations with MODIS-LFMC are nearly identical in all three VOD bands.

385 **Figure 1: Temporal correlations between Ku-VOD and LFM. Correlations of Ku-VOD with Globe-LFMC sites are plotted as point symbols and with MODIS-LFMC as coloured back ground raster (in c and d). The greyscale raster in (a) and (b) shows percentage short vegetation cover.**

All global spatio-temporal pairs of VOD and LFM site measurements together show a weak positive correlation but a large bi-variate scatter (Figure 2 a-c). This scatter between globally distributed VOD and LFM indicates that a unique global VOD-LFM relation does not exist or that such a relationship is modified by other surface and land cover properties or by the scale mismatch between VOD grid cells and LFM site measurements.

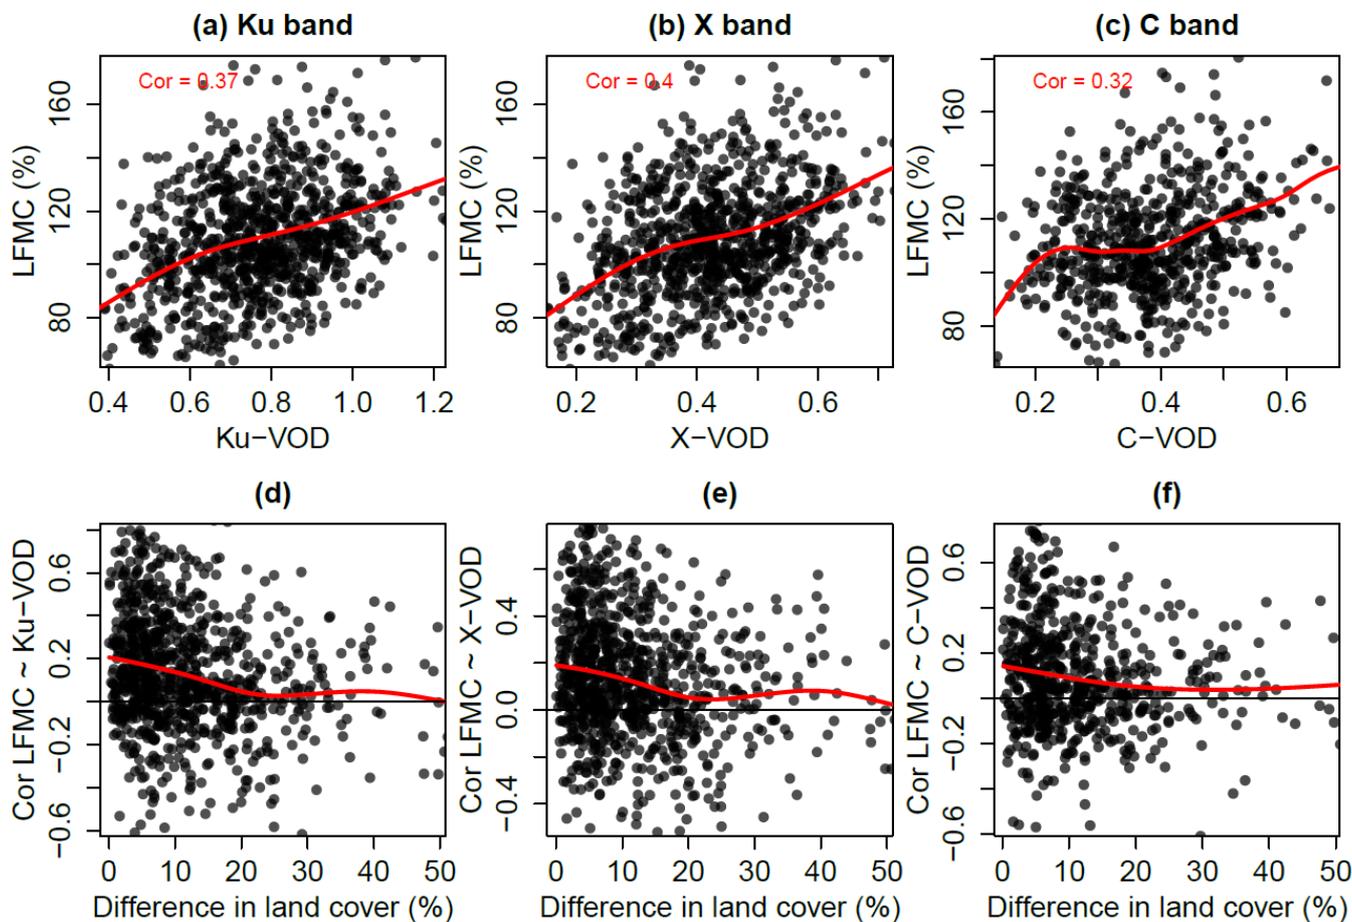

The medium to high positive correlations between VOD and LFM in the majority of sites support earlier studies that identified a relationship between VOD and VWC or LFM (Jackson and Schmugge, 1991; Konings et al., 2019). Despite the strong

395 similarity in correlations between LFMC and the different VOD bands, contaminations by residual effects of RFI could explain  
the slightly lower correlation for C-VOD. The VODCA dataset uses the RFI flagging in LPRM version 6.0, which is based on  
the method proposed by de Nijs et al. (2015). Main contamination areas in AMSR2 in both the C1- (6.9 GHz) and C2- (7.3  
GHz) bands include North America and Europe (de Nijs et al., 2015), where also the majority of Globe-LFMC sites in located.  
We observed that some residual RFI can still be observed in these areas, which was not covered by the masking used in  
VODCA (Figure A 1). As the D2 data combination uses VOD from the same days as Globe-LFMC without any smoothing, it  
400 is likely that the lower correlation between C-VOD and LFMC is affected by residual RFI.

### 3.1.2 Effect of land cover differences between scales

The site measurements of LFMC and the  $0.25^\circ \times 0.25^\circ$  grid cells of the VOD data are representative for very different scales.  
Therefore, we further investigated how a difference in land cover at a site (here defined as the 1 km grid cell in which the site  
is located) and at the  $0.25^\circ$  grid cell affects the temporal correlations between LFMC and VOD. Despite a large variability of  
405 temporal correlations, on average we found decreasing correlations with increasing dissimilarity in land cover distribution  
between the site-scale and the VOD-grid (Figure 2 d-f). For example, the correlation between Globe-LFMC and Ku-VOD  
increased by 0.07 (to median  $r = 0.17$ ) if the land cover difference is less than 10%. In this case, 126 sites had negative  
correlations and 365 sites had positive correlations. Hence, the difference in land cover at a LFMC measurement site and in  
the coarse VOD grid cell can explain a small decrease in the correlation between VOD and LFMC.  
410 Although this analysis allowed to quantify how the correlation between site measurements of LFMC and coarse-resolution  
grid cells of VOD are affected by the land cover differences between both scales, it does not allow to resolve this scale  
mismatch. Only local measurements of passive microwave emissions and derived estimates of VOD in conjunction with LFMC  
samples allow to factor out the scale mismatch for the analysis of relations between LFMC and VOD. However, such  
measurements are rare (Momen et al., 2017). Our results demonstrate the need to better understand the effect of the local to  
415 regional heterogeneity in land cover on coarse-scale VOD estimates in order to make better use of VOD in estimating LFMC.

420 **Figure 2:** (a-c) Global scatterplots and correlation of LFMFC from the Globe-LFMC database against Ku-, X- and C-VOD. (d-f) Scatterplots of the temporal correlation between LFMFC and Ku-VOD (d), X-VOD (e) and C-VOD (f) at each site against the difference in land cover between 1 km (at site) and 0.25° spatial resolution (VOD grid cell) (equation 3). The red lines are smoothing spline fits between the values at the x- and y-axes.

### 3.1.3 Effect of vegetation type

425 Furthermore, we investigated if the correlations between VOD and LFMFC are associated to vegetation type (Figure 3). The comparison of VOD with Globe-LFMC shows higher correlations at higher short vegetation cover within the VOD-grid cell. For example, the median correlation between LFMFC and Ku-VOD is 0.30 if the short vegetation cover is  $\geq 80\%$  and is 0.09 if the short vegetation cover is  $< 80\%$  (Figure 3a). However, despite this average increase in correlation with increasing short vegetation cover, several sites with low short vegetation cover also have correlations  $> 0.5$ . The increase of correlation with short vegetation cover are mirrored by a decrease of correlation with increasing tree cover. For example, the median correlation between Globe-LFMC and Ku-VOD is 0.15 for tree cover  $< 20\%$  and is 0.05 for tree cover  $\geq 20\%$ . The changes in correlation

