Abstract

The role of topography [in determining](#) water transit times and pathways through catchments is unclear, especially in mountainous environments — yet these environments play central roles in global water, sediment, and biogeochemical fluxes. [Since](#) the vast majority of intensively monitored catchments [are in](#) northern latitudes, the interplay between water transit, topography and other landscape characteristics is particularly underexplored in tropical environments. [To address this gap, here](#) we present the results of a multi-year hydrologic sampling campaign ([twice monthly](#) and storm sampling) to quantify water transit in seven small catchments (< [1.3 km² area](#)), across the transition from the Andes mountains to [the](#) Amazon floodplain in southern Peru. We use the stable isotope composition of water ($\delta^{18}\text{O}$) to calculate the fraction of streamflow comprised of recent precipitation (“young water fraction”) for each of the seven small catchments. [Flow-weighted](#) young water fractions (F_{yw}) are [5-26 %](#) in the [high-elevation mountains, 22-52 %](#) [for](#) mid-elevation [mountains](#) and [7 %](#) in the foreland floodplain. Across these catchments, topography does not exert a clear control on water transit; instead stream F_{yw} is [apparently](#) controlled by a combination of hydroclimate ([precipitation regime](#)) and bedrock permeability. Mid-elevation sites are posited to have the highest F_{yw} due to [more frequent and intense rainfall, along with](#) less permeable bedrock [and](#) poorly developed soils. [Lowland soils have low \$F_{yw}\$ due to very low flow path gradients despite low permeability.](#) The data presented here [highlight the complexity of factors that determine water transit in tropical mountainous catchments, particularly highlighting the role of intense orographic precipitation at mountain fronts in driving rapid conveyance of water through catchments. These results have implications for the response of Earth’s mountain “water towers” to climate change and for water-rock reactions that control global biogeochemical cycles.](#)

1. Introduction

The time that water takes to transit through a watershed provides a measure of the age of water as it leaves the system (*sensu* Benettin et al. 2022) and has important physical, chemical, and biological implications. Water transit times through catchments can influence how freshwater resources respond to a changing climate. Catchment transit times can also inform understanding of how water partitions into different fluxes (e.g., discharge vs. evapotranspiration), with implications for determining the age (or seasonal origin) of water used by vegetation (Allen et al., 2019; Kirchner and Allen, 2020; Rempe and Dietrich, 2018). And, transit times are thought to influence water quality and regulate rates of chemical weathering, and thus the alkalinity fluxes that control the geologic carbon cycle, because the flow of water can modulate the saturation state of fluids with respect to mineral weathering reactions (Ameli et al., 2017; Berner, 1978; Maher, 2010, 2011). Mountain watersheds often serve as sources of water, solute and sediment fluxes to lowland ecosystems (Barnett et al., 2005; Gaillardet et al., 1999; Immerzeel et al., 2020; Viviroli et al., 2007), and mountain environments are especially sensitive to changing climate – emphasizing the particular importance of understanding water transit times in these settings. Tropical montane watersheds, in particular, play outsized roles in global water and biogeochemical cycles (Fekete et al., 2002; Meybeck, 1987), yet are underrepresented in studies of terrestrial water transit.

Previous research has suggested that topography, subsurface structure, and hydroclimate all play roles in determining the ages of water moving through mountainous watersheds. Some studies indicate that steeper slopes and shorter flowpaths generally lead to faster water transit (McGlynn et al., 2003; McGuire et al., 2005; Tetzlaff et al., 2009), while others have found that steeper watersheds have slower water transit than more gently sloping catchments (Jasechko, 2016; Lutz et al., 2018). Other work has shown how the permeability of soil and bedrock, and the associated depth of active flow paths, can influence water transit times (Hale et al., 2016; Hale and McDonnell, 2016; Xiao et al., 2021; Asano and Uchida, 2012; Muñoz-Villiers et al., 2016a). Finally, the timing and amount of precipitation can influence water transit through mountain landscapes (Gallart et al., 2020a; Stockinger et al., 2019; von Freyberg et al., 2018a; Wilusz et al., 2017). Disentangling the effects of topography, subsurface structure, and hydroclimate remains challenging, and few studies have tested ideas about the controls on water transit across the dramatic topographic gradients of major mountain ranges, i.e., from steep high relief mountain catchments to the surrounding floodplains.

The stable isotopic composition of stream and river water is a conservative tracer that provides powerful information about catchment transit times. For decades, many studies used time series of stable isotopes of

water in streams and precipitation to calculate stream mean transit times or stream water “ages” (Małozewski and Zuber, 1982; McGuire and McDonnell, 2006), but these calculations were prone to errors arising from aggregation biases and hydrologic non-stationarity (Kirchner, 2016a, b). Instead, recent work focuses on using stable isotope time series to calculate the fraction of water within a reservoir comprised of recent precipitation (e.g., precipitation that fell within the 2-3 preceding months). The fraction of recent precipitation is referred to as the young water fraction (F_{yw}) and is calculated from the ratio between the amplitude of the seasonal cycle of oxygen isotopes in water from streamflow and precipitation (Kirchner, 2016a, b). The young water fraction offers information about water transit over timescales relevant to many hydrologic problems, making it an appropriate tool for untangling the impacts of topography, subsurface structure, and hydroclimate on water transit in tropical watersheds.

