11 **Abstract**

12 A larger antecedent effective precipitation (AEP) indicates a higher probability of a debris flow  
13 ( $P_{df}$ ) being triggered by subsequent rainfall. Scientific topics surrounding this qualitative conclusion  
14 that can be raised, including what kinds of variation rules do they follow, and whether there is a  
15 boundary limit. To answer these questions, Jiangjia Gully in Dongchuan, Yunnan province, China,  
16 is chosen as the study area, and a numerical calculation, rainfall scenario simulation, and Monte  
17 Carlo integration method have been used to calculate the occurrence probability of debris flow under  
18 different AEP conditions and derive the functional relationship between  $P_{df}$  and AEP. The  
19 relationship between  $P_{df}$  and AEP can be quantified by a piecewise function.  $P_{df}$  is equal to 15.88%  
20 even AEP reaches 85 mm indicating that debris flow in nature has an extremely small probability  
21 compared to the rainfall frequency. Data from 1094 rainfall events and 37 historical debris flow

22 events are collected to verify the reasonability of the functional relationship. The results indicate  
23 that the piecewise function are highly correlated with the observation results. Our study confirms  
24 the correctness of the qualitative description of the relationship between AEP and  $P_{df}$ , clarifies that  
25 debris flow is a small probability event compared to rainfall frequency, and quantitatively reveals  
26 the evolution law of debris flow occurrence probability with AEP, which can provide a clear  
27 reference for the early warning of debris flows.

28 **Keywords:** Debris flow, antecedent effective rainfall, Dens-ID, Monte Carlo method

29

## 30 **1 Introductions**

31 The antecedent effective precipitation (AEP) likes a Trojan horse lurking inside a loose soil  
32 mass, which can cooperate with subsequent rainfall at any time to trigger debris flow in a debris-  
33 flow gully. The AEP is equivalent to the precipitation preserved in soil mass before the triggering  
34 rainfall process; it represents the saturation degree of loose soil mass (Segoni et al., 2018a;  
35 Leonarduzzi and Molnar, 2020). Therefore, the soil moisture that has accumulated from antecedent  
36 rainfall since the beginning of a rainfall season has a significant influence on how new storm rainfall  
37 interacts with the loose soil mass within a gully (Fiorillo and Wilson, 2004; Long et al., 2020). The  
38 increase in AEP can decrease the shear strength of a loose solid material provided by shallow  
39 landslides or channel erosion (Papa, et al., 2013; Senthilkumar et al., 2017; Liu et al., 2020), as a  
40 consequence, the supply rate of solid material resources can be significantly enhanced in the  
41 subsequent rainfall process (Wei et al., 2008; Bennett et al., 2014; Zhang et al., 2020). Additionally,  
42 increased AEP and moisture content have been shown to enhance rainfall-induced surface runoff in  
43 a variety of environments (Tisdall, 1951; Luk, 1985; Le Bissonnais et al., 1995; Castillo et al., 2003;

44 Jones et al., 2017; Hirschberg et al., 2021). Thus, AEP plays an important role in the formation of  
45 debris flows (Hong et al., 2018).

46 Rainfall thresholds represent the difficulty degree of debris flow triggered by rainfall (Marra  
47 et al., 2017). Investigations including the influence of AEP on the rainfall threshold can be helpful  
48 to examining the relationship between AEP and debris flow occurrence. Currently, the relationship  
49 between the AEP and rainfall threshold indicates that there is a negative correlation between the  
50 AEP and rainfall conditions that trigger debris flows (Huang, 2013). AEP also represents the  
51 saturation degree of loose soil mass (Zhao et al., 2019a; Abraham et al., 2021), and integrating soil  
52 moisture with rainfall thresholds has been proven effective in improving prediction performance  
53 (Segoni et al., 2018a; Zhao et al., 2019b; Abraham et al., 2020). Scholars also have attempted to  
54 analyze the influence of antecedent soil moisture on the rainfall threshold triggering debris flow  
55 (Cui et al., 2007; Hu et al., 2015), and there is still a negative correlation between antecedent soil  
56 moisture and triggering rainfall conditions (Chen et al., 2017) just like the relationship between AEP  
57 and rainfall threshold. The above investigations show that increasing in AEP can significantly  
58 decrease the rainfall conditions for triggering a debris flow, which in turn means that debris flow is  
59 more likely to occur. Generally, the qualitative description of ‘the greater the AEP, the higher the  
60 probability ( $P_{df}$ ) of subsequent rainfall triggering the debris flow (De Vita et al., 2000; Bel et al.,  
61 2017)’ has gradually become a consensus. Therefore, discovering a specific function to describe this  
62 qualitative description is helpful to further demonstrating the above consensus, revealing a certain  
63 evolutionary law of debris flow with rainfall in nature.

