18	Abstract
19	The stable oxygen ($\delta^{18}O_{leaf}$) and hydrogen ($\delta^{2}H_{leaf}$) isotopes of leaf water act as a bridge
20	that connects hydroclimate to plant-derived organic matter. However, it remains unclear
21	whether the source water (i.e., twig water, soil water, and precipitation) or
22	meteorological parameters (i.e., temperature, relative humidity, and precipitation) are

the dominant controls on $\delta^{18}O_{leaf}$ and δ^2H_{leaf} . Here, we reported seasonal analysis of $\delta^{18}O_{leaf}$ and δ^2H_{leaf} together with isotopes from potential source waters and meteorological parameters along an elevation transect on the Chinese Loess Plateau. We found that δ^2H_{leaf} values were more closely correlated with source water isotopes than $\delta^{18}O_{leaf}$ values, whereas $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values were similarly correlated with meteorological parameters. Dual-isotope analysis showed that the $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values were closely correlated associated because of their similar altitudinal and seasonal responses, and so generated generating a well-defined isotope line relative to the local meteoric water line (LMWL). We also compared the measured $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values with predicted values by the Craig-Gordon model, and found no significant differences between them. We demonstrate that the first-order control on $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values was the source water, and the second-order control was the enrichment associated with biochemical and environmental factors.

Short Summary

What controls on-leaf water isotopes? We answered the question from two perspectives:

respective and dual isotopes. On the one hand, the $\delta^{18}O$ and $\delta^{2}H$ values of leaf water

responded to isotopes of potential source water (i.e., twig water, soil water, and

precipitation) and meteorological parameters (i.e., temperature, RH, and precipitation)

differently, On the other hand, dual δ^{18} O and δ^{2} H values of leaf water yielded a

significant regression line, associated with altitude and seasonality.

1 Introduction

The stable isotope compositions of oxygen and hydrogen (δ^{18} O and δ^{2} H, respectively) are increasingly being used as powerful tracers to follow the path of water from its input as precipitation, movement through the soil, and ultimately to its release as soil evaporation and leaf transpiration (Penna and Meerveld, 2019). Leaf water transpiration plays a key role in regulating water balance at scales ranging from catchment to global. Terrestrial plants can enrich heavier isotopes (²H and ¹⁸O) in leaf water via evaporative fractionation through the stoma (Helliker and Ehleinger, 2000; Liu et al., 2015; Cernusak et al., 2016), which is highly dependent on atmospheric conditions (e.g., temperature and relative humidity) and biophysiological processes (Farquhar et al., 2007; Kahmen et al., 2011; Cernusak et al., 2016). Subsequently, the isotopic signals from the leaf water are integrated into plant organic matter, such as cellulose (e.g., Barbour, 2007; Lehman et al., 2017) and leaf wax (Liu et al., 2016, 2021), as powerful proxies used for paleoclimate reconstruction (Pagani et al., 2006; Schefuß et al., 2011; Hepp et al., 2020). However, although leaf water isotopes are the fundamental parameters in ecohydrology and organic biosynthesis, we still lack an adequate understanding of what controls on-leaf water isotopes, or the relative importance role of source water and hydroclimates controls in influencing leaf water isotopes?—

65

66

64

 $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values are influenced firstly by a plant's source water (mainly water

taken up by roots from the soil; Cernusak et al., 2016; Barbour et al., 2017; Munksgaard et al., 2017), and secondly by the enrichment associated with transpiration (Munksgaard et al., 2017). Soil water for terrestrial plants generally originates from local precipitation, and precipitation isotopes vary spatially and temporally, being subject to controls including temperature, altitude, latitude, distance from the coast, and amount of precipitation (Bowen, 2010; Bowen and Good, 2015; Cernusak et al., 2016). More specifically, soil water isotopes are determined by a mixture of individual precipitation events with distinct isotopic signals and are also affected by evaporation, both of which lead to the development of isotopic gradients in soil water with depth (Allison et al., 1983; Liu et al., 2015). A number of studies have shown that the δ^{18} O and δ^{2} H values of root/xylem water can be used to characterize the water sources used by plants (Rothfuss and Javaux, 2017; Wu et al., 2018; Wang et al., 2019; Amin et al., 2020; Zhao et al., 2020; Liu et al., 2021a). These studies rested substantially on the assumption that no isotopic fractionation of δ^{18} O and δ^{2} H values occurs during water uptake by plant roots (Dawson and Ehleringer, 1991; Ehleringer and Dawson, 1992; Chen et al., 2020), except in saline or xeric environments (Lin and Sternberg, 1993; Ellsworth and Williams, 2007). Some recent studies have shown, however, that the occurrence of isotopic fractionation during root water uptake was probably more common than previously thought, especially with respect to δ^2 H values (Zhao et al., 2016; Wang et al., 2017; Barbeta et al., 2019; Poca et al., 2019; Liu et al., 2021a).