The primary objective of this work was to test the factors controlling young water fractions in streamflow across a dramatic mountain-to-floodplain gradient in the tropics. We collected a five-year time series (2016–2020) of approximately fortnightly stream and precipitation water isotope samples from seven small (< 1.3 km²) catchments in southern Peru spanning an elevation range of more than 3200 m and a gradient in catchment slopes from 38 ° to 4 ° in order to ask the following questions: 1) how do precipitation and stream water isotopes vary seasonally, and how do they differ from one another among different catchments in this setting?, and 2) how does the young water fraction vary among catchments and what topographic, subsurface, and hydroclimatic conditions are related to these variations? By beginning to differentiate among the factors that control the transit of water through tropical mountain systems, which are rarely studied, we offer insights into how projected changes in precipitation patterns may interact with the topography and subsurface conditions to shape water flow.

2. Data and methods

2.1 Study area and sampling design

In this study, we carried out detailed monitoring of seven small (areas ranging from 0.097–1.27 km²) catchments spanning the transition from the eastern flank of the Andes Mountains to the Amazon foreland floodplain (Figs. 1, 2; Table 1). The small catchments (SC) in this study are referred to by their sampling point elevation in meters, followed by “-SC”. Two small catchments (3472-SC and 3077-SC) are in the high Andes mountains, underlain by fractured shale bedrock, with mean slopes ~25–35°. Two mid-

Deleted: As water moves from rainfall to river runoff, it is stored in soil and rock for variable amounts of time. The length of time it takes for rainfall to exit a catchment in streams and rivers, known as the water transit time, exerts an important control on biogeochemical and ecohydrologic processes. While water is within a catchment, it reacts with soil and rock, acquiring solutes (Gibbs, 1970; Drever, 1988), and it interacts with ecosystems, sustaining photosynthesis and transpiration (Allen et al., 2019; Rempe and Dietrich, 2018). Water transit times also influence the availability of freshwater resources and the potential for environmental hazards such as flooding. ¶

¶ Mountainous regions play particularly important roles in the global water cycle, receiving outsized amounts of precipitation and acting as “water towers” that store and gradually release water for drier downstream areas (Barnett et al., 2005; Immerzeel et al., 2020; Meybeck et al., 2001; Viviroli et al., 2007). The impacts of climate change on the water cycle (Scanlon et al., 2018; Wilusz et al., 2017), especially diminished snowpack and warming across altitudinal gradients in mountainous regions, emphasize the importance of understanding water transit times in mountainous systems. Beyond serving as water towers, mountains have high erosion rates, exposing fresh mineral surfaces to chemical weathering processes that control the geological carbon cycle (Gaillardet et al., 1999; Hilton and West, 2020). Mineral weathering reactions in mountainous environments are modulated by a balance between wat... [11]

Moved down [2]: The seven small streams were sampled approximately bi-weekly beginning in April 2016. In addition to stream sampling, precipitation was collected at sites 3077-SC, 1540-SC, 609-SC, 276-SC and 214-SC. For sites 3472-SC and 2432-SC we calculated approximate precipitation oxygen isotope values by linearly interpolating between nearby precipitation samples collected at higher and lower elevations, supported by the observation that in this region precipitation isotopes have a linear relationship with elevation (Ponton et al., 2014). Precipitation was collected in a bucket left out between each sampling trip, with a layer of oil to prevent evaporative loss. Point discharge was manually measured each time a sample was taken. For sites 3077-SC and 609-SC, continuous discharge was measured in 2019 and 2020 with WL16 Global Water Level Loggers. Rainfall amount data are from tipping bucket and Vaisala rain gauges maintained by the Andes Biodiversity and Ecosystem Research Group, a manual rain gauge maintained by the Los Amigos Biological Station, and rain gauges operated by the Servicio Nacional de Meteorología e Hidrología del Perú (SENAMHI). ¶

Figure 2. Satellite imagery with catchment boundaries in white (first column; imagery: Google Earth, Image © 2023, CNES/Airbus and Maxar Technologies), elevation maps with catchment boundaries in red and smoothed stream network in blue (second column), and maps showing hillslope angles with catchment boundaries in black (third column) for each of the seven small catchments in this study. Elevation and slope angles derived from smoothed 8m DEM generated from stereo pairs of WorldView satellite images using the SETSM algorithm (see text),

2.2 Topographic analyses

We determined catchment topographic parameters based on digital elevation models (DEMs) generated from stereo-pairs of WorldView satellite imagery using the SETSM algorithm (Noh and Howat, 2015). We produced smoothed DEMs covering the studied catchment areas at 8m horizontal spatial resolution using a combination of cross-track and in-track image pairs (several different image pairs were needed to cover all the study catchments). Topographic calculations were completed in GrassGIS (v8.2) using available algorithms (GRASS Development Team, 2022). Catchment areas were determined using multiple flow direction (MFD) routing for all except the Tambopata site where only single (D8) flow routing yielded a physically reasonable hydrologic representation. Stream networks (as shown in middle panel of Figure 2) were defined based on a threshold flow accumulation area of 12,500 m², which captured observed streams in the smallest catchment (2432-SC). A single threshold area is probably not appropriate across such diverse terrain but was adopted in our calculations for consistency. For each catchment, three metrics of flow path length were calculated: the distance to the catchment outlet along flowpaths (using `r.stream.distance`; Jasiewicz and Metz, 2011), the distance along flowpaths to the stream network defined by the 12,500 m² accumulation threshold (also using `r.stream.distance`), and the length of all flow path vectors defined by one raster cell spacing between each flow line, calculated using `r.flow`. Because of the very low slope angles on the terrace surfaces, flowline computation was not possible for the two lowland catchments, 276-SC and 214-SC (SETSM-derived DEMs generally capture topographic metrics well, but noise may be relatively more pronounced in flatter terrain; e.g., see Atwood and West, 2022). Flowpath gradients were calculated using `r.stream.slope`, and catchment-wide slope angles with `r.slope.aspect`. Importantly, key topographic metrics such as slope angles and hillslope lengths are dependent on elevation model resolution as well as threshold values used to define stream channels (e.g., see comparison in Clark et al. 2016 for the region in this study). Consequently, care should be taken in making any comparison with analogous values from other studies.