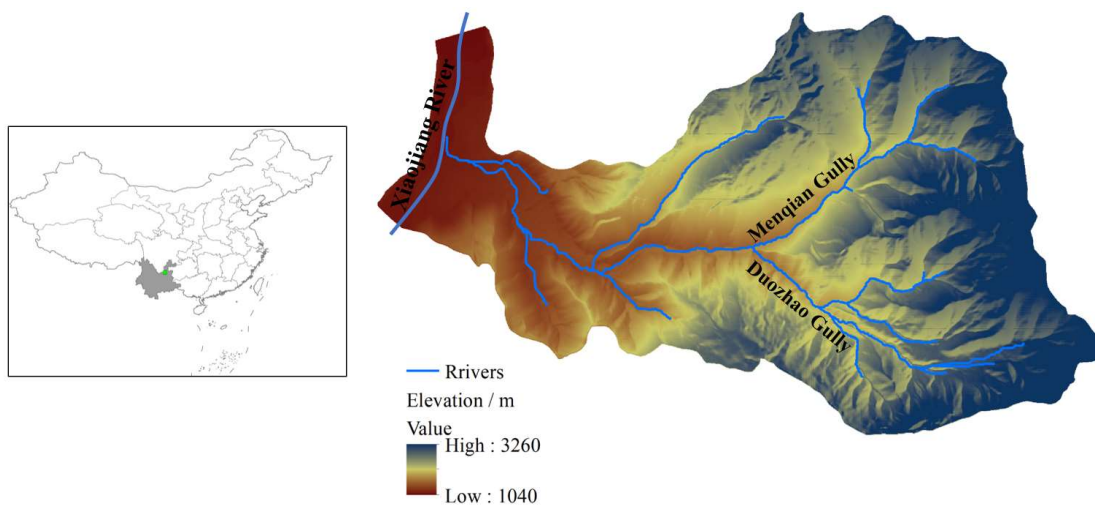

64 To quantify the evolution law of  $P_{df}$  with the changing AEP, a numerical model denoted as the  
65 Dens-ID can correlate the rainfall parameters (I and D) with the debris flow density (Zhang et al.,

2020; Long et al., 2020; Zhang et al., 2023), and it has been used to construct the rainfall intensity-duration (ID) threshold curves under different AEP conditions. The ID threshold curves with upper and lower bounds can delineate the closed region in the ID coordinate system, which represents the set of all rainfall conditions that can trigger debris flow at a certain AEP. Consequently, the probability of natural rainfall falling into a closed region is equivalent to  $P_{df}$ , which can then be calculated based on Monte Carlo integration. The next section introduces the basic information of study area including the rainfall and debris flow event data collected from the study area. The third section addresses how to establish the functional relationship between the AEP and Pdf using the Dens-ID and Monte Carlo integration method. Section 4, 5 and 6 discuss the results and state the conclusions of this study, respectively.

## 2 Study areas

The Jiangjia Gully (JJG) is a primary tributary of the Xiaojiang River, which is located in the Dongchuan District of Kunming City, Yunnan Province, China (Fig.1). As shown in Fig.1, JJG has a drainage area of 48.6 km<sup>2</sup> with elevations ranging from 1040 to 3260 m. In this gully, the relative relief from the ridge to the valley reaches 500 m, and most of the slope gradient is greater than 25°. Slopes within JJG are covered by abundant loose soil with a thickness of more than ten meters. Shallow landslides are frequently triggered by intense rainfall processes in JJG, providing a large number of solid materials for debris flow (Yang et al., 2022). Before 1979, the Menqian and Duozhao gullies are the two main tributaries of JJG, accounting for 64.7% of the entire drainage area. The upstream areas of the two main tributaries are the initiation zones of the debris flows, and the channels of the upstream tributaries are narrow and V-shaped (Zhang et al., 2020). However, several check dams have been constructed in the Duozhao gully since 1979, which have significantly reduced debris flow activity in this sub-gully (Zeng et al., 2009). Currently, Menqian Gully with the area of 13.2 km<sup>2</sup> is the primary source area. The slope gradient of its both sides is very steep, e.g., the mean slope in Menqian Gully is 32° and the maximum slope can reach 70°.