In addition to the plant source water, leaf water is also isotopically enriched through the

evaporative process of transpiration. The enrichment of ¹⁸O and ²H by leaf water transpiration can be predicted using the Craig-Gordon model (C-G model)₂₇ which This model was originally initially proposed to describe the evaporative enrichment of a freely evaporating water body (Craig and Gordon, 1965) but and has since been modified for plant leaves under steady-state conditions (Dongmann et al., 1974; Farquhar and Cernusak, 2005). However, the C-G model fails to explain the intra-leaf heterogeneity of δ¹⁸O_{leaf} and δ²H_{leaf} (Cernusak et al., 2016; Liu et al., 2021b), which is currently explained described using a two-pool model (Leaney et al., 1985; Song et al., 2015) and/or an advection advection diffusion model, as the *Péclet* effect (Farquhar and Lloyd, 1993; Farquhar and Gan, 2003). Subsequently, more complicated models have been developed to cover non-steady-state conditions (Ogée et al., 2007). These models put the emphasis onemphasize a mechanistic understanding of leaf water isotopic fractionation, but the relevant parameters cannot be strictly constrained or precisely monitored, which hinders the use of these models under natural conditions (Plavcová et al., 2018).

In this study, we This study combined the effects of measured source water isotopes and C-G model-predicted transpiration on $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values. Our objectives were to deeply deepen the understanding of the controls on the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values, and how explore the seasonal variations of these controls vary with the seasons. Based upon these objectives, we repeatedly sampled soils, twigs, and leaves in May, July, and September (representing spring, summer, and autumn, respectively) from the same $\frac{10}{2}$

ten plots that were distributed along an elevation transect. Simultaneously, we obtained the relevant meteorological parameters (e.g., temperature, relative humidity, and precipitation) from sites close to the sampling plots along the transect and used these to predict the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values. The combined analysis of concurrent measurements of $\delta^{18}O$ and $\delta^{2}H$ values in soil water, twig water, and leaf water with the predicted $\delta^{18}O$ and $\delta^{2}H$ values of leaf water from the C-G model associated with the surrounding meteorological parameters will help to identify the factors that control $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values. Furthermore, we performed an isotope-based line analysis of the dual $\delta^{18}O$ and $\delta^{2}H$ values of leaf water, associated with altitude and seasonality. This study will improve our understanding of the environmental signals preserved within the $\delta^{18}O$ and $\delta^{2}H$ values extracted from plant organic biomarkers associated with leaf water.

2. Materials and Methods

124 2.1 Study area

The Qinling Mountains form the dividing line between northern and southern China and mark the boundary between the watersheds of the Yellow and Yangtze rivers. Mt. Taibai (Fig. 1; 33. 96 °N, 107.77 °E) rises to 3767 m above sea level (asl) and is the peak in the Qinling Mountains; it has a warm temperate ecosystem characterized by a rich diversity of flora and fauna. The mean annual temperature at the bottom of Mt. Taibai is 12.9°C, and mean annual precipitation is 609.5 mm (Zhang and Liu, 2010). The climate, soil, and vegetation vary significantly along our slope transect, exhibiting a remarkable vertical geo-ecological zonation (Fig. 1). The area contains a variety of

climate zones: warm temperate (< 1300 m asl), temperate (1300 - 2600 m asl), cool temperate (2600 - 3350 m asl), and alpine (> 3350 m asl). The soil types vary from yellow loess soil at low elevations, spectacular rocky outcrops at middle elevations, and glacial remnants at high elevations. The vVegetation along the transect consists is mainly of coniferous and broadleaf forests and alpine and subalpine vegetation (Fig. 1; Liu, 2021). The dominant species range from Quercus variabilis, Q. aliena, Betula albosinensis, B. utilis, Abies fargessi, and Larix chinensis forests to Rhododendron clementinae and R. concinnum alpine (Supplementary table S1). 2.2 Sampling strategy Plants and soils were sampled in May, July, and September 2020, and samples were collected from 10 plots (3 × 3 m) covering all of the vegetation zones along the northern slope of Mt. Taibai, extending from 608 to 3533 m asl (Fig. 1). Among the plots, six sites (i.e., site 2, 3, 4, 5, 8, 10; Fig. 1) were selected as being the closest to the weather stations along the elevation transect, and they were used order to obtain the insitu meteorological data for analysis. For the plants, one or two dominant deciduous and coniferous trees were chosen in each plot across the vegetation zone (Supplementary Table S1,-). and sSeveral large leaves (3 to 10 large leaves were choosen for sampling: a small number were collected in broadleaf forests and a large number in coniferous forest depending on leaf size) and suberized twigs were collected for each species. Three to ten large leaves were chosen for sampling, and a small number were collected in broadleaf forests and a large number in coniferous forests, depending on leaf size. The leaf samples were conducted in the context of the intact

leaves on account because of the likely isotopic gradients within a leaf (Helliker and Ehleringer, 2000; Liu et al., 2016). Our sampling period was between 12 pm and 15-3 pm because maximum diurnal enrichment of the leaf water isotopic composition occurs during this part of the day (Romero and Feakins, 2011; Liu et al., 2021). The twigs were collected at the same time simultaneously by cutting suberized twigs, and all of the twigs were cut into the samples that were 3-4 cm long. The leaf and twig samples were immediately placed into glass vials with screw caps and sealed with polyethylene parafilm. For the soils, 3-three surface soil samples (less than 10 cm deep) were collected from around the sampled plants using a small metal scoop at each plot. All sampling plots were located on slopes far from rivers and surface water bodies, which ensured that the soil water in each plot was derived exclusively from precipitation. Although the surface soil layers were collected only as the being representative of soil water in this study, these samples could provide a relatively good source of water for the plants, as supported by a prior study conducted along the same elevation transect (Zhang and Liu, 2010). The soil samples were tightly sealed in a polyethylene zipper bag on site. All plant and soil samples were stored in a cool box (~ 4 °C) in the field and immediately transported to the laboratory. The altitude of each plot was determined using a handheld GPS unit with an error of ± 5 m. 2.3 Isotope analysis The water in the plant and soil samples was extracted using an automatic cryogenic vacuum extraction system (LI-2100 Pro, LICA United Technology Limited, Beijing,