430

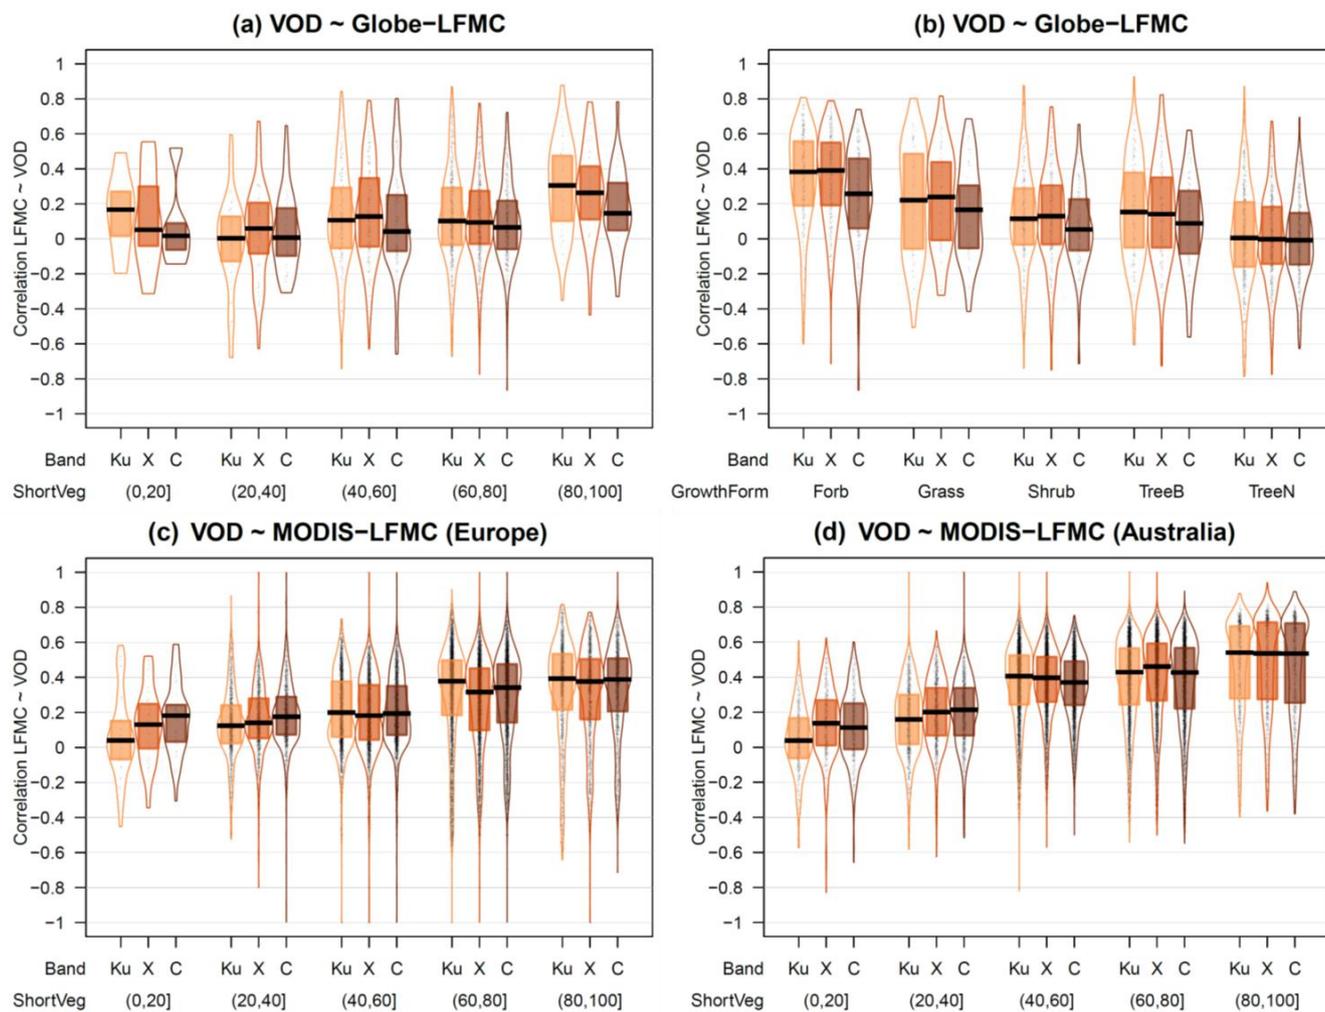

with short vegetation or tree cover are similar for all three VOD bands but Ku-VOD shows in the majority of vegetation cover fractions higher correlations than the other two bands. The dependency of the correlation between LFMC and VOD on vegetation type is more pronounced if we use MODIS-LFMC instead of Globe-LFMC site measurements. Thereby we find  
435 for all VOD bands and both in Australia and Europe a general increase of the correlation with increasing short vegetation cover (or decreasing tree cover) (Figure 3c-d).

The dependency on vegetation composition becomes clearer when we compute the correlation between VOD and LFMC separately for each sampled plant species at each site and then grouped the plant species in growth forms (Figure 3b). We find the highest correlation for forbs (median  $r = 0.38$  for Ku-VOD), followed by grass ( $r = 0.22$ ), broad-leaved trees ( $r = 0.15$ ),  
440 shrubs ( $r = 0.11$ ), and finally needle-leaved trees ( $r = 0$ ). The order of median correlations is the same for X- and C-VOD. However, the results show that despite low median correlations for some growth form classes, also high correlations are possible at some sites for all growth forms. For example, the percentile 90% of the correlation between LFMC and Ku-VOD is 0.7 for forbs, 0.65 for grass, 0.55 for shrubs, 0.61 for broadleaved trees and 0.40 for needle-leaved trees. These results demonstrate that especially Ku-VOD is related to LFMC and that the relationship is closest for short vegetation types such as  
445 forbs, grasses and shrubs.

These results are in agreement with earlier studies that established the relation between VOD and VWC or LFMC based on observations from crops and grasses (Jackson and Schmugge, 1991; Konings et al., 2019). The more homogenous canopies of short vegetation than of forest canopies might cause the generally higher correlations between VOD and LFMC at many herbaceous sites than at forest sites. However, based on the additional high 90% percentiles of correlations at some tree-  
450 dominated sites, we assume that coarse-resolution VOD data is also sensitive to LFMC at forest sites but that the relationship is in many cases masked by the mismatch between land cover at the local site and the coarse VOD grid cell. This assumption is also supported by the findings of Holtzman et al. (2021) who report a correlation of  $r = 0.76$  between L-VOD and leaf water potential as measured locally in a deciduous forest and by Momen et al. (2017) who were able to model X-VOD from measurements of leaf water potential and LAI for two mixed deciduous forests.

455

460 **Figure 3: Statistical distributions of the temporal correlation between VOD and LFM stratified by vegetation type. (a and b) Correlation with measurements from the Globe-LFMC database stratified by (a) the percentage cover of short vegetation and (b) by the growth form of the sampled plant. (c and d) Correlation with MODIS-LFMC in (c) Australia and (d) Europe stratified by the percentage cover of short vegetation.**

### 3.2 Estimating LFM at site-level

#### 3.2.1 Model performance in site-level calibration

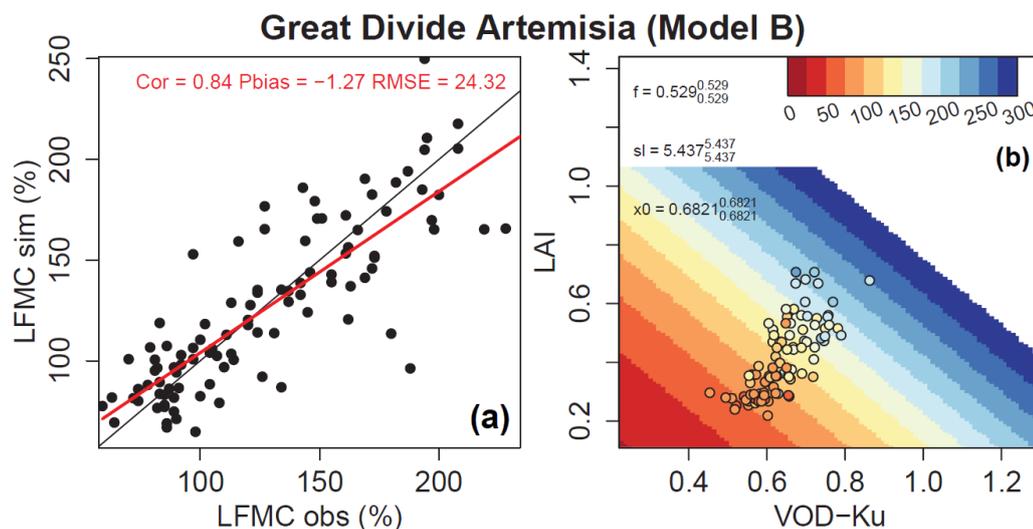

465 Based on the finding that Ku-VOD shows slightly higher correlations with LFM than X- or C-VOD and given the longer temporal overlap of Ku-VOD with Globe-LFMC observations, we used Ku-VOD as input to four different models to estimate LFM. We separately calibrated each model at each of 216 Globe-LFMC sites that were selected based on the criteria for the

data collection D3 (section 2.5). An example of the calibration of model B for one species at one site is shown in Figure 4. The example demonstrates a very good fit between observed and estimated LFMC (correlation  $r = 0.84$ ). This example corresponds approximately to the 90%-ile highest correlation between observed and estimated LFMC from model B and is therefore among the best results of all sites. The model response function shows that the estimated LFMC increases with both daily Ku-VOD and monthly LAI, which is supported by the observed LFMC (Figure 4 b). In this model, the performance of the estimated LFMC is most strongly influenced by the parameter  $sl$  (e.g.,  $r = 0.95$  between  $sl$  and RMSE) while also the parameter  $x0$  has a strong effect on the model performance (e.g.,  $r = -0.65$  between  $x0$  and RMSE). This example shows that LFMC from site-level observations can be estimated from coarse resolution Ku-VOD (and LAI) observations.

Across all sites and vegetation types, the estimated LFMC from model B shows a better fit against the observed LFMC than the estimates from the other three models (Figure 5). Model B achieves correlations of  $0.64_{0.36}^{0.86}$  (median and 5% and 95%-percentiles), followed by model D with  $0.54_{0.66}^{0.83}$ , model A with  $0.45_{0.16}^{0.75}$ , and finally model C with  $0.41_{0.06}^{0.75}$ . Also for the RMSE, model B shows the lowest error with  $RMSE = 29_{11.5}^{60.7}\%$ -LFMC. The other three models show higher RMSE with model C having the highest error ( $RMSE = 44.9_{10.1}^{64.3707}\%$ -LFMC). Please note the high 95%-ile of the RMSE for model C, which indicates that it was not possible to successfully fit model C at some sites.