91 Bedrock that mainly consists of slates formed in lower Proterozoic crops out in the unvegetated or  
92 sparsely vegetated lower part. The bedrock is fragmented and mostly disintegrates into clasts with  
93 the size more than 20 mm. The upper part of the bedrock is lain by soil mantles with thicknesses of  
94 0.5–20 m, which are covered by grasses and shrubs, or are used for terrace farming. The soil mantle  
95 is poorly sorted and composed of particles from clay to boulder. The translational zone from the  
96 upper to the lower parts of the slope is prone to shallow landslides. Some landslides directly evolve  
97 into debris flows, while the others release sediment to the channel, which is mobilized by runoff in  
98 debris flow events (Yang et al., 2022).

99

100

Fig.1 Location of JJG

101 Steep terrain provides a beneficial potential energy condition for transporting a large amount  
102 of loose solid materials from JJG to Xiaojiang River. Consequently, debris flows in JJG can be easily  
103 triggered by high-intensity rainstorm or long-duration rainfall processes (Zhang et al., 2020). The  
104 solid material necessary for a debris flow in a gully may be from shallow landslides (Iverson et al.,  
105 1997; Gabet and Mudd, 2006; Zhang et al., 2020; Long et al., 2020) or runoff-induced bed erosions  
106 (Berti and Simoni, 2005; Coe et al., 2008; Tang et al., 2020; Bernard and Gregoretti, 2021). In JJG,  
107 shallow landslides are the main sources for the solid material supply (Zhang et al., 2014; Liu et al.,  
108 2016; Yang et al., 2022), which is consistent with the assumptions of Dens-ID (Zhang et al., 2020).  
109 Thus, JJG is used as the study zone for deriving the function that describes the relationship between

110 AEP and  $P_{df}$ .

### 111 **3 Methods and data**

#### 112 **3.1 Dens-ID**

113 Debris flow gullies characterized by a solid source supply from landslides are widely  
114 distributed in southwest China (Zhang et al., 2014). For this type of debris flow gully, our previous  
115 study proposed Dens-ID aiming at correlating debris-flow density to rainfall parameters based on  
116 water-soil coupling mechanism (Zhang et al., 2020; Long et al., 2020). Den-ID assumes debris flow  
117 to be a water-soil mixture, it contains three core simulating contents including hydrological  
118 simulation, water-soil coupling to calculate the water-soil-mixture density, and correlating density  
119 to rainfall parameters.

120 (1) Simulating hydrological process: the purpose is to provide parameters for estimating  
121 rainfall-induced runoff and the supply volume of rainfall-induced loose solid materials. Based on  
122 the digital elevation model (DEM) of a gully, Den-ID can simulate the rainfall-induced runoff and  
123 water diffusion in the vertical direction within the soil mass. The rainfall infiltration border is  
124 controlled by Equation 1.

$$125 \quad -D(\theta) \frac{\partial \theta}{\partial z} + K(\theta) = I(t) \quad (1)$$

126 where  $\theta$  is the soil water content;  $D(\theta) = K(\theta)/(d\theta/d\psi)$ , which represents the soil water  
127 diffusivity;  $z$  is the soil depth, which is positive downwards along the soil depth as the topsoil is  
128 taken as the origin point;  $K(\theta)$  is the hydraulic conductivity;  $I(t)$  is the rainfall intensity; and  $\psi$  is  
129 the soil matrix suction. When the rainfall intensity is less than the surface infiltration capacity,  
130 Equation 1 is used to represent this physical process; whereas the case of precipitation intensity  
131 exceeding the infiltration capacity of topsoil means that the surface is saturated, and the excess

132 precipitation from the topsoil is converted into runoff. Therefore, the pressure infiltration of each  
 133 grid cell is not considered.

$$134 \quad \frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[ D(\theta) \frac{\partial \theta}{\partial z} \right] - \frac{\partial K(\theta)}{\partial z} \quad (2)$$

135 Equation 2 is the Richard differential infiltration equation (Richards, 1931), which is used to  
 136 describe the water movement along the vertical direction within soil mass after precipitation  
 137 infiltrates into topsoil. Dens-ID uses the finite-difference method to solve Eqs. 1 and 2 and can  
 138 provide the runoff depth (denoted as  $dw(i, t)$ ), soil water content, and soil matrix suction for each  
 139 grid cell. Dens-ID then calculates the runoff volume using runoff depth  $dw(i, t)$  in Equation 3.

$$140 \quad V_w(t) = \sum_{t=1}^T \sum_{i=1}^n S_g * dw(i, t) \quad (3)$$

141 where  $n$  represents the total number of grid cells that can generate runoff at time  $t$ ,  $V_w(t)$  represents  
 142 the total volume of runoff within a gully at time  $t$ ,  $S_g$  represents the area of the grid cell generating  
 143 runoff, and  $T$  represents the total duration of a rainfall process.