2.3 Stable isotope data analysis

Samples were analyzed for stable isotopes of water ($\delta^{18}\text{O}$ and δD), with results reported here using permille notation relative to the Vienna Standard Mean Ocean Water standard. The stream oxygen or hydrogen isotope composition is referred to as $\delta^{18}\text{O}_{\text{stream}}$ and $\delta\text{D}_{\text{stream}}$ and precipitation oxygen and hydrogen isotope composition as $\delta^{18}\text{O}_{\text{precip}}$ and $\delta\text{D}_{\text{precip}}$. The analyses were carried out via two Los Gatos Research Liquid Water Isotope Analyzers (LGR) (Caltech and Lawrence Berkeley National Lab) and a Picarro L2130i Cavity Ring Down Spectrometer (Chapman University). The internal error of isotope measurements on the Picarro was 0.1 ‰ or better for $\delta^{18}\text{O}$ and 2 ‰ or better for δD . On the LGR at Lawrence Berkeley National Lab the internal error was 0.1 ‰ or better for $\delta^{18}\text{O}$ and 1 ‰ or better for δD . On the LGR at Caltech the internal error was 0.3 ‰ or better for $\delta^{18}\text{O}$ and 1 ‰ or better for δD . Long-term accuracy on certified isotope standards was within one standard deviation of the known isotopic values.

Young water fractions were calculated for each small catchment following Kirchner (2016a, 2016b).

Stream and precipitation oxygen isotope data were fit with Equation (1):

$$C(t) = a_s \times \cos(2\pi ft) + b_s \times \sin(2\pi ft) + k \quad (1)$$

where C is the concentration of a tracer in stream or precipitation, t is time, f is the frequency of the interval, a and b are the cosine and sine coefficients and k is the vertical shift. The fit to stream and precipitation isotope data was performed with and without stream discharge and rainfall amount weighting.

The young water fraction was then calculated using Equations (2-4):

$$A_{\text{stream}} = \sqrt{a_s^2 + b_s^2} \quad (2)$$

$$A_{\text{precip}} = \sqrt{a_p^2 + b_p^2} \quad (3)$$

$$F_{\text{yw}} (\%) = A_{\text{stream}} / A_{\text{precip}} \quad (4)$$

where A is the amplitude of the seasonal cycle in stream and precipitation oxygen isotopes. In addition to calculating young water fractions using all of the stream water isotope data, we divided isotope data from each site into quartiles according to observed stream runoff and calculated young water fractions (again using Equations 1-4) for each quartile of stream runoff (*sensu* Gallart et al., 2020b).

In order to assess the uncertainty of the young water fraction estimates, we bootstrapped observations of stream and precipitation isotope values for each site. For each bootstrap resampling, we drew one sample at random from the complete dataset for each catchment and then repeated this resampling from the complete dataset until we had drawn the same number of random samples as the original dataset (e.g., for a dataset with 50 observations, we sampled 50 times, each time from the full dataset). We repeated this process

10,000 times for each stream and precipitation isotope dataset at each site. We then calculated F_{yw} from equations 1-4 for each of those 10,000 bootstrapped datasets. This procedure allowed us to constrain the young water fraction as a distribution of values for each site.

For comparative purposes, we also generated a null dataset of young water fractions across all sites. To do this, we first took individual stream and precipitation isotope values from each site and subtracted each observation from the site's mean stream and precipitation isotope value. This approach allowed us to normalize for differences in stream and precipitation isotope values across sites due to orographic effects. We combined the site-specific normalized stream and precipitation isotope datasets to create null datasets containing normalized stream ($n = 394$) and precipitation ($n = 257$) isotope values for all sites. We then bootstrapped with replacement from the complete dataset, as described above, by drawing 394 observations from the stream dataset and 257 observations from the precipitation dataset. We repeated this 10,000 times each for the null stream and precipitation datasets and calculated F_{yw} from equations 1-4 for each of those 10,000 bootstrapped datasets.

3. Results

3.1 Rainfall and stream discharge

The frequency of storms and the amount of precipitation vary across the Andes Mountains to Amazon floodplain transition due to orographic effects. Sites 214-SC and 276-SC have mean annual precipitation of ~ 3200 mm (Rapp and Silman, 2012) and 2479 ± 275 mm (Amazon Conservation Association, unpublished data), respectively. As moisture moves across the foreland floodplain and reaches the Andean foothills and mid-elevation mountains, mean annual precipitation increases: at 872 m (closest to site 609-SC) mean annual precipitation is 5371 ± 507 mm (SENAMHI). The highest precipitation is measured in the mid-elevation mountains: at 1379 m mean annual precipitation is 10425 ± 1214 mm. At 2161 m the mean annual precipitation is 8325 ± 687 mm. Precipitation amounts then decrease towards the high-elevation mountainous sites: At 2912 m mean annual precipitation is 4110 ± 418 . Site 1540-SC has the largest and most frequent rains (Fig. 3a), consistent with it being one of the sites with the greatest mean annual precipitation. Site 609-SC has the second most frequent and most intense rains, while the high-elevation 3077-SC and foreland floodplain 276-SC have less frequent and less intense rains. The changes in hydroclimate from mountain foothills to high-elevation mountains are also reflected in stream discharge patterns (Fig. 3b); specifically, Site 609-SC has a flashier hydrograph and lower baseflow index than site 3077-SC.