China). The auto-extraction process was set for 3 hours, and the extraction rate of water

174

175

- 177 from samples was more than 98%. The isotopic composition of soil water was measured
- using a Picarro L2130-I isotope water analyzer (Sunnyvale, CA, USA) at the State Key
- 179 Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese
- 180 Academy of Sciences. The analytical accuracies were $\pm 0.1\%$ for $\delta^{18}O$ and $\pm 1\%$ for
- δ^2 H. The isotopic measurements of twig and leaf water were conducted using an isotope
- 182 ratio mass spectrometer coupled to a high-temperature conversion elemental analyzer
- 183 (HT2000 EA-IRMS, Delta V Advantage; Thermo Fisher Scientific, Inc. USA) at the
- 184 Huake Precision Stable Isotope Laboratory on the campus of Tsinghua Shenzhen
- 185 International Graduate School. The measurement precisions were \pm 0.2% and \pm 1%
- for δ^{18} O and δ^{2} H, respectively. The isotopic composition of δ^{18} O and δ^{2} H is expressed
- 187 as an isotopic ratio:

188
$$\delta_{sample}(\%_0) = (\frac{R_{sample} - R_{standard}}{R_{standard}}) \times 1000$$
 (1)

- where δ_{sample} represents δ^{18} O or δ^{2} H, and R_{sample} and $R_{standard}$ indicate the ratio
- of $^{18}\text{O}/^{16}\text{O}$ or $^{2}\text{H}/^{1}\text{H}$ of the sample and standard, respectively. The $\delta^{18}\text{O}$ and $\delta^{2}\text{H}$ values
- are reported relative to the Vienna mean standard ocean water (VSMOW). In addition,
- 192 the mean monthly $\delta^{18}O$ and $\delta^{2}H$ values of precipitation were determined using the
- 193 Online Isotope in Precipitation Calculator (Bowen and Revenaugh, 2003).
- 2.4 Modeling isotopes of leaf water
- 195 The C-G equation can be approximated as (Cernusak et al., 2022),

196
$$\delta_e = \delta_s + \varepsilon^+ + \varepsilon_k + (\delta_v - \delta_s - \varepsilon_k) \times \frac{e_a}{e_i}$$
 (2)

- where δ_e is the predicted $\delta^{18}O$ and δ^2H values at the evaporative sites within leaves,
- 198 δ_s is the δ^{18} O and δ^{2} H values of source water (equivalent to twig water in our study),

- 199 ε^+ is the equilibrium fractionation between liquid water and vapour, and ε_k is the
- 200 kinetic fractionation during the diffusion of vapour through the stomata and the
- 201 boundary layer.
- 202 In our analysis, we calculated Δ_v (the enrichment of atmospheric vapour relative to
- 203 source water) as $\Delta_v = (\delta_v \delta_s)/(1 + \delta_s)$, and the values of Δ_v is often close
- 204 to $-\varepsilon^+$ at the isotopic steady state (Barbour, 2007; Cernusak et al., 2016); therefore
- 205 we can calculate δ_v as $\delta_v = -\varepsilon^+ + (1 \varepsilon^+)\delta_s$. In addition, $\frac{e_a}{e_i}$ is the ratio of the
- 206 water vapour pressure fraction in the air relative to that in the intercellular spaces and
- 207 is equal to the relative humidity (RH) in the air at the steady state (Cernusak et al.,
- 208 2022). Thus, Equation (2) can be derived as,

209
$$\delta_e = (1 - h)(\varepsilon^+ + \varepsilon_k) + (1 - \varepsilon^+ h)\delta_s$$
 (3)

- 210 In Equation (3), where δ_s represents the isotopic values of twig water, and h is the
- 211 mean annual or monthly RH (MARH or MMRH) in this study. The equilibrium
- fractionation (ε^+) varies as a function of temperature (Bottinga and Craig, 1969), and
- can be equated to $\delta^{18}O$ and $\delta^{2}H$, as follows (Majoube, 1971):

214
$$\varepsilon_o^+(\%_0) = \left[\exp\left(\frac{1.137}{(273+T)^2} \times 10^3 - \frac{0.4156}{273+T} - 2.0667 \times 10^{-3} \right) - 1 \right] \times 1000$$
 (4)

215
$$\varepsilon_H^+(\%_0) = \left[\exp\left(\frac{24.844}{(273+T)^2} \times 10^3 - \frac{76.248}{273+T} + 52.612 \times 10^{-3}\right) - 1 \right] \times 1000$$
 (5)