By investigating the model performance for different vegetation growth forms, we generally found that model B performed best and that the ranking of model performance for the other three models is similar for all vegetation types (Figure 5). We found the highest correlation between estimated and observed LFMC for shrubs ( $0.73_{0.46}^{0.87}$ , model B), followed by forbs and grasses ( $0.67_{0.44}^{0.83}$ ), broad-leaved trees ( $0.55_{0.32}^{0.86}$ ), and needle-leaved trees ( $0.50_{0.28}^{0.70}$ ). The lowest median correlation was found for model C for broad-leaved trees ( $0.35_{0.14}^{0.62}$ ). While the models A, B and D resulted in only positive correlations between observed and estimated LFMC, model C produced at five sites negative correlations. In terms of the RMSE, needle-leaved trees had the lowest error with  $RMSE = 15\%$ -LFMC (median for model B), followed by shrubs ( $RMSE = 19\%$ ), broad-leaved deciduous trees ( $RMSE = 35\%$ ) and forbs and grasses ( $RMSE = 39\%$ ). The results indicate that the performance of the models to estimate LFMC from Ku-VOD depends on vegetation type. Thereby the temporal correlation can be well estimated for all vegetation types using model B. The absolute values of estimated LFMC show low to medium errors for most vegetation types except for broad-leaved evergreen trees.

495 **Figure 4: Example of the fit of model B using daily Ku-VOD and monthly LAI for *Artemisia tridentata* ssp. at the site Great Divide, Colorado (40.76°N, 107.85°W). (a) Scatterplot of estimated against observed LFMFC. (b) Distribution of observed LFMFC (points) and estimated LFMFC (coloured background) in relation to daily Ku-VOD and monthly LAI.**

### 3.2.2 Suitability of model structures

500 The logistic regression model B based on daily VOD and mean monthly LAI outperforms other model structures. The improved performance of model B (using VOD and monthly LAI) over model A (only using VOD) demonstrates that the dynamics in LAI needs to be considered in order to provide good estimates of LFMFC. The parameter  $f$  in model B defines the relative contribution of VOD or LAI to the estimated LFMFC. The higher values of  $f$  for trees than for grasses and forbs (Table 2) shows that VOD needs to be higher weighted to predict the LFMFC of forest sites while a lower weight of VOD (and higher relative contribution of monthly LAI) is necessary to predict the LFMFC of grasses and forbs. The higher weighting of VOD to predict LFMFC of trees corresponds to the findings of Zhang et al. (2019) who found that canopy biomass has a stronger effect on short-wavelength VOD than leaf water potential in temperate forests.

Model C adapted the relationship between VOD and LFMFC as proposed by Jackson and Schmugge (1991) and Konings et al. (2019) (i.e. equation 2). Hence, this model used VOD to account for VWC and used LAI to account for canopy biomass. Model C resulted on average in low correlations and high errors between estimated and observed LFMFC. While this model could not be fitted successfully at some sites, it also reached good performances at others. These results suggest that the relationship between VOD and LFMFC as denoted in equation 2 is valid for some sites but it might not be valid for all sites or is overly sensitive to scale mismatches in the local measurements and the coarse-scale VOD and LAI data.

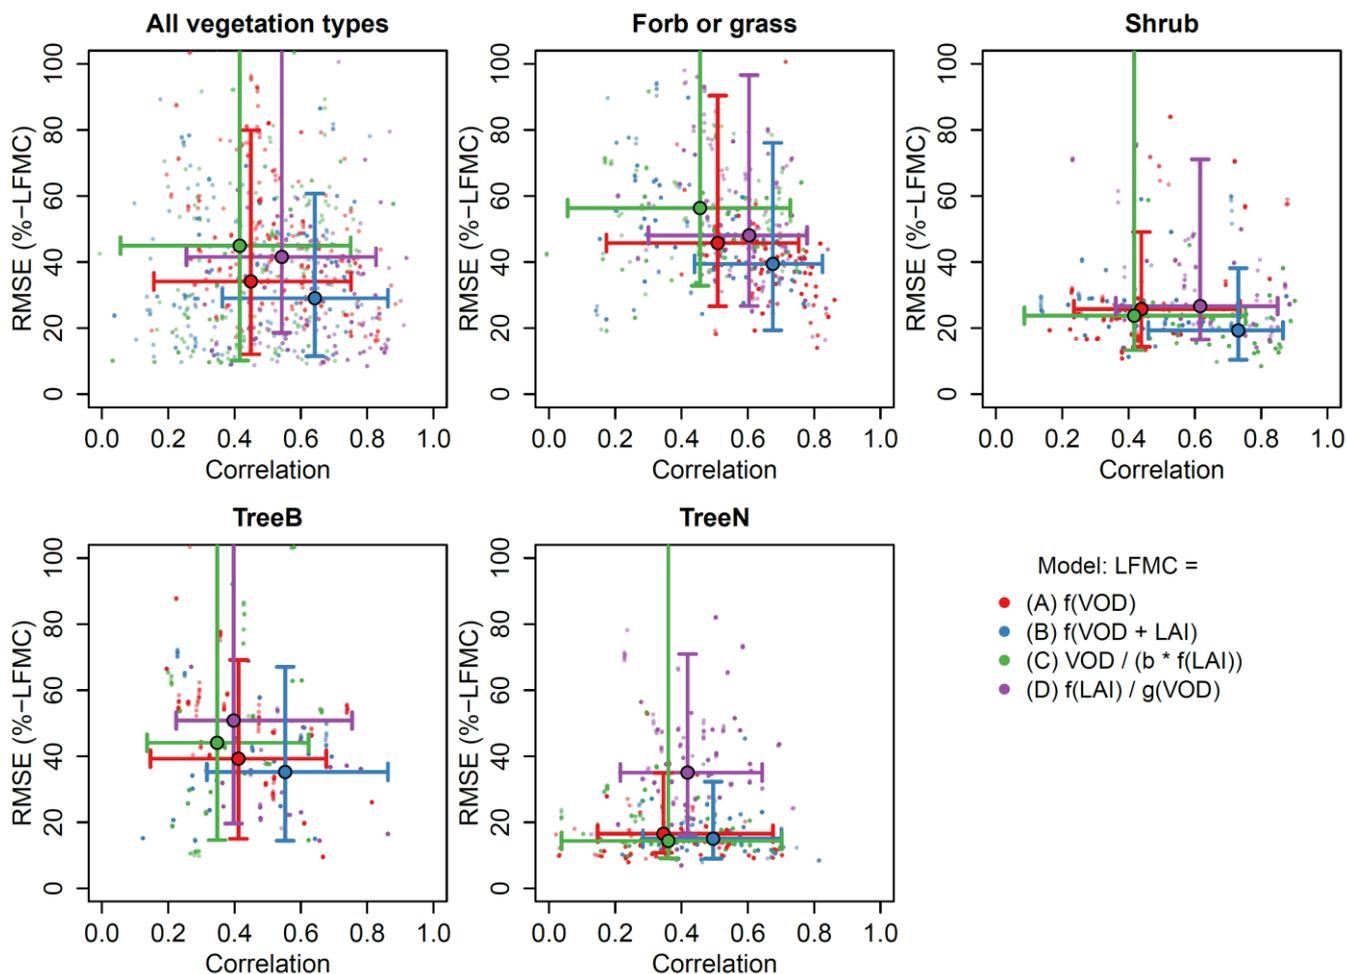

Model D adapted the relationship between VWC and LAI as suggested by Sawada et al. (2016) and estimated canopy biomass based on VOD. As this model resulted in better performance than model C, it indicates that VOD is indeed a valuable predictor

515

for canopy biomass and VWC can be indeed estimated from LAI at many sites. Model D achieved on average higher correlations between estimated and observed LFMC than model A (only using VOD), which shows that LAI is required to predict temporal dynamics in LFMC. However, model D had higher errors than model A, which indicates that using VOD only as predictor for canopy biomass is not sufficient but that the VOD information in model A provides information of absolute values (and hence reduces errors) of LFMC.

Models A, C and D with lower performance have a low flexibility in how they use VOD and LAI to estimate LFMC: model A only uses VOD; model C uses VOD to account for VWC and LAI to account for biomass; and model D uses LAI to account for VWC and VOD to account for biomass. On the other hand, model B allowed to combine daily VOD and monthly LAI in a flexible way to estimate LFMC and reached highest performance. These results demonstrate that flexible model structures are needed in order to estimate LFMC from VOD and LAI. This finding is supported by several studies that identified that the relative contributions of changes in biomass and vegetation water content (or leaf water potential) depends on land cover type (Momen et al., 2017; Zhang et al., 2019; Konings et al., 2021b).

530 **Figure 5:** Performance of the models A-D using daily Ku-VOD (and monthly LAI in models C-D) after calibrating each model at  
 each site. Shown is the root mean squared error (RMSE) and correlation coefficient between estimated and measured LFMC. Small  
 dots are results from different parameter sets at each site, big dots and bars are the median and range from the 5 to 95%-iles across  
 all sites, respectively.