144 (2) Calculating supply amount of loose solid materials and density of the water-soil mixture:  
 145 taking hydrological parameters such as soil water content and soil matrix suction as inputs, Dens-  
 146 ID uses Equations 4 and 5 to estimate the supply amount of rainfall-induced loose solid materials  
 147 within a gully. Equation 4 calculates safety factor  $F_s$  of each grid cell as a function of the matrix  
 148 suction and soil moisture.  $F_s > 1$  indicates that the grid cell is stable and cannot supply solid material  
 149 to the gully, whereas a grid with  $F_s < 1$  can provide solid material in the form of a shallow landslide.

$$150 \quad F_s = \frac{\tan \varphi}{\tan \beta} + \frac{c + \psi \tan(\varphi^b)}{\gamma_t d_s \cos \beta \sin \beta} \quad (4)$$

151 where  $F_s$  represents the safety factor of each grid cell,  $c$  is the soil cohesion force,  $\varphi$  is the internal  
 152 friction angle,  $\varphi^b$  is related to the matrix suction and is approximately equal to  $\varphi$  as the low matrix  
 153 suction is small,  $d_s$  is the soil depth, and  $\psi$  is the matrix suction which is a function of soil water

154 content and can be described by the Van Genuchten model (Van Genuchten, 1980).

155 Equation 4 is used to estimate the total volume of solid materials from all the unstable grid  
156 cells during a rainfall process.

$$157 \quad V_s(t) = \sum_{t=1}^T \sum_{j=1}^m S_g * ds(j, t) \quad (5)$$

158 where  $m$  represents the number of grid cells that can provide solid material at time  $t$  and  $V_s(t)$  is the  
159 total volume of solid material within a gully at time  $t$ . At time  $t$ , the density of the water-soil mixture  
160 after full coupling between runoff and solid material can be calculated using Equation 6.

$$161 \quad \rho_{mix}(t) = \frac{\rho_w V_w(t) + \rho_s V_s(t)}{V_{mix}(t)} \quad (6)$$

162 where  $\rho_{mix}(t)$  is the density of the water-soil mixture,  $\rho_w$  is the water density,  $\rho_s$  is the density of  
163 the soil particles, and  $V_{mix}(t)$  is the volume of the water-soil mixture, which is the sum of  $V_w(t)$   
164 and  $V_s(t)$ .  $V_w(t)$  and  $V_s(t)$  are the key variables that can be derived using Eqs. 3 and 5.

165 (3) Correlating density to rainfall parameters including rainfall intensity and duration: after  
166 firstly presetting the density of the water-soil mixture as  $\rho_{mix}$ , Dens-ID also needs to simulate many  
167 rainfall scenarios including long durations with low-intensity rainfall and short durations with high-  
168 intensity rainfall in order to obtain a sufficient number of  $[D_i, I_i]$ . Using each  $[D_i, I_i]$  as input, Dens-  
169 ID then can calculate the density using Equation 6. If the calculated density is equal to  $\rho_{mix}$ , the  $[D_i,$   
170  $I_i]$  combination is saved by Dens-ID. After Dens-ID completes the trial calculations, all combination  
171 data of  $[D_i, I_i]$  that satisfy the constraints of the preset density ( $\rho_{mix}$ ) can be collected as a dataset.  
172 Each collected  $[D_i, I_i]$  within the dataset corresponds to the preset  $\rho_{mix}$ , accordingly, Dens-ID can  
173 correlate rainfall parameters (D and I) to debris flow density (Long et al., 2020). Dens-ID can derive  
174 ID threshold curves by fitting the selected  $[D_i, I_i]$  data, and each ID curve corresponds to a debris  
175 flow density value (Zhang et al., 2020). As the density of debris flow in JJG varies in a specific