- The kinetic fractionation (ε_k) can be calculated for $\delta^{18}O$ and δ^2H as (Farquhar et al.,
- 217 2007<u>; Cernusak et al., 2016</u>):

218
$$\varepsilon_k^0(\%_0) = \frac{28r_s + 19r_b}{r_s + r_b}$$
 (6)

219
$$\varepsilon_k^H(\%) = \frac{25r_s + 17r_b}{r_s + r_b}$$
 (7)

220 where r_s and r_b are the resistances of the stomatal and boundary layers, respectively,

and the inverse of the conductance of the stomatal and boundary layers, respectively. Previous studies found stomatal and boundary layer conductance values of 0.49 and 2.85 mol m⁻² s⁻¹, respectively (Cernusak et al., 2016; Munksgaard et al., 2017), resulting in ε_k^0 and ε_k^H values of 26.7 and 23.8, respectively. 2.5 Statistical analysis Statistical analysis (i.e., the mean, maximum and minimum values, as well as the standard deviation) of the isotopes extracted from the precipitation, soil, twig, and leaf samples was performed to define the range and distribution of the $\delta^{18}O$ and $\delta^{2}H$ values across the seasons. The Pearson correlation method was used to assess the various correlations between the $\delta^{18}O$ and $\delta^{2}H$ values among the different water types (i.e., precipitation, soil water, twig water, and leaf water). Hierarchical cluster analysis was used to show the relationships among $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values and potential source water isotopes (δ^{18} O and δ^{2} H values in precipitation, soil water, twig water, and leaf water), and meteorological parameters such as mean annual and monthly precipitation (MAP and MMP), mean annual and monthly temperature (MAT and MMT), and mean annual and monthly relative humidity (MARH and MMRH). A one-way analysis of variance (ANOVA) combined with a post hoc Tukey's least significant difference (LSD) test was performed to identify the significant differences in the isotopic compositions of precipitation, soil, twig, and leaf waters across the months. Comparisons of the relationships of δ¹⁸O and δ²H in the soil and leaf water were performed by using analysis of covariance using covariance analysis (ANCOVA) to compare slopes across

months. The structural equation model (SEM) was used to explain the respective effects

241

of source waters (i.e., twig water, soil water, and precipitation) and meteorological parameters (i.e., temperature, precipitation, and RH) on $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values. The validated SEMs generated a good model fit, as indicated by a non-significant χ^{2} test (p > 0.05), a high comparative fit index (CFI > 0.95), and a low root mean square error of approximation (RMSEA < 0.05). A special SEM was constructed based on the Mantel R values in AMOS (version 24.0.0). Moreover, we used the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Draxler and Rolph, 2003) to calculate air mass back-trajectory for a central site (34.13°N, 107.83°E, 2270 m asl) in the study area. These trajectories were initiated four times daily (at 00:00, 06:00, 12:00, and 18:00 UTC)₃ and their air parcel was released at 2300 m asl for May, July, and September 2020 and moved backwards by winds for 120 h (5 days).

3. Results

256 3.1 Differing response of δ^{18} O and δ^{2} H values of leaf water

The measured $\delta^{18}O$ and $\delta^{2}H$ values of leaf water responded differently to source water isotopes (Fig. 2a) and meteorological parameters (Fig. 2b) across the seasons. Cluster analysis showed that the leaf water $\delta^{18}O$ and $\delta^{2}H$ values ($\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$) were clustered with the twig water $\delta^{18}O$ and $\delta^{2}H$ values ($\delta^{18}O_{twig}$ and $\delta^{2}H_{twig}$; Fig. 2a), and also with MARH, MAT, and MMT (Fig. 2b). The $\delta^{2}H_{leaf}$ values were more closely correlated with isotopes of the potential source waters (e.g., twig water, soil water, and precipitation) than the $\delta^{18}O_{leaf}$ values in different months (Fig. 2a), whereas. In contrast, leaf water $\delta^{18}O$ and $\delta^{2}H$ values were comparatively correlated with meteorological

parameters (Fig. 2b) across months. These correlations were more significant in summer (July) and autumn (September) than those in spring (May).—

3.2 Comparisons of measured and predicted $\delta^{18}O$ and $\delta^{2}H$ values of leaf water The $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values predicted by the C-G model were compared with the measured $\delta^{18}O$ and $\delta^{2}H$ values across all three months (Fig. 3). The C-G models explained 49% and 70% of the observed variations in the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values, respectively (Fig. 3a, c). The slopes of the relationships for both $\delta^{18}O$ and $\delta^{2}H$ values of leaf water were less than one, which suggests that part of the bulk leaf water is derived from unenriched vein water. However, there were no significant differences in $\delta^{18}O_{leaf}$ (p=0.54; Fig. 3b) and $\delta^{2}H_{leaf}$ values (p=0.93; Fig. 3d) between the C-G model predicted values and the measured values.