535 **3.3 Estimating LFMC spatially using spatial cross-validation**

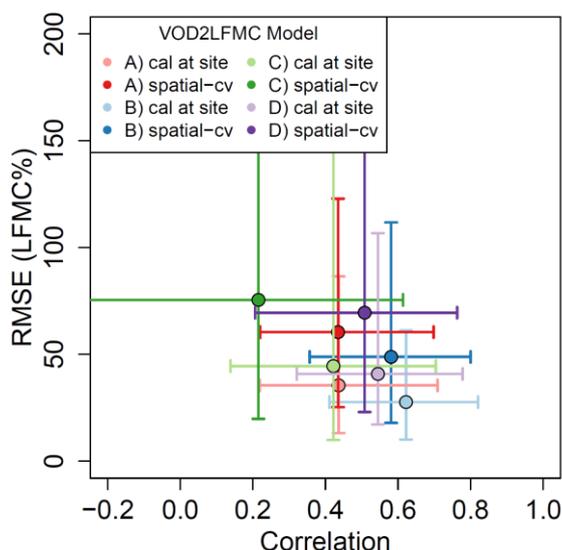

In a next step, we investigated the applicability of the four models in space, which requires an estimate of the model parameters  
 for each of the 0.25° VOD-grid cells. Therefore, we first analysed the correlation of the estimated parameters of each model  
 with land cover properties of the VOD-grid cell (e.g. shown for model B in Figure A 2). We found that some of the optimized  
 model parameters are highly correlated with land cover information while other parameters can be estimated based on the  
 covariation between parameters. For example, in model B the parameter  $x0$  had the strongest correlation with the percentage  
 540 tree cover ( $r = 0.74$ ), the parameter  $sl$  with the parameter  $x0$  ( $r = -0.74$ ) and then with tree cover ( $r = -0.32$ ), and the parameter

545  $f$  with the parameter  $sl$  ( $r = 0.3$ ) (Figure A 2). Based on those findings, we used random forest to predict first for each VOD-grid cell the parameter  $x0$  from percentage tree cover and then the parameter  $sl$  from tree cover and the parameter  $x0$ . Finally, we predicted the parameter  $f$  from tree cover and the parameters  $x0$  and  $sl$ . We performed the same step-wise approach to predict the parameters with random forest for the other models and then applied each model to the  $0.25^\circ$  grid cell by using the predicted parameters to estimate LFMC. We applied this approach within a 20-fold spatial cross validation to evaluate the performance of the estimated LFMC in space.

### 3.3.1 Model performance in spatial cross-validation

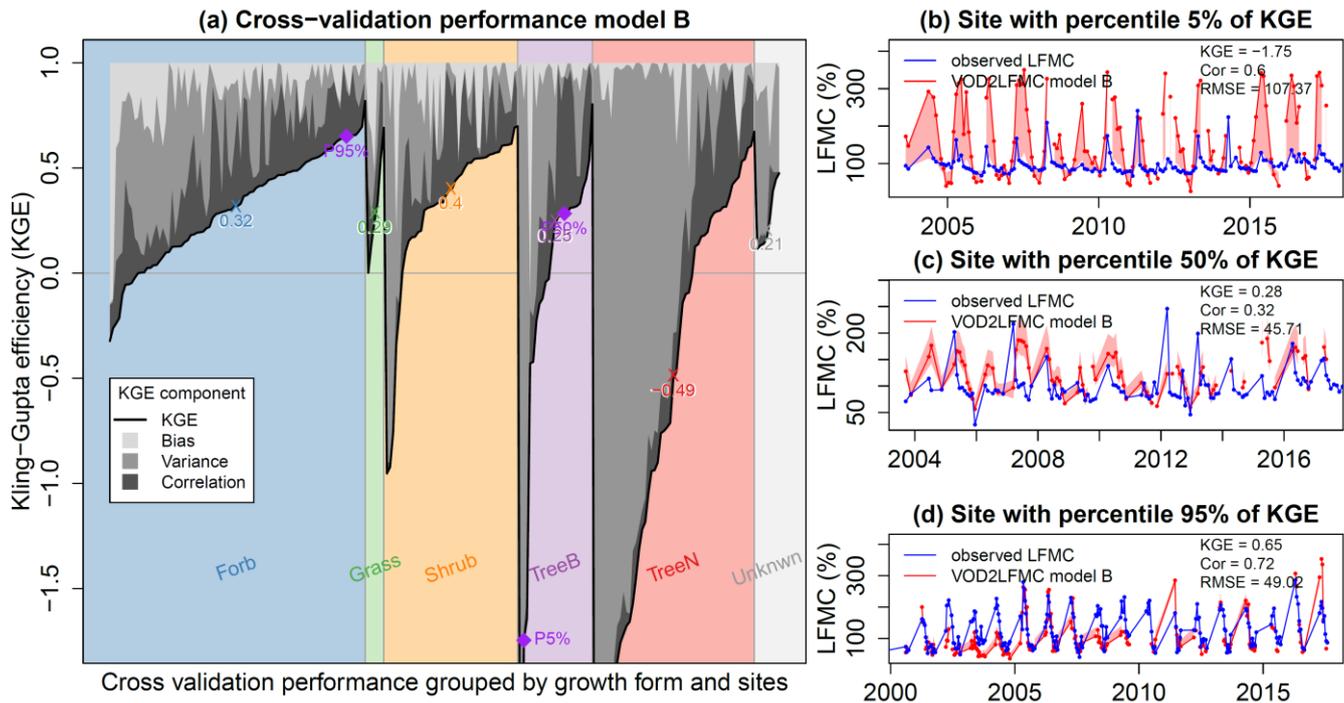

550 As expected, the performance of all models slightly decreased in cross validation in comparison to the site-level calibration results (Figure 6). However, the ranking in model performance remained the same with model B showing the best performance. For example, model B had correlations of  $0.58_{0.30}^{0.84}$  in spatial cross validation samples ( $0.64_{0.36}^{0.86}$  in site-level calibration, see section 3.2), which corresponds to a decrease of 0.06 of the median correlation in comparison to the calibration against the site data. The RMSE in spatial cross validation was  $48.8_{17.9}^{111.8}$  %-LFMC for model B (RMSE =  $29_{11.5}^{60.7}$  %-LFMC in site-level calibration). Like model B, also models A and D experienced small decreases in correlation and increases in RMSE in spatial cross validation (Figure 6). However, model C experienced strong decreases in correlation from median  $r = 0.42$  in site-level calibration to  $r = 0.22$  in spatial cross validation. These results demonstrate that the parameters of model C could not be reliably estimated in space in order to obtain a sufficient performance in estimating LFMC but that especially model B can be applied in space and results in a comparable performance in estimated LFMC between site-level calibration and spatial cross validation.

560 **Figure 6: Performance of the models A-D using Ku-VOD after calibrating each model for each species at each site (cal at site) and after using sites as test data in spatial cross validation after the application of random forest to predict model parameters (spatial-cv). Shown is the root mean squared error (RMSE) and correlation coefficient between estimated and measured LFMC. Dots and bars are the median and range from the 5 to 95%-iles across all sites, respectively.**

565

570

**Figure 7: Performance of model B using Ku-VOD in spatial cross validation at each site grouped by the sampled vegetation growth form of LFMFC measurements. (a) Kling-Gupta efficiency with its components caused by bias, variance and correlation. Purple dots represent the 5%, 50% and 95%-iles of the KGE across all sites. The time series of the sites corresponding to those percentiles are shown in panels (b, 5% = site with low performance, broad-leaved tree site), (c, 50% = site with medium performance, broad-leaved tree site) and (d, 95% = site with good performance, forb site).**

575

We then performed a more detailed evaluation of the cross validation results of the best-performing model B by investigating the Kling-Gupta efficiency (KGE) and its components for each site and each vegetation growth form (Figure 7). We found the highest KGE in cross validation for shrubs (median KGE = 0.4) and forbs (median KGE = 0.32). Grasslands (median KGE = 0.29) and broad-leaved trees (median KGE = 0.25) had lower performance and needle-leaved trees had overall low performance (median KGE = -0.49). However, the variability in KGE was high within all vegetation types. All grass sites and 88% of the forb and shrub sites had positive KGE but only 38% of the needle-leaved sites had positive KGE. In most sites with low KGE, KGE is dominated by a mismatch between the observed and estimated variance of LFMFC. This can be seen for example in the LFMFC time series in Figure 7 b, which is representative for a broadleaved tree site with low KGE and corresponds to the percentile 5% of the KGE across all sites. However, the correlation between observed and estimated LFMFC is still moderate at such sites, which indicates that the temporal dynamic of the estimated LFMFC has still a moderate agreement

580

with the observed LFMC. For sites with medium and high KGE (Figure 7 c and d), the error is in most cases a mixture of a  
585 mismatch in mean values (bias), variance or not-perfect correlation. For example, the time series in Figure 7 c and d  
demonstrate that the model B fits well the mean, variance and correlation of the observed LFMC.

### 3.3.2 Spatial applicability of model structures

The ranking in performance of the four models in spatial cross validation resembles the ranking of the performance in site-  
level calibrations. On the one hand, the large variability in performance at site-level calibration and the strong decrease in  
590 performance in spatial cross validation for model C demonstrates that this model cannot be successfully applied and transferred  
to estimate LFMC globally. On the other hand, the results demonstrate that model B can be successfully used to estimate the  
spatial-temporal dynamics of LFMC, whereby the parameters of model B can be estimated from observed tree cover using  
random forest. Medium to high performance of the estimated LFMC can be expected for herbaceous vegetation, shrublands  
and for most broad-leaved trees. On average, a low performance and underestimation of the observed variance can be expected  
595 for needle-leaved trees, but this is not the case for all sites with needle-leaved trees.

The application of model B in estimating LFMC results in performances (i.e. median RMSE = 48.8% in global spatial cross-  
validation) that are comparable with other studies that estimated LFMC based on optical satellite observations. For example,  
estimated LFMC reached errors of 40% (Yebra et al., 2018), 45% (Caccamo et al., 2011) and 44% (Nolan et al., 2016) across  
validation sites in Australia (Yebra et al., 2018) and approx. 34% in a global study with MODIS data (Quan et al., 2021). Rao  
600 et al. (2020) used Landsat-8 and Sentinel-1 Radar backscatter to estimate LFMC for the western US using a neural network  
model and obtained RMSE of 25% across vegetation types. They obtained the lowest errors for mixed and needle-leaved  
forests (RMSE = 20% and 22%) and the highest errors for grasslands (RMSE = 31%). While our results are similar for site-  
level calibrations of model B (i.e. RMSE = 15% for needle-leaved trees and 39% for grasslands), we found higher performance  
for grasslands than for needle-leaved trees in spatial cross validation. In summary, our estimates of LFMC from coarse-  
605 resolution VOD and LAI data reach medium to high performances that are comparable with other studies that use more data  
with higher spatial resolution or data from optical satellite systems for which the physical relations between LFMC and surface  
reflectance are established for several years (Yebra et al., 2013).