176 interval of  $1.2\text{--}2.3\text{g/cm}^3$  (Zhang et al., 2014; Zhuang et al., 2015; Long et al., 2020), the threshold  
177 curve that corresponds to the boundary value can form a closed area with the I- and D-axes in the  
178 ID coordinate system. The case of monitoring or forecasting rainfall falling into this closed area  
179 indicates that the rainfall condition may trigger debris flow. The verification results in JJG show  
180 that Dens-ID can effectively describe the mechanism and process of debris flow formation, and its  
181 prediction accuracy is approximately 80.5%, which is 27.7% higher than that of statistical models  
182 (Zhang et al., 2020). Such a high prediction accuracy can further indicate that the closed area formed  
183 by the derived ID curves has a very reasonable location and coverage in the ID coordinate system,  
184 providing extremely reliable analytical data in this study.

### 185 **3.2 JJG data for model Dens-ID**

186 The JJG datasets for Dens-ID are terrain data, hydrological parameters, and soil mechanical  
187 parameters. The DEM is the basal data for deriving other terrain data, including slope length,  
188 gradient, and river channels; the spatial resolution of the DEM is 0.5 m, and a DEM with a grid size  
189 of 10 m was generated using the resampling technology in ArcGIS. The hydrological parameters  
190 are related to the soil types within JJG; the five key parameters are the saturated soil water content,  
191 residual soil water content, the two parameters of soil water characteristic curve including  $n$  and  $m$ ,  
192 and the infiltration rate of topsoil. The soil mechanical parameters are the soil cohesion force and  
193 internal friction angle obtained through direct shear tests on the soil samples. Detailed data are  
194 available in Zhang et al. (2020) and Long et al. (2020).

### 195 **3.3 Historical rainfall and debris flow data**

218 a low initial rainfall condition that any ID curve cannot derived from Dens-ID. The purpose of  
 219 increasing AEP by an interval of size 5 is to get adequate ID curves, which will be helpful to  
 220 calculate  $P_{df}$  under different AEP conditions.

### 221 **3.4 Monte Carlo method for calculating the definite integral**

222 Because of the boundary of the debris-flow density in JJG (1.2–2.3g/cm<sup>3</sup>), Dens-ID produces  
 223 the corresponding upper and lower boundary curves under a specific AEP condition. The two  
 224 boundary curves can be described using the power function.

$$225 \begin{cases} f(D)_{up} = I_{up} = \alpha_1 D^{\beta_1} & D \in [a_1, b_1] \\ f(D)_{low} = I_{low} = \alpha_2 D^{\beta_2} & D \in [a_2, b_2] \end{cases} \quad (8)$$

226 These two threshold curves can delineate an enclosed area in the ID coordinate system, denoted  
 227 as  $W_{ID}$ . The independent variable (D) and dependent variable (I) in Equation 8 also form a closed  
 228 rectangular region in the ID coordinate system, denoted as  $R_{ID}$ . In the ID coordinate system, the  
 229 coverage of  $R_{ID}$  is larger than that of  $W_{ID}$ , as will be shown in detail in Section 4.1. Limited within  
 230  $R_{ID}$ , any rainfall processes located in  $W_{ID}$  can trigger debris flow. If the probability of rainfall  
 231 process falling into the range of  $W_{ID}$  under random conditions is determined, the occurrence  
 232 probability of debris flow can be estimated. Many physical phenomena are stochastic in nature and  
 233 governed by stochastic partial differential equations with nondeterministic initial/boundary  
 234 conditions or integral equations (Peres and Cancelliere, 2014; Yan and Hong, 2014). Albert (1956)  
 235 proposed the Monte Carlo method for solving integral equations. This method is subsequently used  
 236 to estimate the peak flow and volume of debris flow (Donovan and Santi, 2017; Paola et al., 2017),  
 237 entrainment of the underlying bed sediment (Han et al., 2015), and risk assessment (Calvo and Savi,  
 238 2009; Li et al., 2021). The rainfall process is randomly selected within the  $R_{ID}$ , and the probability

239 of the chosen one falling into the  $W_{ID}$  can be determined using  $W_{ID}/R_{ID}$ . The physical meaning of  
 240 the Monte Carlo solving definite integral lies on calculating the area enclosed by the function curve  
 241 and horizontal axis. Therefore, the area of  $W_{ID}$  can be calculated by the difference in the definite  
 242 integral formula of the two equations in Equation 8.

$$243 \quad W_{ID} = S_{up} - S_{low} = \int_{a_1}^{b_1} f(D)_{up} dD - \int_{a_2}^{b_2} f(D)_{low} dD \quad (9)$$