3.3 Variation of $\delta^{18}O$ and $\delta^{2}H$ values of different waters with seasons and altitude. There was a significant correlation between $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values ($R^{2}=0.81, p < 0.01$; Fig. 4), with significant clusters of $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values across the months, and values being higher in May, intermediate in July, and lower in September (Fig. 4). Within each month, the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values were depleted in ^{2}H and ^{18}O at higher altitudes relative to lower altitudes. Likewise, the potential types of source water (i.e., twig water, soil water, and precipitation) exhibited consistent variations across the months, showing values that were relatively higher in May, intermediate in July, and lower in September (Supplementary Fig. S1). The correlations between $\delta^{18}O$ and $\delta^{2}H$

values among the source waters were also significant (Supplementary Fig. S2), but. Still, the slopes and coefficients of determination (R²) between the δ^{18} O and δ^{2} H values showed decreasing trends for precipitation, soil water, twig water, and leaf water from the three sampling months, except for soil water in May (Supplementary Fig. S2). In addition, the ANCOVA tests showed no significant differences for the regression lines for precipitation (df = 0.47, F = 2.49, p = 0.11 > 0.05), twig water (df = 53.2, F = 0.42, p = 0.66 > 0.05), and leaf water (df = 437.3, F = 2.78, p = 0.08 > 0.05) across the months, but a significant difference for soil water across the months (df = 308.8, F = 10.9, p < 0.05).

4. Discussion

4.1 δ^{18} O and δ^{2} H values of leaf water

A recent global meta-analysis indicated that $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values reflect environmental drivers differently and showed that $\delta^{2}H_{leaf}$ values more strongly reflect xylem water and atmospheric vapour $\delta^{2}H$ values, whereas $\delta^{18}O_{leaf}$ values more strongly reflect air relative humidity (Cernusak et al., 2022). Our sSeasonal and localized observations along an elevation transect on the Chinese Loess Plateau supported these differing differred responses of $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values to isotopic composition of the potential source water and meteorological parameters (Fig. 2). This resulted from is likely due to the range of variation in precipitation isotopic values compared with that in leaf water evaporative enrichment is larger for $\delta^{2}H_{leaf}$ than $\delta^{18}O_{leaf}$ values (Cernusak et al., 2022). We In addition, we found stronger correlations between $\delta^{2}H_{leaf}$ and isotope

values of the source water (twig water, soil water, and precipitation) than between $\delta^{18}O_{leaf}$ values and the source water isotope values (Fig. 2a). This is consistent with the global meta-analysis (Cernusak et al., 2022). However, our localized observational study did not show a significantly different response of $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values to meteorological parameters, and theywhich responded at an almost equivalent magnitude (Fig. 2b). These observations suggest that plant organic isotopic proxies such as leaf wax (Sachse et al., 2012; Liu et al., 2016) and cellulose (Barbour, 2007; Lehman et al., 2017), which originate from $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values, can provide comparative information that indicates climatic signals (e.g., temperature, RH, and precipitation) in natural archives. These results argued with the recent global meta-analysis that $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values reflect climatic parameters (i.e., RH and temperature) differently (Cernusak et al., 2022).

The results of the cluster analysis showed that the isotope values of leaf water ($\delta^{18}O_{leaf}$ and δ^2H_{leaf}) and twig water ($\delta^{18}O_{twig}$ and δ^2H_{twig}) were clustered into one group, but those of soil water ($\delta^{18}O_{soil}$ and δ^2H_{soil}) and precipitation ($\delta^{18}O_p$ and δ^2H_p) were clustered into another (Fig. 2a). This indicates that the direct source water of $\delta^{18}O_{leaf}$ and δ^2H_{leaf} should be $\delta^{18}O_{twig}$ and δ^2H_{twig} , providing the source water isotope basis for the C-G model. In the C-G model (see Equation 2), besides the source water isotopes, the equilibrium fractionation factor (ε^+) and atmospheric vapour enrichment (Δ_v) depend on the temperature at the isotopic steady state. Thus, the $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values were predicted to be associated primarily with temperature, RH, and source

water, which is consistent with the results from the cluster analysis that the $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values were clustered with temperature (MAT and MMT) and RH (MARH; Fig. 2b). Based on the C-G model, we plotted the measured and predicted $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values (Fig. 3a, c) and observed no significant differences between the measured and predicted values of $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values (Fig. 3b, d). This is because our three-repeated samplings take place during the day when leaf water is generally near isotopic steady state because chloroplasts are mostly located near tooccur during the day when leaf water is generally near an isotopic steady state because chloroplasts are mostly located near the evaporative sites (Cernusak et al., 2016). The non-steady state effects on leaf water isotopes were expected at night because of low stomatal conductance (Cernusak et al., 2005; Cuntz et al., 2002; Cernusak et al., 2016). Although the slopes of the predicted and measured $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values were less than one, the C-G model still provides a reasonable framework for guiding the analysis of the different controls on $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values.