## 3.4 Global LFMC estimates

### 3.4.1 Global spatial-temporal patterns

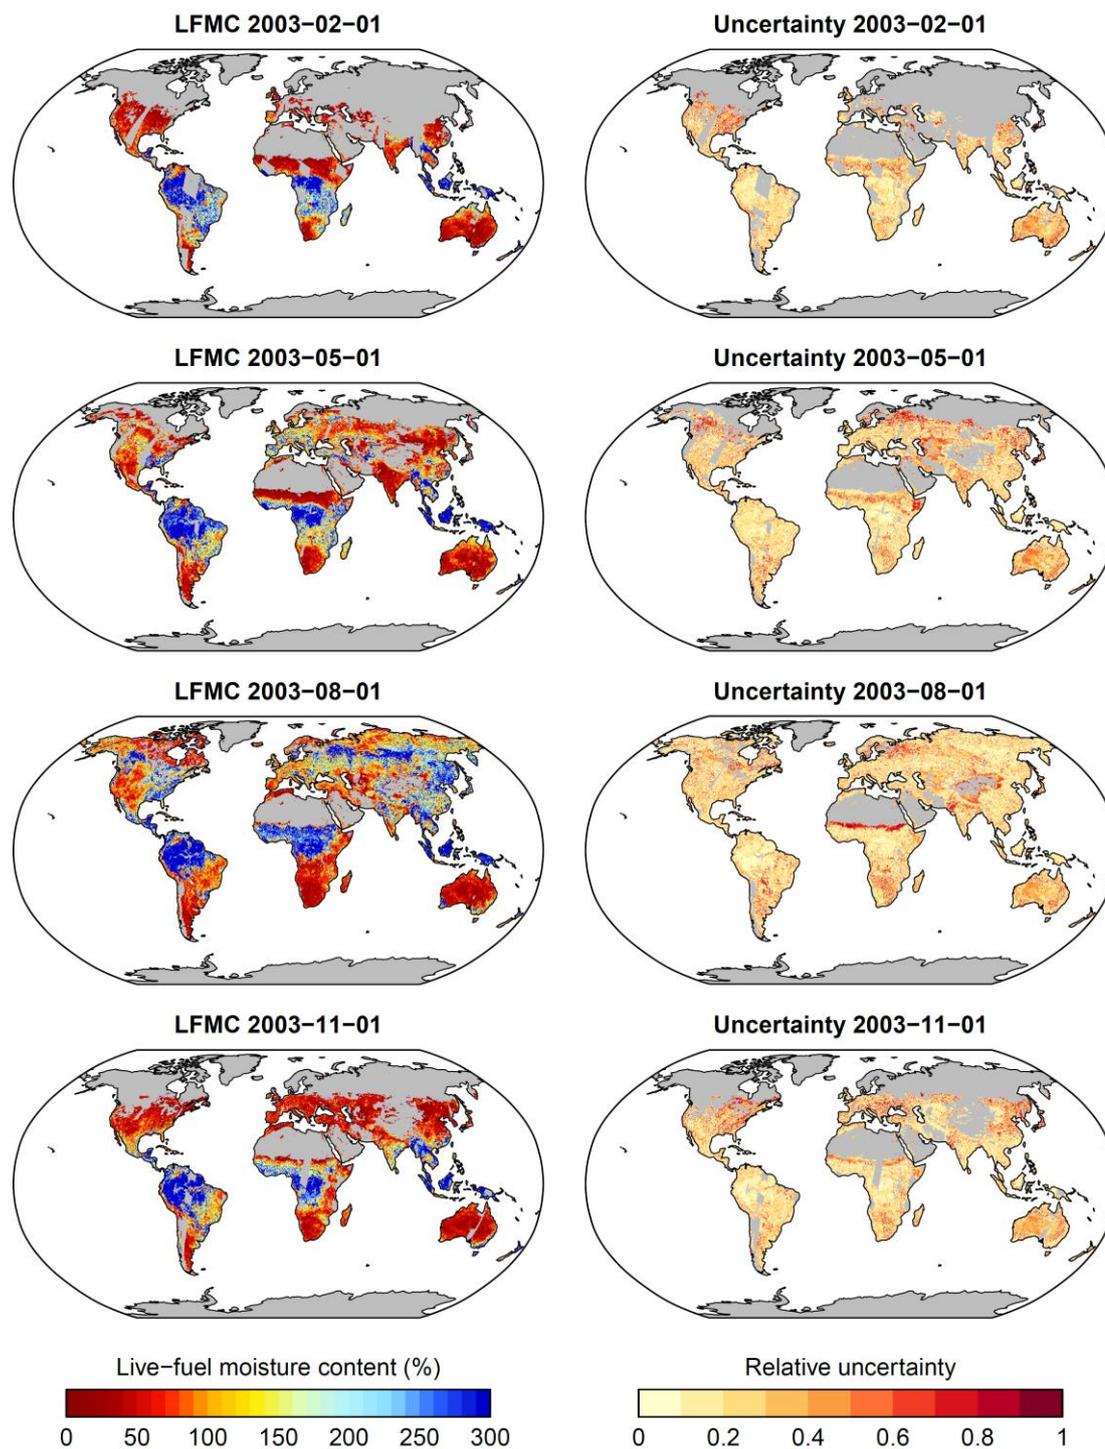

610 Finally, we applied model B and the associated RF-based parameters to global data of Ku-VOD, LAI and tree cover to estimate  
LFMC globally at  $0.25 \times 0.25^\circ$  spatial resolution and at daily sampling for the period February 2000 to July 2017 (overlapping  
period of Ku-VOD and MODIS LAI). As an example, we show global estimates for four days in the year 2003 (Figure 8). The  
four days cover the different seasons in northern ecosystems as well as wet and dry seasons in tropical Africa. The four maps  
show generally high LFMC in wet tropical regions (Amazon and Congo basins, SE Asia), medium LFMC in many sub-tropical

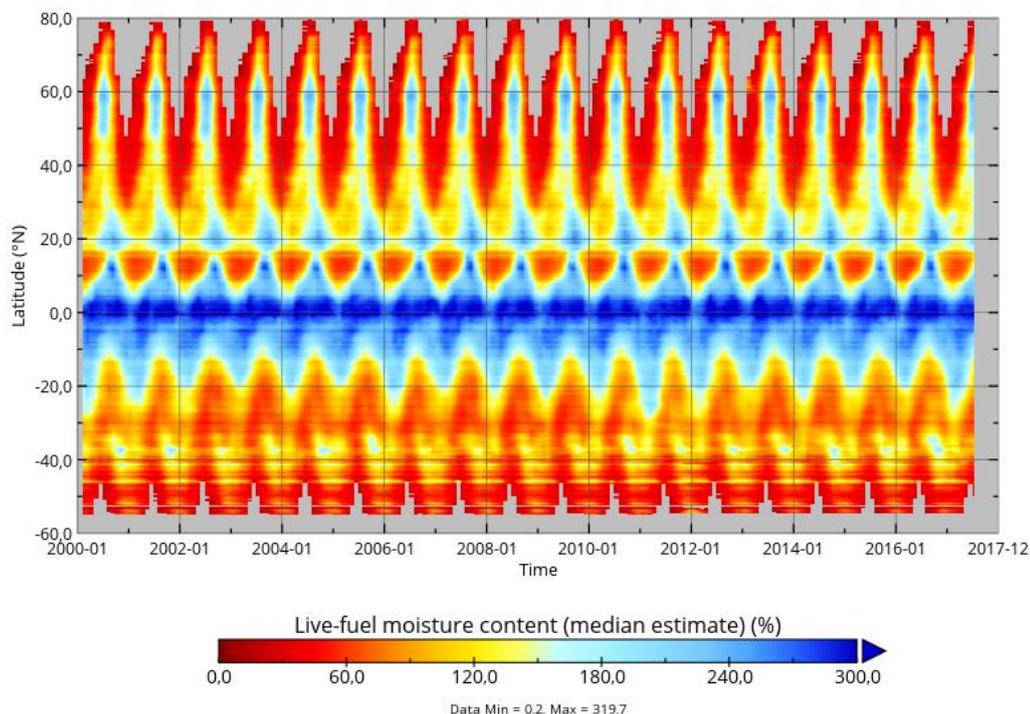

615 and temperate regions and low LFMC in Savannah and desert regions. Seasonal changes in LFMC generally follow wet and  
dry seasons in semi-arid regions and the course of the phenological development as commonly seen in other vegetation  
properties (i.e. LAI or productivity). For example, the Sahel in northern Africa shows high LFMC in August (wet season) and  
low LFMC in February (dry season). Similar seasonal changes between wet and dry seasons can be seen in South America,  
the southern United States, the Mediterranean, India, eastern Asia and Australia. The seasonal changes in LFMC are also  
620 visible in the Hovmöller diagram (Hovmöller, 1949) shown in Figure 9. Thereby, equatorial regions show continuously high  
LFMC with a very weak seasonality. Northern subtropical regions between 5 and 18°N show prolonged dry seasons with low  
LFMC towards northern latitudes. Northern mid and high latitudes (> 30°N) show higher LFMC during the summer months  
than during spring and autumn.

The large similarity of the global seasonal changes in LFMC with similar changes found in other vegetation properties such  
625 as LAI or gross primary productivity might seem astonishing at first view because LFMC represents a relative property of  
moisture content and not an absolute property of vegetation cover or biomass (like LAI). However, seasonal changes in leaf  
cover are highly correlated with LFMC, especially in short vegetation regions. For example, MODIS LAI has an across-site  
median temporal correlation with measurements of the Globe-LFMC dataset between  $r = 0.30$  and  $r = 0.50$  for regions with  
short vegetation cover > 80% (Figure A 4). Hence the Globe-LFMC site-level data shows indeed a strong coupling between  
630 LFMC and LAI, which is then also reflected in our global estimates of LFMC. This suggests a close coupling of LFMC  
increases with leaf development and of LFMC decreases with leaf cavitation and shedding.