A Monte Carlo simulation was performed to assess the uncertainty associated with the young water fraction calculations, using resampling with replacement to generate 10,000 stream and isotope datasets, and then applying equations (1–4) to each dataset. In order to assess the differences in young water fraction distributions between sites, a null dataset was generated using all of the stream and precipitation isotope data across all of the sites, by subtracting each individual isotope value from the site-specific mean isotope value. We then applied the same Monte Carlo resampling routine and equations (1–4) to the null dataset.

3.2 Oxygen and hydrogen isotopes in streamflow and precipitation

The $\delta^{18}\text{O}_{\text{stream}}$ and $\delta^{18}\text{O}_{\text{precip}}$ values follow an orographic trend across the transition from high Andes mountains to foothills (3472-SC to 609-SC), with the highest elevation streams showing the most isotopic depletion (Figs. 4–6). The $\delta^{18}\text{O}_{\text{precip}}$ trends are similar to those reported previously for this region (e.g., Ponton et al., 2014), here adding seasonal information. Our new data reveal that along this same mountain-to-foothill transition, $\delta^{18}\text{O}_{\text{precip}}$ and $\delta\text{D}_{\text{precip}}$ display marked seasonal cycles (amplitude $\delta^{18}\text{O}_{\text{precip}} \sim 4\text{--}5\text{‰}$). The average volume-weighted $\delta^{18}\text{O}_{\text{precip}}$ seasonal cycle amplitude is greatest in the high Andes mountains (4.3 ‰) and mid-elevation mountains (4.5 ‰) and lowest in the mountain foothills (3.7 ‰) and foreland floodplain (3.2 ‰) (Table 2; Figs. 4, 6).

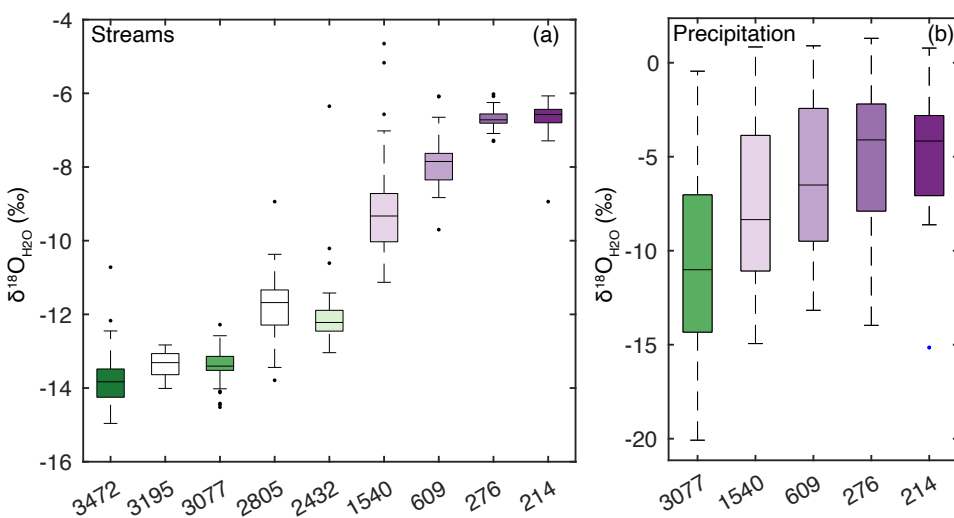

Figure 4. (a) $\delta^{18}\text{O}_{\text{stream}}$ for small catchments and mesoscale catchments 3195–Clark and 2805–Clark (from Clark et al., 2014; boxes left uncolored). (b) $\delta^{18}\text{O}_{\text{precip}}$ for precipitation collected near five of the small catchments. Colors range from dark green to dark purple as a function of elevation. Boxes show the interquartile range, whiskers show the non-outlier maximum and minimum and circles indicate outliers.