4.2 Dual $\delta^{18}O$ and $\delta^{2}H$ plots of leaf water

There was a significant linear correlation between the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values, with remarkable clusters associated with the three months analyzed in this studystudied (Fig. 4). As is well-known, the LMWL, generated by precipitation $\delta^{18}O$ and $\delta^{2}H$ values at the local scale, serves as an important reference line for inter-comparisons among different waters. Furthermore, the regression lines of the $\delta^{18}O$ and $\delta^{2}H$ values from soil water, twig water, and leaf water (Supplementary Fig. S2) suggest that the leaf water

isotopes could well inherit isotopic signals of source waters that originate from twig water, soil water, and ultimately precipitation. The slopes and intercepts of the δ^{18} O and δ^2 H values decreased significantly from precipitation, soil water, twig water, and leaf water for each month, except for soil water in May (Supplementary Fig. S2). Such patterns have been observed in the a number of previous calibration studies (Brooks et al., 2010; Evaristo et al., 2015; Sprenger et al., 2016, 2017; Wang et al., 2017; Benettin et al., 2018; Barbeta et al., 2019; Penna and Meerveld, 2019; Liu et al., 2021a). The slopes of the LMWLs were lower in July (6.79) relative to those from May (7.04) and September (6.85), but were not significantly different (ANCOVA test: df = 0.47, F = 2.49, p = 0.11 > 0.05). This suggests that the local water vapour from precipitation was derived from the same source across the seasons, but was subject to different intensities of evaporation as the temperature changed through the seasons (Li et al., 2019; Wu et al., 2019, 2021). The slopes of the δ^{18} O and δ^2 H values from the soil, twig, and leaf waters were also much smaller than the LMWLs across the months due to the occurrence of secondary evaporation in the other water types.

In the dual isotope plot of leaf water, there were well-defined clusters of $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values across the three months: ^{18}O and 2H were depleted in September, there were intermediate values in July, and ^{18}O and 2H were enriched in May (Fig. 4). When focusing on each month, relatively higher isotopic values occurred at low elevations, but lower isotopic values were present at high elevations despite there being no, or only weak, correlations between the the $\delta^{18}O_{leaf}$ and δ^2H_{leaf} values and altitude

(Supplementary Fig. S3). The correlations between the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values and altitude, and between the $\delta^{18}O_{twig}$ and $\delta^{2}H_{twig}$ values and altitude, were not significant and weak across the three months; however, the $\delta^{18}O_{p}$ and $\delta^{2}H_{p}$, and also the $\delta^{18}O_{soil}$ and $\delta^{2}H_{soil}$ values, were significantly correlated with altitude (Supplementary Fig. S3), which suggests that besides source water (precipitation and soil water), other factors associated with plants also affect the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values.

The dual isotope plot of $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values show a significant isotope line: y = 4.52x - 50.7 ($R^{2} = 0.81$, p < 0.01; Fig. 4), but relatively shallower slopes (3.53, 1.86, and 2.81 in May, July, and September, respectively) of $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values were observed across the seasons (Supplementary Fig. S2). Such a correlation was supported by a recent study that conducted consecutive measurements of $\delta^{18}O$ and $\delta^{2}H$ values in xylem/leaf water in Switzerland and indicated that leaf water provided the great potential to determine the source water of plants (Benettin et al., 2021). Our local study showed remarkable clusters in the measured (Fig. 4) and the C-G model predicted (Fig. 3) $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values across the months and the consistencies of respective $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values with potential source water isotopes across months (Supplementary Fig. S1). These findings of temporally consistent dynamics among the water types (i.e., precipitation, soil water, twig/stem water, and leaf water) have been observed in a number of previous studies (Phillips and Ehleringer, 1995; Cernusak et al., 2005; Sprenger et al., 2016; Berry et al., 2017; Liu et al., 2021a).

The isotopic inheritance from precipitation to leaf water indicates that seasonal variations of $\delta^{18}O_p$ and δ^2H_p values are the first-order control on the temporal patterns seen in the leaf water. The seasonal dynamics of the $\delta^{18}O_p$ and δ^2H_p values reflect the combined effects of such things as temperature, altitude, and precipitation amount, which are associated with orographic conditions, as well as sub-cloud evaporation, moisture recycling, and differences in the vapor source (Dansgaard, 1964; McGuire and McDonnell, 2007; Li et al., 2016; Penna and Meerveld, 2019; Wu et al., 2019). In this study, we used the HYSPLIT model to demonstrate the ultimate cause of the seasonal variations of $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values; that is, the monthly dynamics of the $\delta^{18}O_{p}$ and $\delta^2 H_p$ values. The monthly variations of the $\delta^{18} O_p$ and $\delta^2 H_p$ values from the Global Network for Isotopes in Precipitation (GNIP, http://www.iaea.org/) at Xi'an station (1985-1992 AD), which is ~100 km from our study transect, were enriched in ¹⁸O and ²H in May relative to July and September (Fig. 5a, b). The cluster mean of the moisture transport routes from HYSPLIT (Draxler and Rolph, 2003) and the climatological 850 hPa wind vectors showed that the main moisture sources were from western China and central Asia in May, the China-India Peninsula and Bay of Bengal, and local moisture recycling and convection (Fig. 5c, d, e). The seasonal variations in $\delta^{18}O_p$ and δ^2H_p values are consistently related to the onset, advancement, and retreat of the Asian summer monsoon and associated changes in the large-scale monsoon circulation (e.g., Zhang et al., 2020, 2021). As the summer monsoon starts in mid-May, the rainfall season starts in southern China; however, our study area is controlled mainly by moisture from the westerlies (Chiang et al., 2015) with relatively higher vapour, $\delta^{18}O_p$,

and $\delta^2 H_p$ values (Fig. 5c, a, b). In July, the summer monsoon reaches its strongest phase₃ and the rainfall belt shifts to central and northern China, where the southerly wind brings plenty of moisture from the China-India Peninsula and the Bay of Bengal with lower vapour, $\delta^{18}O_p$, and $\delta^2 H_p$ values (Fig. 5d, a, b). When the summer monsoon withdraws in September, the study area is controlled mainly by-moisture-from local moisture recycling and convection (Fig. 5e). Soil water stores the June-August monsoon rainfall with its lower $\delta^{18}O$ and δ^2H values, resulting in even lower $\delta^{18}O_p$ and δ^2H_p values in September than in July (Supplementary Fig. S1), and thus resulting in significantly lower $\delta^{18}O$ and δ^2H values of leaf water (Fig. 4).