Areas without estimates of LFMC (grey areas in Figure 8 and 9) occur because of several reasons. 1) Missing data in deserts  
and ice-covered regions are because the model was not applied to grid cells with less than 5% vegetation cover. 2) Missing  
data in northern latitudes in winter months are either because of months without LAI observations because of low solar zenith  
635 angles, snow or cloud cover, or because Ku-VOD observations were not available over frozen soils. 3) Other days with missing  
observations in some regions are because of missing coverage of passive microwave sensors or were masked in the VODCA  
dataset because of RFI.

640 **Figure 8:** Example of global patterns of LFMC and associated uncertainties as estimated with model B for four selected days in 2003, representing typical days during the northern seasons and the wet and dry seasons in Africa. Grey areas (missing data) is because of missing vegetation cover or gaps in the LAI or VOD data.

**Figure 9: Hovmoeller diagram of monthly LFMC as estimated from model B using daily Ku-VOD and monthly LAI.**

645

### 3.4.2 Uncertainties and observational support

The uncertainty estimates of the global LFMC estimates are on average low (global mean relative uncertainty = 0.28) and do not show distinct spatial patterns (Figure 8, right column). Larger relative uncertainties tend to occur at low LFMC, i.e. at seasonally dry conditions or in transitions areas to deserts (e.g. the Sahel, border of Sahara, Central Asia, parts of Australia) and in the boreal forest regions in Russia and Canada. The higher uncertainty over boreal forests corresponds to the lower correlations between LFMC and Ku-VOD and between estimated and observed LFMC after site-level calibration, and to the lower performance in spatial cross-validation for sites with needle-leaved trees.

The analysis of the estimated global patterns of LFMC needs to be compared with the number of observations that are supporting the global estimates. The majority of pairs of Ku-VOD and Globe-LFMC observations come from the western US and from sites in the Mediterranean, western Africa and southern Australia (Figure A 3a). The available Globe-LFMC observations cover mean annual temperatures between -0.3 and 27°C and annual total precipitation between 202 and 1465 mm (Figure A 3c). This indicates that boreal and polar regions and very wet tropical regions are generally not supported by Globe-LFMC observations. Likewise, the observations cover tree coverages between 0 and 79% but no observations are available at high tree cover with high mean annual temperature > 20°C (i.e. in tropical forests) (Figure A 3d).

660 We additionally estimated the number of supporting observations in space as a function of mean annual temperature, tree  
cover, maximum Ku-VOD and maximum LAI (Figure A 3b). Therefore a random forest regression was fitted to the number  
of observations per site in the Globe-LFMC database and by using mean annual temperature, tree cover, mean annual  
maximum Ku-VOD, and mean annual maximum LAI as predictors. The fitted random forest model was then applied to each  
0.25 x 0.25° grid cell to provide an estimate of how many observations are actually supporting a LFMC estimate in a grid cell.  
665 We found that the global LFMC estimates are not supported by any site-level LFMC observations with similar conditions in  
most of the tropical forests and in the boreal forests in Eurasia. However, most temperate and semi-arid regions are supported  
by Globe-LFMC observations. In addition, large areas of high northern latitudes (including most of the polar Tundra regions)  
are supported by Globe-LFMC observations because they have similar conditions of low tree cover, LAI and Ku-VOD like  
some sites in mountainous areas in the western US or the existing sites in Alaska. However, as many sites in mountainous  
670 regions have low correlations between VOD and LFMC (Figure 1), the plausibility of LFMC estimates in northern latitudes is  
questionable. However, the global estimates of LFMC have strong observational support by site-level observations in many  
fire-prone regions such as in western Canada, the western US and Mexico, in southern South America, in the Mediterranean,  
central Asia, parts of China, southern and eastern Africa, and southern and eastern Australia. This provides confidence that the  
LFMC estimates can be used as a predictor for fire dynamics in most fire-prone ecosystems.

### 675 **3.5 Applicability of the LFMC estimates and future directions**

We envision several applications of the global Ku-VOD-based estimates of leaf moisture content (expressed as LFMC) but  
also want to raise attention to the limitations of the dataset in other applications. The VOD-based LFMC estimates are suitable  
to investigate large-scale patterns of vegetation responses to drought, mainly in regions where the estimates are supported by  
several Globe-LFMC observations (Figure A 3b). Several remotely sensed vegetation properties such as spectral vegetation  
680 indices, LAI, sun-induced fluorescence or derived variables of plant productivity are frequently used to monitor drought effects  
on vegetation (e.g. Jiao et al., 2021; Crocetti et al., 2020) or to investigate the processes how water availability affects  
vegetation growth. The VOD-based LFMC estimates can complement such analyses by providing information on large-scale  
changes in leaf moisture content. The LFMC estimates can be applied to investigate the effects of drought or long-term climate  
trends on fuel moisture. However, detailed analysis of the temporal dynamics of the VOD-based LFMC data under limited  
685 water availability or drought is beyond the scope of this analysis and needs to be further investigated.

Generally, the main application of LFMC data is the assessment of fire risks (Chuvieco et al., 2010). The high temporal  
frequency and long period of the VOD-based LFMC dataset allow investigating short-term to long-term changes in fuel  
moisture and hence fire risk at a large scale. For example, Previously, VOD datasets have been used as proxies for fuel  
conditions in global empirical models of burned area (Forkel et al., 2017; Kuhn-Régner et al., 2021) and helped to explain  
690 how trends in climate conditions and vegetation affect large-scale trends in the burned area (Forkel et al., 2019). However, the  
interpretation of VOD effects on the prediction of burned area was hampered in those studies by the unclear role of VOD as a  
proxy for fuel loads (biomass) or live fuel moisture content. The VOD-based LFMC estimates overcome this problem by

translating VOD into LFMC. Besides in empirical models for large-scale burned area, the VOD-based LFMC estimates can be used to investigate changes in fire radiative energy or fire emissions, which both depend on fuel moisture content. Further  
695 investigations need to assess the predictive performance of the VOD-based LFMC data within large-scale empirical modelling studies to predict burned area or other properties of fire dynamics.

However, the coarse spatial resolution of the VOD-based LFMC data ( $0.25^\circ \times 0.25^\circ$ ) prevents applications in regional and local fire risk assessment. At a small scale, differences in vegetation structure and topography are the main controls on fire ignitions and propagation (Chuvieco et al., 2010), which are not accounted for in the VOD-based LFMC dataset. Hence, an  
700 application of the VOD-based LFMC estimates for regional fire risk assessment should be tested with caution, especially in heterogeneous landscapes or mountainous regions. However, our cross-validation results suggest that the LFMC estimates can be applied in large homogenous landscapes with short vegetation types.

Furthermore, the VOD-based LFMC estimates can contribute to the evaluation and improvement of fuel moisture simulations in global fire-enabled vegetation models such as from the fire-model inter-comparison project (FireMIP) (Rabin et al., 2017).  
705 FireMIP models simulate live and dead fuel moisture either based on fire danger indices (e.g. the Nesterov index, Thonicke et al. (2010)) or based on empirical functions with soil moisture or relative humidity (Rabin et al., 2017). FireMIP models have been intensively evaluated for simulations of burned area, fire emissions, LAI, plant productivity and biomass (Hantson et al., 2020) and the simulated fuel moisture has a strong effect on simulations of burned area and fire emissions (Li et al., 2019). However, fuel moisture has not yet been evaluated in those models. Hence, we propose that the VOD-based LFMC estimates  
710 or other global products (Quan et al., 2021) can be used in benchmarking activities of global fire-enabled vegetation models. Finally, we propose several further developments of the VOD-based LFMC datasets. First, the relation between VOD and LFMC requires a more detailed investigation in needle-leaved forests to explain the large variability in VOD-LFMC correlations and model performances. Second, the temporal coverage of the LFMC estimates can be extended back to 1987 by using more long-term LAI datasets. This would allow the use of older LFMC field data in model calibration and an extended  
715 analysis of long-term LFMC changes. Third, an estimation of LFMC for different vegetation types within a VOD-grid cell can be explored as the site-level model calibration was performed for different growth forms. As the Globe-LFMC database provides LFMC samples for different plant species, model parameters could be estimated per growth form. Fourth, LAI data at their original spatial resolution within the VOD-based models could be used to provide LFMC estimates at higher spatial resolution.