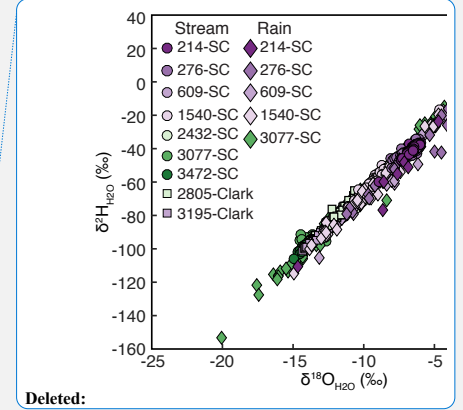

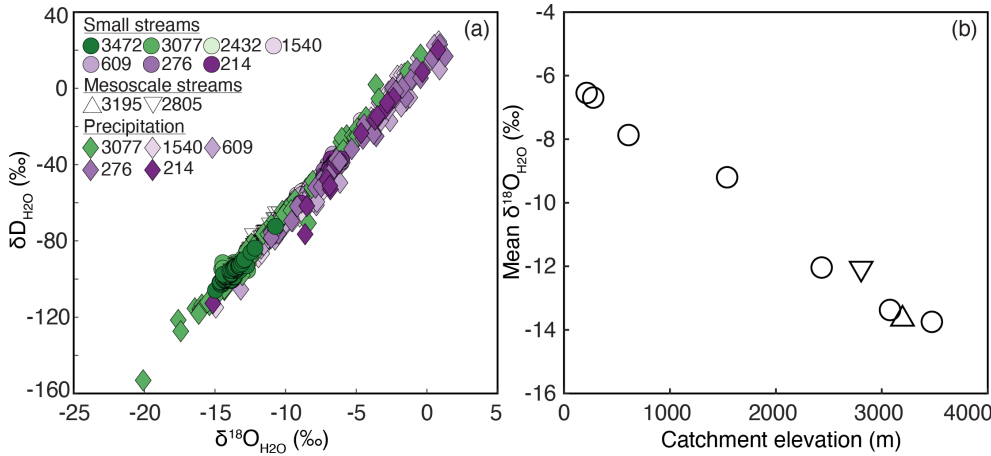

Figure 5. (a) $\delta^{18}\text{O}$ and δD of stream and precipitation. Colors for the small catchment data points range from dark green to dark purple as a function of elevation. (b) mean $\delta^{18}\text{O}_{\text{stream}}$ (not flow-weighted) as a function of sampling point elevation for small catchments and mean catchment elevation for mesoscale catchments. Circles represent small catchment stream isotopes, triangles show mesoscale catchment stream isotopes (from Clark et al., 2014) and diamonds show precipitation isotopes.

Relative to the $\delta^{18}\text{O}_{\text{precip}}$ inputs, $\delta^{18}\text{O}_{\text{stream}}$ values are damped. The degree of isotope dampening and therefore the amplitude of the $\delta^{18}\text{O}_{\text{stream}}$ seasonal cycle varies between the small catchments situated from mountain-to-foothill (Fig. 5). The seasonal amplitude of $\delta^{18}\text{O}_{\text{stream}}$ values is smallest within the Andes mountains (3472-SC, 3077-SC, 2432-SC) and foreland floodplain sites (276-SC and 214-SC) and highest for the mid-elevation mountain (1540-SC) and mountain foothills sites (609-SC) (Fig. 5). Of the two mesoscale catchments, 3195-Clark has a smaller seasonal amplitude in $\delta^{18}\text{O}_{\text{stream}}$ than 2805-Clark. Dual isotope space ($\delta^{18}\text{O}_{\text{H}_2\text{O}}$ and δD) reveals no significant deviation from the local meteoric water line (Fig. 5), indicating no significant evaporative signal in the stream waters for any of the sites in this study.

3.3. Young water fractions

Young water fractions (F_{yw}) vary between the catchments across the mountain-to-floodplain transition. Fig. 8 shows the distribution of unweighted and flow-weighted F_{yw} obtained from the bootstrap resampling routine. Our bootstrap resampling offers one way of addressing the uncertainty associated with young water fraction calculations and demonstrates the reliance of F_{yw} on the inclusion (or exclusion) of a sampling

event. 3472-SC, 3077-SC and 2432-SC have flow-weighted F_{yw} between 5 and 25%. Mesoscale catchment 3195-Clark, draining approximately 50 km² of Andean shales, has a flow-weighted F_{yw} of 10%, on the lower end of the range of flow-weighted F_{yw} seen in the three small Andean catchments. At mid-elevations, 1540-SC, which drains granitic intrusions, has a flow-weighted F_{yw} of 52%. The second mesoscale catchment, 2805-Clark, which drains a 165 km² area including Andean shales and granitic intrusions, has a flow-weighted F_{yw} of 27%. 609-SC, in the foothills of the Andes and underlain by colluvium, has a flow-weighted F_{yw} of 22%. 276-SC, located on a foreland floodplain fluvial terrace, has a flow-weighted F_{yw} of 7%. For comparison, the null dataset, generated from a compilation of isotope data from all sites, yields F_{yw} of 7%. In addition to changes in the mean values across the Andes-Amazon gradient, the distributions from the bootstrap resampling routine change across the region, with wider distributions for the mid-elevation catchments and tighter distributions in the high Andes and Amazon lowland catchments.

Figure 9 shows the relationship between key catchment characteristics and the weighted best estimate of stream young water fraction (Fig. 9). There is no apparent relationship between F_{yw} and slope angle or flow path length, calculated either as median distance to the stream network or the average length of all flow paths (Fig. 9b,c,d). There is, however, some coherent pattern in F_{yw} across these catchments, including a “humped” relationship with elevation (Fig. 9a) and a positive relationship with mean annual precipitation from the nearest rain gauges (Fig. 9e). Additionally, all the sites (except for 276-SC, most likely due to a small number of sampling points) point to an increase in the stream young water fraction with increasing discharge quartiles (Fig. 7). These observations may help to explain the decoupling of F_{yw} and topography at these sites, as explored below.