4.3 Framework of controls for $\delta^{18}O$ and $\delta^{2}H$ values of leaf water

To delineate the mechanisms that control the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values, we used the SEMs to quantify the complex interactions among $\delta^{18}O_{leaf}$ or $\delta^{2}H_{leaf}$ values, and source waters, and meteorological parameters (Fig. 6). The coefficients of determination (R²) were 0.48 and 0.71 for the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values, respectively, indicating that the models explained more variance for $\delta^{2}H_{leaf}$ values than $\delta^{18}O_{leaf}$ values (Fig. 6). The SEMs showed that potential source waters (i.e., twig water, soil water, and precipitation) had stronger effects on $\delta^{2}H_{leaf}$ relative to $\delta^{18}O_{leaf}$ values, while the meteorological parameters showed weak effects on both $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values (a little larger for $\delta^{2}H_{leaf}$ than $\delta^{18}O_{leaf}$ values). This is consistent with our above correlation analysis (Fig. 2). Surprisingly, MMT had significant—and—strong effects on $\delta^{18}O_{p}$ and $\delta^{2}H_{p}$ values, suggesting that temperature plays a key role in determining $\delta^{18}O_{p}$ and $\delta^{2}H_{p}$ values, but

this finding is not discussed further here. Collectively, the SEMs also showed that source water exerts the first-order control but affects $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ differently; the meteorological parameters had a weak control on $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$, with a relatively stronger more substantial effect on $\delta^{2}H_{leaf}$ than $\delta^{18}O_{leaf}$ values.

443

444

A schematic representation of the controls on $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values (respective and dual) is shown in Fig. 7, and. It involves multiple processes associated with the hydroclimatic and biochemical factors that affect $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values. The meteorological parameters (temperature, RH, and precipitation) exerted distinct effects on the δ^{18} O and δ^{2} H values of the source water, and thus on the δ^{18} O_{leaf} and δ^{2} H_{leaf} values, as demonstrated above by the SEM. Significant isotopic fractionation occurred mainly at two key locations across the vertical soil profiles and leaf architectures from precipitation to leaf water. First, an isotopic gradient across the vertical soil profile appeared because of evaporation from the surface soil layers (Ehleringer et al., 1992; Goldsmith et al., 2012; Evaristo et al., 2015). This evaporative isotopic fractionation causes an isotopic linear trajectory down the soil profile (Goldsmith et al., 2012; Rothfuss and Javaux, 2017; Wu et al., 2018; Wang et al., 2019; Amin et al., 2020; Zhao et al., 2020; Liu et al., 2021a). Second, there were significant isotopic heterogeneities <u>because of transpiration</u> associated with the $\delta^{18}O_{leaf}$ (Helliker and Ehleringer, 2000; Farquhar and Gan, 2003; Gan et al., 2003; Song et al., 2015) and $\delta^2 H_{leaf}$ values (Šantrůček et al., 2007; Liu et al., 2016; Liu et al., 2021b) within a leaf, which depends substantially on veinal structures (Liu et al., 2021b). The within-leaf heterogeneity of

(Gan et al., 2003; Farquhar and Gan, 2003; Cernusak et al., 2005, 2016). Collectively, the soil evaporation and leaf transpiration results inproduce isotopic enrichment above source water (precipitation or soil water). Soil evaporation leads to an isotopic gradient across the vertical soil profile, which provides water sourceproviding water sources for plant roots uptake without isotope fractionation during the process (Dawson and Ehleringer, 1991; Ehleringer and Dawson, 1992; Chen et al., 2020). During the water transport between roots and leaf petioles, isotopic compositions of xylem water remains unaltered from that in soils (i.e. soil immobile water), until it reaches to the leaf, which undergoes water loss (Ehleringer and Dawson, 1992). Within the leaf, transpiration leads to significant isotopic enrichment (Helliker and Ehleinger, 2000; Liu et al., 2015; Cernusak et al., 2016), which is highly dependent on meteorological parameters (e.g., temperature and relative humidity). However,

Moreover, the hydroclimatic meteorological factors parameters (e.g., temperature, RH, precipitation, etc.) varied with altitude and seasonality, yielding an isotopic water line (LWL) in the dual-isotope plot (Fig. 4). The LWL generation provides an important

baseline for leaf-derived organic matter such as cellulose (e.g., Barbour, 2007; Lehman

et al., 2017) and leaf wax (Liu et al., 2016, 2021). The slope of the LWL was shallower

than the LMWL, with an intersection angle θ (Fig. 7). We speculate that θ probably

varies with the hydroclimatic and biochemical factors associated with evaporation,

inspiration, and biochemistry, but the relationship between θ and these hydroclimatic

the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values can be explained using the *Péclet*-modified C-G model

and biochemical factors required further exploration. Overall, the LWL is controlled primarily by altitude and seasonality, as these are the main influences on the hydroclimatic and biochemical factors.