## 720 4 Conclusions

This study assessed the relation between short-wavelength VOD from passive microwave satellite observations and leaf moisture content (expressed as LFMC) globally and successfully developed and applied a method to estimate LFMC from VOD globally at  $0.25^\circ \times 0.25^\circ$  spatial resolution, at daily time steps and for the period from February 2000 to July 2017. We achieved our three objectives as follows:

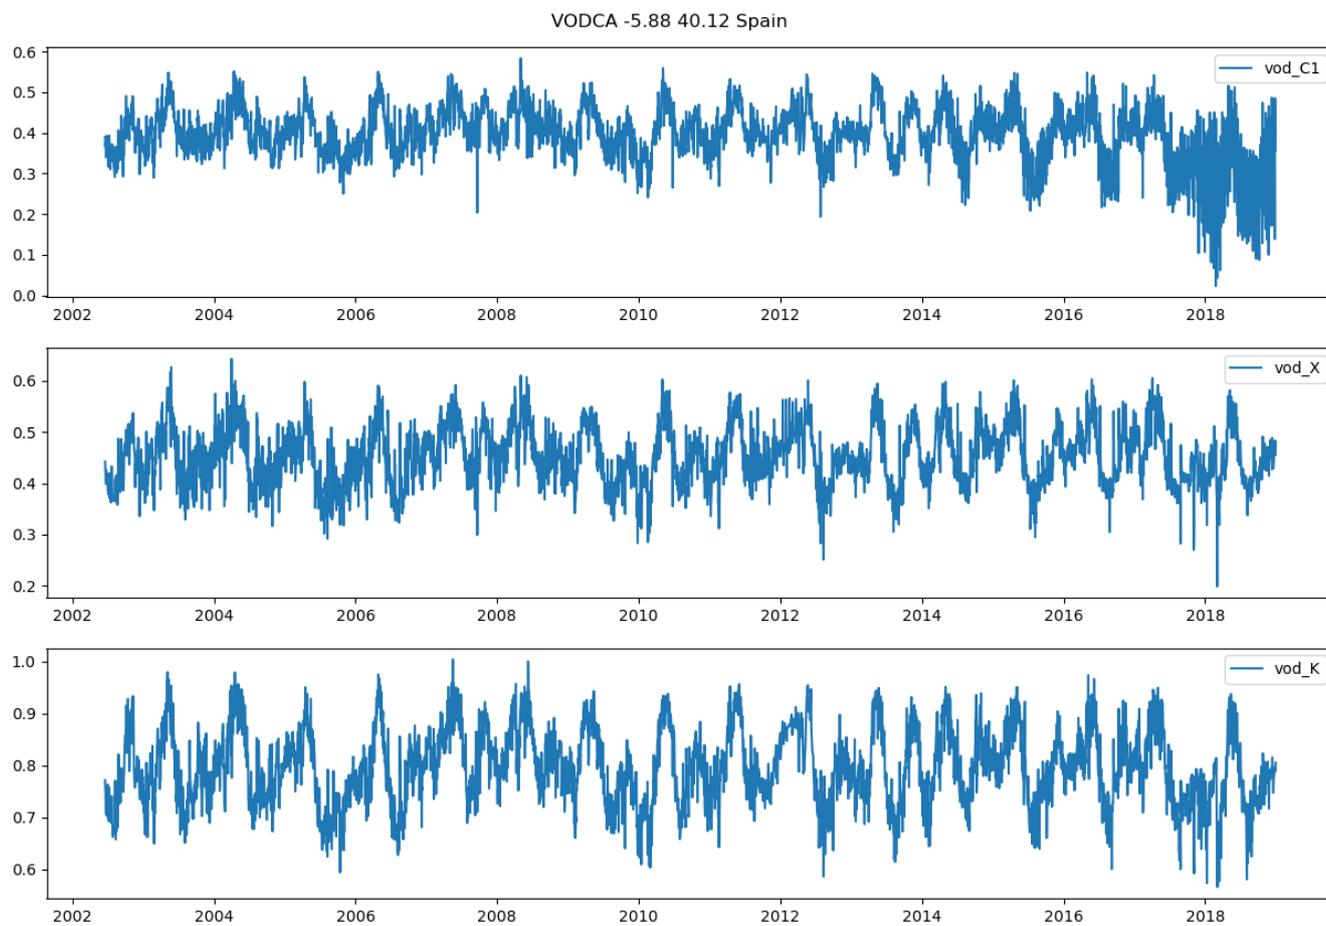

- 725 1) We investigated the relationship between VOD and LFMC. VOD and LFMC are in the majority of sites or grid cells  
positively correlated, whereby Ku-band VOD has slightly higher correlations than X- or C-VOD. The correlation between  
VOD and LFMC is on average higher for short vegetation types such as forbs, grasses and shrubs than for trees but also  
several forest sites show high correlations. Broad-leaved forests show higher correlations than needle-leaved forest. These  
results confirm earlier studies about the VOD-LFMC relation and demonstrate additionally that coarse-scale VOD is  
730 sensitive to LFMC at forest sites if the land cover distribution locally is similar to the coarse grid cell.
- 2) We tested different model structures to estimate LFMC from VOD. A logistic regression model that uses daily Ku-VOD  
and monthly LAI as predictors for LFMC outperformed alternative model structures in site-level calibration and spatial  
cross-validation. The comparison of model structures demonstrates that LAI is needed in addition to VOD as a proxy for  
either canopy biomass or vegetation water content to reach acceptable model performances.
- 735 3) We applied spatial cross validation to assess the transferability of model structures in space and applied the best-  
performing model to estimate LFMC globally. The obtained model performances are comparable with results from  
previous studies that estimated LFMC based on visible/near-infrared satellite observations. Medium to high performance  
of the VOD-based LFMC estimates can be expected for herbaceous vegetation, shrublands and for most broad-leaved  
trees in many fire-prone regions such as in western Canada, the western US and Mexico, in southern South America, in  
740 the Mediterranean, central Asia, parts of China, southern and eastern Africa, and southern and eastern Australia. Large  
variability in performance and high uncertainties can be expected in needle-leaved forests, whereby especially estimates  
in boreal forest have low observational support.

We propose to use VOD-based estimates of LFMC to investigate short-term drought effects and long-term climate effects on  
vegetation leaf moisture at large scale, for large-scale assessments and empirical modelling of fire dynamics, or to benchmark  
745 global fire-enabled vegetation models.

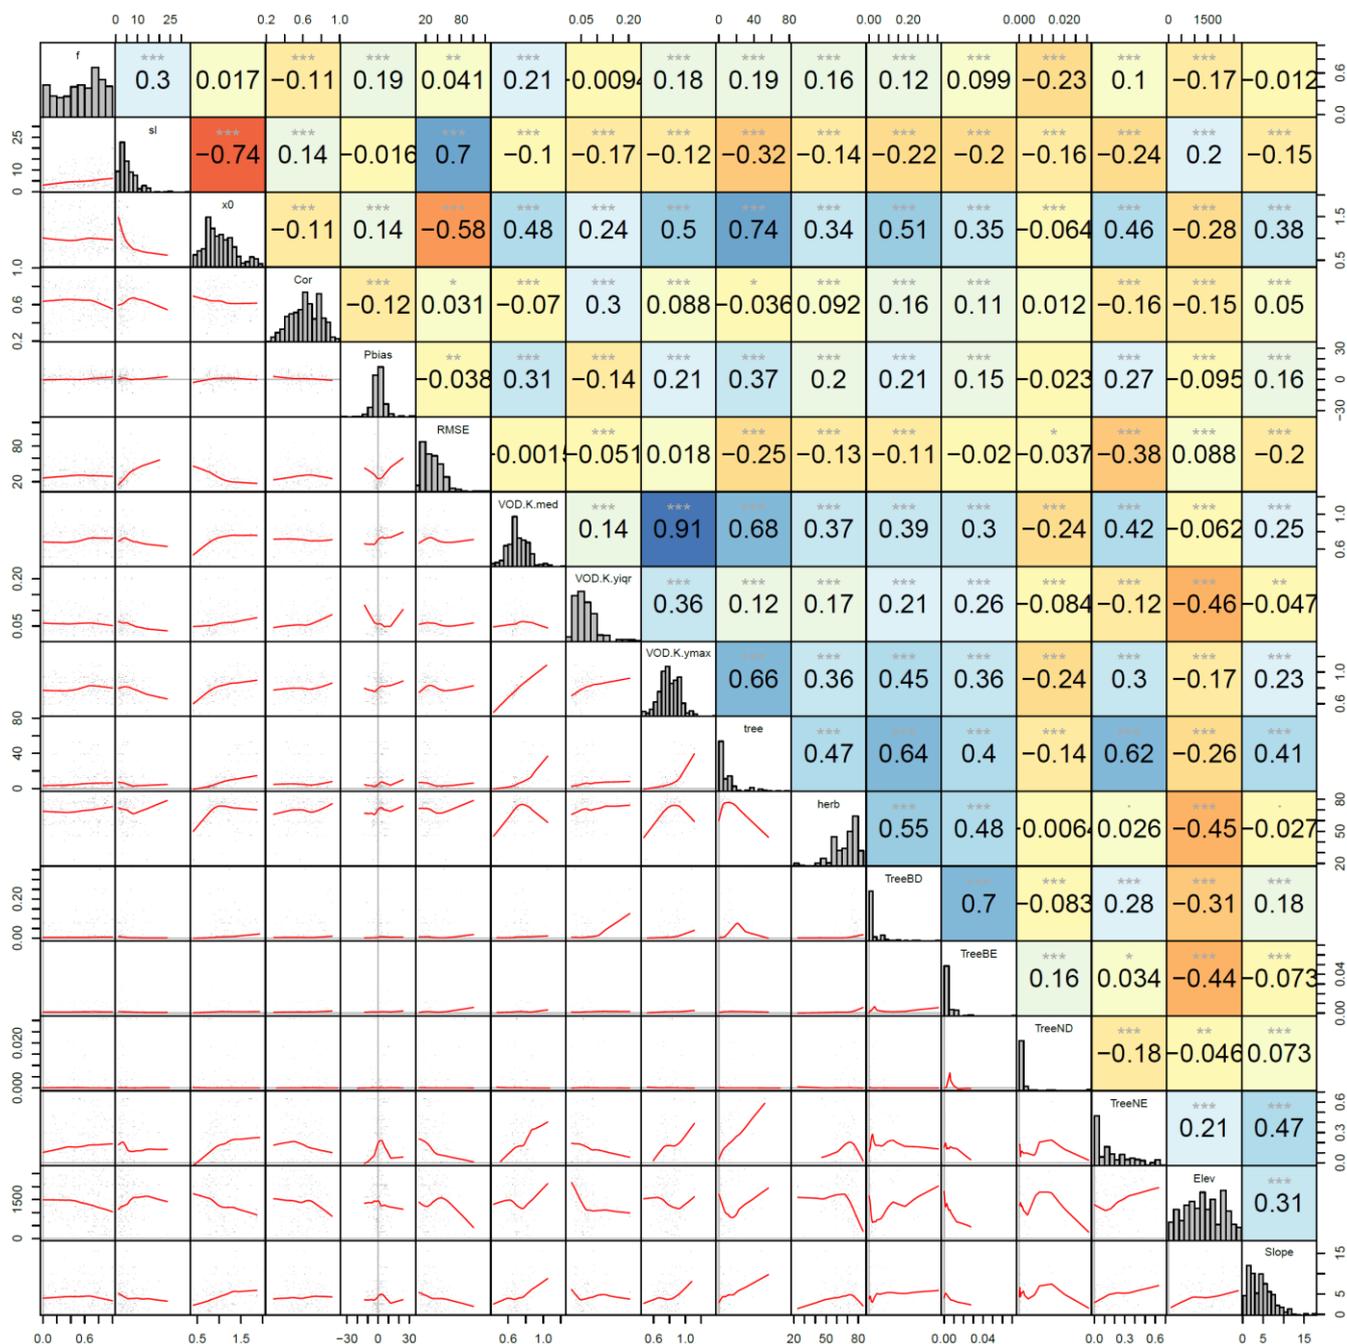

Data availability. The global LFMC results of model B will be made available at zenodo.