4. DISCUSSION

4.1 Hydroclimate and permeability control stream young water fractions

The small catchments in the high Andes Mountains (3472-SC, 3077-SC and 2432-SC) all have low F_{yw} , with flow-weighted F_{yw} between 5–26 % and relatively tight distributions resulting from the bootstrap resampling routine. The mid-elevation small catchments show a wider range of bootstrap F_{yw} values, tending toward much higher F_{yw} (Fig. 8). A larger range of F_{yw} values obtained from the bootstrap resampling routine indicates that the F_{yw} is sensitive to the inclusion or exclusion of points that lead to higher F_{yw} (i.e., streams with greater amplitude in $\delta^{18}O$ have more variable isotope values that lead to a wider spread of F_{yw} values). The F_{yw} values inferred from the mesoscale catchments studied by Clark et al. (2014) are consistent with the patterns from the small catchments. The mesoscale catchment in the high Andes, has a similar F_{yw} to that of the high elevation small catchments (flow-weighted $F_{yw} = 10$ %). In contrast, the mesoscale catchment that spans across the high- to mid-elevations (2805-Clark) has a flow-weighted F_{yw} of 27 %, consistent with a mixture of water with low F_{yw} from upstream portions of the study region and water with high F_{yw} from the mid-elevations. Overall, our data point to low and tightly distributed F_{yw} in the high mountains, but higher and more broadly distributed F_{yw} in the mid-elevations.

The F_{yw} values found this study are broadly similar to those from other mountainous regions previously studied but with some potentially interesting differences. Mountainous watersheds in Germany were found to have a flow-weighted median F_{yw} of 13 % and a 10-90th percentile range of 4-17 % (Lutz et al., 2018), while Swiss Alpine streams had flow-weighted median F_{yw} of 20 %, and a 10–90th percentile range of 10–38 % (von Freyburg et al., 2019). In comparison, the high Andean sites in this study have flow-weighted F_{yw} of 5–26 %, at the lower end of these other studies, while the mid-elevation mountainous sites (1540-SC and 2805-Clark) had somewhat higher flow-weighted F_{yw} (52 % and 27 %, respectively) than found previously. Potential reasons for these differences are discussed below. At larger spatial scales, Jasechko et al. (2019) found a global flow-weighted mean F_{yw} of 34 % and 10-90th percentile range of 4–53 %. The Andes-Amazon results all fall within these global ranges, although the lowland sites have amongst the lowest F_{yw} observed anywhere (flow weighted $F_{yw} = 7$ %, unweighted $F_{yw} 3$ %).

We attribute the low F_{yw} observed in the high mountain sites [in our study at least in part](#) to high permeability of the fractured shale bedrock. Fractures create conduits for fluid flow that can be magnified by dissolution of reactive minerals, such as the sulfides that are relatively abundant in the Paleozoic shale underlying our Andes Mountains catchments. Previous studies of stream hydrochemistry in the region have emphasized the importance of sulfide mineral oxidation as a primary weathering process (Burt et al., 2021; Torres et al., 2016), and pyrite oxidation is known to generate porosity and permeability in shale bedrock (Gu et al., 2020). In our conceptual model of water transit, the combination of pore-scale chemical weathering and regional stresses create a fractured subsurface that is conducive to long fluid flow paths, leading to overall low young water fractions in Andean streams.

The mid-elevation catchments differ in two respects that we think can explain the distinct transit times inferred for these streams. The [higher \$F_{yw}\$ values for watersheds between 2805 and 609 m coincide with a shift to a flashier hydroclimate; there are more rainfall events of higher magnitude at the mid-elevations](#) compared to either the high Andes or the Amazon lowlands (Fig. 3a; also see Clark et al., 2016). Correspondingly, the stream hydrograph at 609-SC is flashier than at 3077-SC (Fig. 3b; these are the two catchments with a semi-continuous discharge record). A comparison of stream baseflow indices for sites 3077-SC and 609-SC shows a higher baseflow index for site 3077-SC (BFI = 0.77) and lower baseflow index for site 609-SC (BFI = 0.64). We interpret the first-order shift in F_{yw} values from the high Andes (where baseflow indices are high) to the mid-elevations (where baseflow indices are lower) as being related to this change towards a [wetter, stormier climate](#), suggesting a primary role for hydroclimate forcing in determining transit times in these mountainous catchments. An important role for precipitation and discharge regimes has emerged from other recent transit time studies focused on single catchments with higher temporal resolution data collection (Gallart et al., 2020b; von Freyberg et al., 2018b; Stockinger et al., 2016). [We see some slight variability in the amplitude of \$\delta^{18}O_{stream}\$ as a function of discharge in our results \(Fig. 6, following Gallart et al., 2020b\). These trends are consistent with our interpretation that precipitation regime plays a key role in determining water transit times at our sites, but](#) we lack data across the range of discharge that would be needed for robust quantitative analysis of this effect. Higher frequency sampling across gradients such as those in the Andes, though daunting given the logistical challenges of this environment, would be an interesting target for future work.