5 Conclusion

Along an elevation transect on the Chinese Loess Plateau, precipitation, soil water, twig water, and leaf water were repeatedly sampled to explore the controls on $\delta^{18}O_{leaf}$ and $\delta^2 H_{leaf}$ values associated with meteorological parameters and source water. The effects of meteorological parameters and source water on $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values were different, and the dual δ^{18} O_{leaf} and δ^{2} H_{leaf} plot generated an isotopic line. We found that $\delta^2 H_{leaf}$ values were more closely correlated with source water isotopes than $\delta^{18} O_{leaf}$ values, whereas δ¹⁸O_{leaf} and δ²H_{leaf} values were similarly correlated with meteorological parameters. The observations suggest that plant organic isotopic proxies such as leaf wax and cellulose originating from $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values can provide comparative climatic information. Additionally, the dual-isotope analysis showed that the $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values were closely correlated because of their similar altitudinal and seasonal responses. The first-order control on $\delta^{18}O_{leaf}$ and $\delta^{2}H_{leaf}$ values was the source water (i.e., precipitation), and the meteorological parameters had a comparative effects on both δ¹⁸O_{leaf} and δ²H_{leaf} values, which varied with altitude and season. The δ¹⁸O_{leaf} and δ²H_{leaf} values were controlled by the combined effects of source water and hydroclimate that varied with altitude and season. In the future, we will investigate the relationship of an intersection angle θ with the hydroclimatic and biochemical factors.

- 747 Fig. 1 Sample sites (red dots) and weather stations (open triangles) that distribute along
- 748 vertical vegetation zones across the Mt. Taibai transect on the Chinese Loess Plateau
- 749 (a). The meteorological parameters (precipitation, temperature, and RH) vary with

- 750 stations along elevation transect (b). Mean annul (MAP, MAT, MARH) and montly
- 751 (MMP, MMT, MMRH) precipitation, temperature, and relative humidity. The
- subscripts refer to the month. The vertical vegetation distribution was adopted from Liu,
- 753 2021.
- 754 Fig. 2 Heatmaps of correlations (r) between leaf water δ^{18} O and δ^{2} H values and
- 755 potential source water $\delta^{18}O$ and $\delta^{2}H$ values (twig water, soil water, and precipitation
- 756 δ^{18} O and δ^{2} H values; a), and meteorological parameters (e.g., MAP, MMP, MAT, MMT,
- 757 MARH, MMRH). The hierarchical cluster analysis of the isotopes of leaf water and
- 758 source water (a), and meteorologica parameters (b). The subscripts (p, soil, twig, leaf)
- refer to precipitation, soil water, twig water, and leaf water. * Corrected significance at
- 760 p < 0.05; ** corrected significance at p < 0.01; *** corrected significance at p < 0.001.
- 761 Fig. 3 Measured leaf water isotopic composition for δ^{18} O (a) and δ^{2} H (c) values against
- values predicted by the C-G model. Boxplots show no significant differences for $\delta^{18}O$
- 763 (b) and δ^2 H (d) values between measured and predicted leaf water. The dotted lines
- show one-to-one lines.
- 765 Fig. 4 Correlation of leaf water δ^{18} O and δ^{2} H values across months and altitude. Leaf
- 766 water δ^{18} O and δ^{2} H values were the higher in May, intermediate in July, and lower in
- September, and while within each month, those isotopic values were relatively lower at
- high altitudes and higher in lower altitudes.
- 769 **Fig. 5** Variation of monthly mean precipitation δ^{18} O (a) and δ^{2} H (b) values at Xi'an
- 770 station from Global Network of Isotopes in Precipitation (GNIP) and cluster mean of
- 771 moisture transport routes using HYSPLIT model in May (c), July (d) and September
- 772 (e), 2020. Background in (c-e) is the average precipitation (mm/day) and 850 hPa wind
- vectors (arrows, m/s) in May (c), July (d) and September (e) in 1979-2016 AD based
- on the database of the Global Precipitation Climatology Center (GPCC) (Becker et al.,
- 775 2011) and the Modern-Era Retrospective analysis for Research and Applications
- 776 (Rienecker et al., 2011).
- 777 **Fig. 6** Structural equation model (SEM) of leaf water δ^{18} O (a) and δ^{2} H (b) values. The
- 778 structural equation models considered all plausible pathways. Solid lines indicate

significant positive (red) or negative (blue) effects, and dashed lines indicate nonsignificant effects. Grey lines indicate correlations between two variables. Numbers on the arrow indicate significant standardized path coefficients, proportional to the arrow width. The coefficients of determination (R2) represent the proportion of variance explained by the model. Fig. 7 Schematics of the respective and dual isotopes of $\delta^{18}O$ and $\delta^{2}H$ values from precipitation to leaf water, associated with physical (evaporation at soil profile and transpiration at leaf level) and biochemical processes. The dual isotopes of $\delta^{18}O$ and δ^2 H values yield an isotopic water line, the slope of which was lower than the LMWL. The intersected angle varied with hydroclimates, associated with altitude and seasonality.