## Appendix

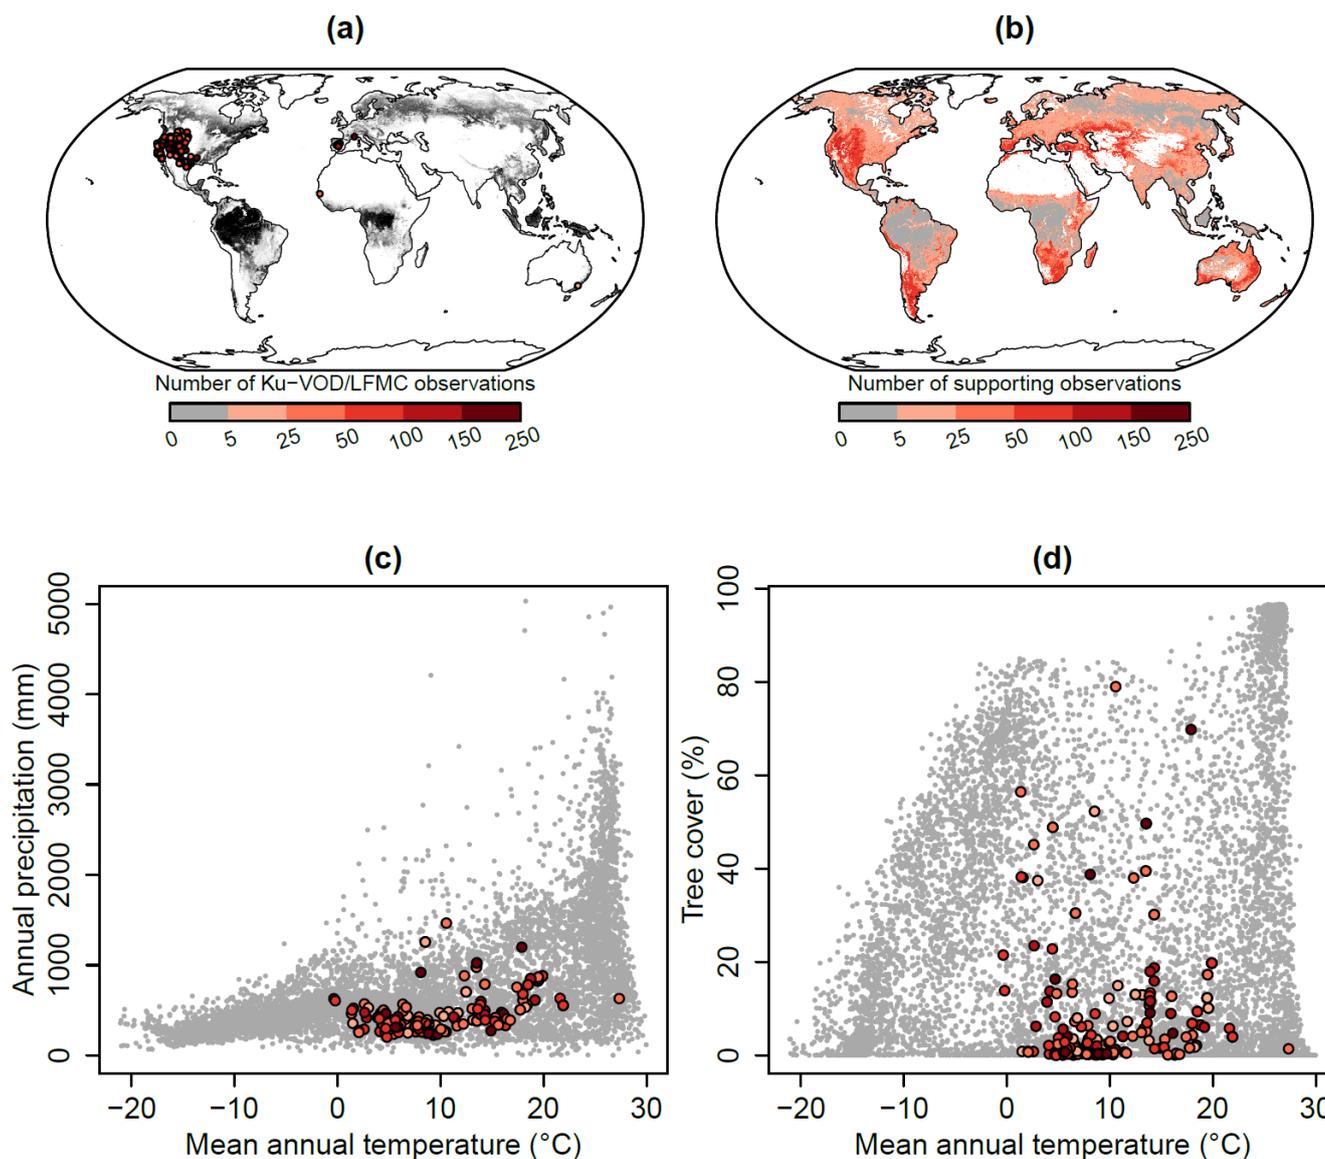

**Figure A 1:** Example time series of C-, X- and Ku-VOD over a grid cell in Spain (5.88°W, 40.12°N), where the C-VOD time series shows a high level of noise likely caused by RFI in the later years.

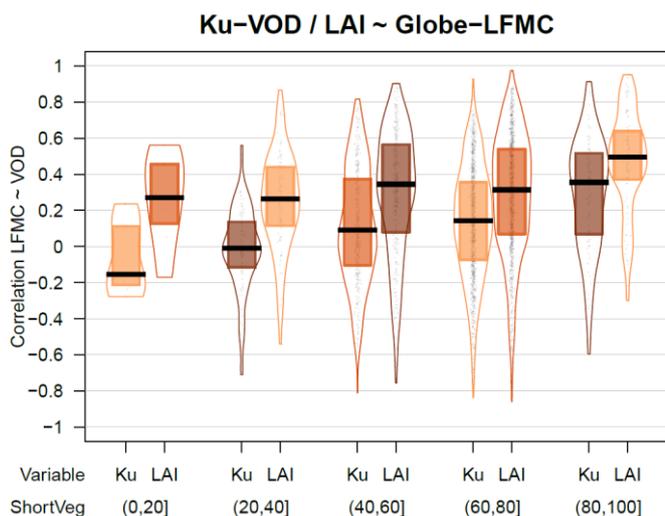

755 **Figure A 2: Across-site correlations between the site-optimized parameters  $f$ ,  $sl$ , and  $x0$  of model B with model performance measures and land cover properties of the corresponding  $0.25^\circ$  grid cells. Numbers and blue to red colours in the upper triangle display Spearman correlation coefficients. Red lines in the lower triangle are loess-fits between x- and y-values. Grey bars along the diagonal are histograms of each variable. Correlation (Cor), percent bias (Pbias) and RMSE of predicted and observed LFMFC; temporal**  
 760 **median of Ku-VOD (VOD.K.med); multi-year mean of the annual inter-quartile range of Ku-VOD (VOD.K.yiqr); multi-year mean of annual maximum Ku-VOD (VOD.K.ymax); tree and short vegetation cover from Song et al. (2018); tree cover of broad-leaved**

deciduous (TreeBD), broad-leaved evergreen (TreeBE), needle-leaved deciduous (TreeND), and needle-leaved evergreen (TreeNE) trees (ESA CCI Land cover V2.0.7 dataset); elevation (Elev) and slope from the CGIAR CSI SRTM digital elevation model.

765 Figure A 3: Distribution of the number of joint observations of Ku-VOD and Globe-LFMC measurements. (a) Distribution of Globe-  
LFMC sites overlaid over the percentage tree cover. (b) Spatial estimate of the number of supporting observations that indicates  
how many pairs of Ku-VOD/Globe-LFMC observation are available with similar mean annual temperature and vegetation  
conditions (i.e. LAI, tree cover, Ku-VOD). To create this map a random forest regression was fitted to the number of observations  
shown in (a) and by using mean annual temperature, tree cover, mean annual maximum Ku-VOD, and mean annual maximum  
770 LAI as predictors. The fitted random forest model was then applied to each  $0.25^\circ$  grid cell to provide an estimate of how many  
observations are actually supporting a LFMC estimate in a grid cell. (c and d) Number of observation within the global feature space  
of mean annual temperature and annual total precipitation (c) and mean annual temperature and tree cover (d).

775 **Figure A 4: Statistical distributions of the temporal correlation between Ku-VOD or LAI and measurements from the Globe-LFMC database stratified by the percentage cover of short vegetation.**