Superimposed on the overall differences that characterize the mid-elevation catchments, the F_{yw} in 1540-SC stands out as especially high (Fig. 9; [flow-weighted \$F_{yw}\$ > 50%](#)). Unlike the other catchments in our study that are characterized by sedimentary bedrock, this catchment is underlain by a granitic intrusion (Clark et al., 2014). [The especially high \$F_{yw}\$ in this part of the study region may be related](#) to the low permeability of

Deleted: All else being equal, catchment topography is expected to control water transit times; steeper flow paths should produce shorter transit times (e.g., following Darcy's Law), while greater relief may generate longer flow paths and consequently longer transit times. Yet, despite much effort to demonstrate such effects, past work has shown no systematic relationship between catchment topography and isotope-based young water fractions, including in regional studies and across global compilations (e.g., Tetzlaff et al., 2009b). Similarly, in our results, we find no simple relationship between catchment topography and F_{yw} across the Amazon-Andes gradient studied here (Fig. 98).¶

Deleted: 8

Deleted: mean

Deleted: estimate

Deleted: when amount-weighted

Deleted: We attribute the

1255 this granite bedrock, which prevents water from infiltrating deeply and leads to rapid, near-surface flow paths over the steep topography. In their study in Oregon, USA, Hale et al. (2016) found that catchments with low permeability bedrock showed much shorter water transit times than catchments with high permeability bedrock, as well as a stronger relationship between topography and water transit times. The high F_{yw} values we find at our sites 1540-SC and 2805-Clark are consistent with the argument that low permeability bedrock and steep slopes conspire to quickly deliver water to streams.

1260 Despite the dominance of low-permeability clay-rich soils on the fluvial terraces (Rigsby et al., 2009; Latrubesse et al., 2010), young water fractions for sites 276-SC and 214-SC are extremely low (< 7 %, even when flow-weighted). We suggest that surface flow may be limited at these sites by the very low slope angles on the terrace surfaces that make up most of the catchment areas (mean catchment slopes ~ 3–4 °). Even if low permeability drives flow paths to approximate surface conditions (e.g., Hale et al., 2016), low young water fractions can be explained if the flow path gradients are simply too low to facilitate rapid conveyance of water in this lowland terrain, at least under baseflow conditions (in contrast to the much steeper, low permeability, granitic watershed at 1540-SC where young water fractions are high).

1270 A perhaps surprising outcome of our study is that topography does not exert a stronger control on young water fractions despite the dramatic contrast across our study region, from the steep, high relief terrain of the Andes to the gentler slopes of the foothills and eventually the flat terrace surfaces of the floodplain (Fig. 2). All else being equal, catchment topography is expected to control water transit times; steeper flow paths should produce shorter transit times (e.g., following Darcy's Law), while greater relief may generate longer flow paths and consequently longer transit times. Such effects have been evident in some regional studies (e.g., McGuire et al., 2005). Yet, despite much effort, past work has struggled to find a systematic relationship between catchment topography and isotope-based young water fractions, including in regional studies and across global compilations (e.g., Tetzlaff et al., 2009b). Similarly, in our results, we see aspects where topography is important – especially on the low-slope terraces of the floodplain – but find no simple relationship between catchment topography and F_{yw} across the Amazon-Andes gradient (Fig. 9), with other factors instead apparently more important in this tropical setting.

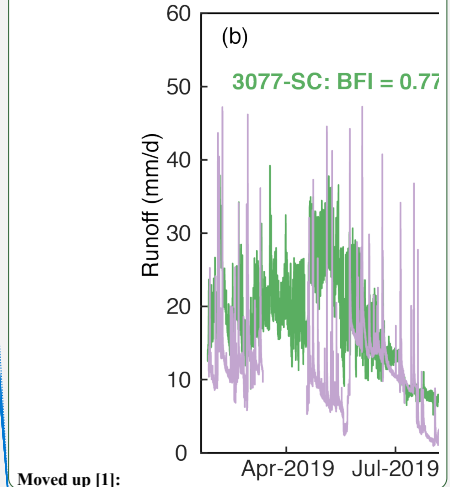

1285 **4.2 Implications for the role of mountains in modulating water, erosional, and biogeochemical fluxes.**

The role of mountains as water towers, and particularly the response of these freshwater resources to climate change, depends in part on water transit times through mountain catchments. In revealing the importance of hydroclimate in determining transit times through mountain catchments, our results suggest

~~Deleted: surficial ...near-surface flow paths over the steep topography.~~

~~Formatted: Subscript~~

~~Deleted: Altogether, then, we interpret the highly variable transit times across the Andean catchments as being related principally to a combination of hydroclimate and bedrock permeability, with these factors outweighing the influence of catchment topography.~~

Moved up [1]:

~~Deleted: The low young water fractions observed in the foreland floodplain also highlight the intersection of permeability and slope. ...espite the dominance of low-permeability clay-rich soils on the fluvial terraces (Rigsby et al., 2009; Latrubesse et al., 2010), young water fractions for sites 276-SC and 214-SC are extremely low (< 7 %, ... [36])~~

~~Deleted: 8..., with other factors instead apparently more important in this tropical setting.~~

Figure 6. (a) Precipitation return interval for rain gauges near sites 3077-SC, 1540-SC, 609-SC and 276-SC. (... [37])

1510 that shifting precipitation regimes may be important in determining not just how much precipitation falls over mountain regions (or indeed the balance of snow and rain), but also the fate of precipitation as it makes its way through mountain catchments. If our spatial comparison of catchments across the Andes-Amazon region translates to temporal trends, then a flashier rainfall regime in the future might be expected to produce a wider range of transit times including higher young water fractions in streams draining mountainous terrain.

1515 Our observation of higher young water fractions at catchments with more precipitation echo other studies showing that young water fraction increases at higher discharge (Gallart et al., 2020b; von Freyberg et al., 2018a). In this sense, our results are consistent with recent studies suggesting that catchments can amplify rainfall variability (Müller Schmied et al., 2020) and that the young water fraction can vary on interannual timescales and is vulnerable to extreme weather events (Stockinger et al., 2019). The implications for
1520 downstream flooding and the buffering of droughts may warrant further consideration.

The hydrology of mountainous catchments may play important geological roles, too. River discharge, and particularly discharge variability, exerts a primary control on erosion (e.g., Tucker and Bras, 2000). Longer transit times may dampen the relationship between precipitation variability and the river incision that drives
1525 mountain erosion; systematic relationships between topography and water transit times could therefore either dampen or amplify erosional efficiency of a given precipitation regime. Catchment hydrology has also been invoked as central to the role of mountain building in the global carbon cycle over geologic timescales (Maher and Chamberlain, 2014). This argument depends on both the exposure of fresh minerals for chemical weathering by rapid erosion, as well as systematic changes in hydrologic flow paths
1530 associated with mountain building. The mountainous sites within this study display a wide range of values in flow-weighted F_{yw} (from ~5–52 %; Fig. 9), with no systematic relationship between topography and F_{yw} . Although a global compilation of stream F_{yw} shows a general negative correlation between topographic relief and F_{yw} (Jasechko et al., 2016), that relationship is notably weak — and the F_{yw} from the small catchments studied here emphasize how other environmental factors (hydroclimate, catchment architecture)
1535 play important roles in determining the F_{yw} of streamflow. Moreover, when comparing across the high Andes and Amazon lowlands, there is remarkably little difference in F_{yw} despite dramatic differences in topography: catchments with average slope angles of ~5° and ~35° have similar flow-weighted F_{yw} : 5 % for site 3077-SC and 7 % for site 276-SC. This result argues against a systematic shift in water transit times associated with mountain building, but rather a variable response modulated by climatic and geologic

1550 factors — although our results do point to a wider range in F_{yw} associated with mountains than lowlands, at least for the tropical setting of the Andes-Amazon system.

1555 While our results, and especially the F_{yw} of lowland catchments, may be specific to the Andes-Amazon setting, we expect the hydroclimatic and geological effects that we document here to be more generally relevant in other mountainous regions, too. Orographic controls on precipitation tend to force the highest precipitation, as well as the most intense rainfall, along mountain fronts and at mid-elevations. In addition to the Andes, similar patterns have been shown in the Himalaya (Bookhagen and Burbank, 2006) and the European Alps (Napoli et al., 2019), and models predict complex spatial patterns of orographic precipitation that depend on several factors including climatic variables (e.g., Barros and Lettenmaier, 1994; Roe and Baker, 2006). The dependence of catchment transit times on hydroclimate, as we find in the Andes and as reported in other recent work (von Freyberg et al., 2018b; Gallart et al., 2020b), suggests that orographic effects on rainfall regime may be a primary determinant of hydrologic processes in major mountain ranges. Similarly, we expect fractured bedrock, and associated high permeability, to be generally characteristic of mountain systems as seen in our work and other studies (e.g., Muñoz-Villers et al., 2016; Moon et al., 2017), though our results also highlight how the geological complexity of mountains – such as the presence of a granitic intrusion in our study area of the Andes – can introduce heterogeneity. Full understanding of the role of mountainous regions in water, sediment, and geochemical cycles will depend on evaluating the role of these multiple factors in determining hydrological behavior.

1570 5. Conclusions

We collected stream and precipitation samples for analysis of O and H stable isotope ratios at seven streams and four rainfall stations spanning the Andes-Amazon gradient. Samples were collected approximately twice monthly over a period of four years. The calculated stream young water fraction varied significantly between sites. For the highest elevation sites (3472-SC, 3077-SC and 2432-SC), flow-weighted young water fractions varied between 5–26%. For the mid-elevation small catchments (1540-SC and 609-SC), flow-weighted young water fractions were higher, at 22–52%. Catchments in the foreland floodplain had low young water fractions of 7% when flow weighted and 2–3% when not weighted.

1580 We suggest that the low young water fractions for the Andean catchments are a result of long flow paths in fractured shale. High young water fractions observed at mid-elevation sites result from a stormier climate, and in the case of 1540-SC, granitic bedrock with poorly developed soils and low permeability, meaning that water moves through the catchment faster. In the lowlands, low permeability clay terraces and low

relief together generate low young water fractions, [highlighting the importance of the very low surface topography gradients in this setting](#). Thus a combination of topography, climate, and bedrock properties conspire to determine water transit [across the Andes-Amazon transition](#). Our results emphasize the complexity of the role of mountainous regions in the hydrological cycle [with more factors than just topography likely to control young water fractions at the global scale](#). Accounting for the multiple factors that control water transit will be important for fully understanding the role of mountain water towers in water, sediment, and carbon fluxes.

Deleted: in this setting

Deleted: and potentially help to explain why it has been difficult to identify a simple topographic control on young water fractions at the global scale.

Acknowledgements

This work was funded by NSF award EAR-1455352 to AJW. We thank the Andes Biodiversity and Ecosystem Research Group (ABERG) for field support and access to rainfall data. ABERG rainfall data were collected with support of NSF DEB LTREB 1754647 to Miles Silman. We thank Alex Sessions and Fenfang Wu at Caltech, Markus Bill at Lawrence Berkeley National Lab and Fernando Silva at Chapman University for support with the stable isotope measurements. We thank Greg Goldsmith for support with stable isotope measurements and for helpful discussions. We thank Julien Emile-Geay for helpful discussions with respect to data analysis.