244 where  $S_{up}$  and  $S_{low}$  represent the area enclosed by the two threshold curves and the horizontal axis,  
 245 respectively, and  $a_1$ ,  $b_1$ ,  $a_2$ , and  $b_2$  are the boundary values of  $D$  in the two curves. For the upper  
 246 boundary line (or lower boundary), if the probability distribution function of  $D$  between  $[a_1, b_1]$  is  
 247  $p(D)$ , Equation 10 can be derived by substituting  $p(D)$  into Equation 9.

$$248 \quad \begin{cases} S_{up} = \int_{a_1}^{b_1} f(D)_{up} dD = \int_{a_1}^{b_1} \frac{f(D)_{up}}{p(D)} p(D) dD \approx \frac{1}{n} \sum_{k=1}^n \frac{f(D_i)_{up}}{p(D_i)} \\ S_{low} = \int_{a_2}^{b_2} f(D)_{low} dD = \int_{a_2}^{b_2} \frac{f(D)_{low}}{p(D)} p(D) dD \approx \frac{1}{n} \sum_{k=1}^n \frac{f(D_i)_{low}}{p(D_i)} \end{cases} \quad (10)$$

$$249 \quad W_{ID} = \frac{1}{n} \sum_{k=1}^n \frac{f(D_i)_{up}}{p(D_i)} - \frac{1}{n} \sum_{k=1}^n \frac{f(D_i)_{low}}{p(D_i)} \quad (11)$$

250 where  $n$  represents the number of random samples drawn from the variation range of  $D$ , and  $p(D_i)$   
 251 is the probability density distribution function of  $D$  in the interval  $[a_1, b_1]$  or  $[a_2, b_2]$ . The key to  
 252 solving Equation 10 depends on sampling from  $p(D)$ . The following steps are used to explain how  
 253 samples were taken using  $p(D_i)$ .

254 Step 1: Based on the probability density distribution function  $p(D)$ , the cumulative probability  
 255 distribution function can be derived by  $cdf(D) = \int_{-\infty}^D f(D) dD$ ;

256 Step 2: Assume that  $U^{(i)}$  obeys a uniform distribution within  $[0, 1]$ , which can be randomly collected  
 257 from this interval and denoted as  $U^{(i)} \sim U(0, 1)$ .

258 Step 3: Substitute  $U^{(i)}$  into the inverse function of the cumulative probability distribution  $cdf(D)$  to  
 259 obtain random sample  $D^{(i)}$ , denoted by  $D^{(i)} = cdf^{-1}(U^{(i)})$ . Then, a dataset composed of  $n$  data  
 260 points of  $D^{(i)}$  is obtained.

261 Step 4:  $W_{ID}$  can be calculated by substituting  $n$  data points of  $D^{(I)}$  into Equation 10, and the  $P_{df}$   
 262 ( $P_{df} = \frac{R_{ID}}{W_{ID}}$ ) corresponding to a specific AEP is determined.  $P_{df}$  represents the probability that the  
 263 subsequent precipitation process may trigger debris flow for a certain AEP. Thus, the influence of  
 264 the AEP on the occurrence probability of debris flows can be quantified.

### 265 3.5 Correlation analysis between numerical and observation results

266 The relationship between the AEP- $P_{df}$  fitted through the observational data is used as a  
 267 reference standard, and the correlation analysis method is used to verify the function of the AEP- $P_{df}$   
 268 derived by Dens-ID. Correlation analysis is used to study the degree of linear correlation between  
 269 variables, which is represented by correlation coefficient  $r$ :

$$270 \quad r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}} \quad (12)$$

271 where  $x$  represents the  $P_{df}$  derived from the observed data,  $y$  represents the  $P_{df}$  derived from Dens-  
 272 ID,  $\bar{x}$  and  $\bar{y}$  represent the averages,  $r$  represents the correlation coefficient, and  $n$  represents the  
 273 number of samples.  $|r| \geq 0.8$  can be regarded as a high correlation between two variables;  $0.5 \leq |r| < 0.8$   
 274 represents a moderate correlation;  $0.3 \leq |r| < 0.5$  represents a low correlation; and  $|r| < 0.3$  indicates the  
 275 degree of correlation between the two variables is weak and can be regarded as uncorrelated.

## 276 4 Results

### 277 4.1 ID threshold curves and warning zone closed by the derived curves

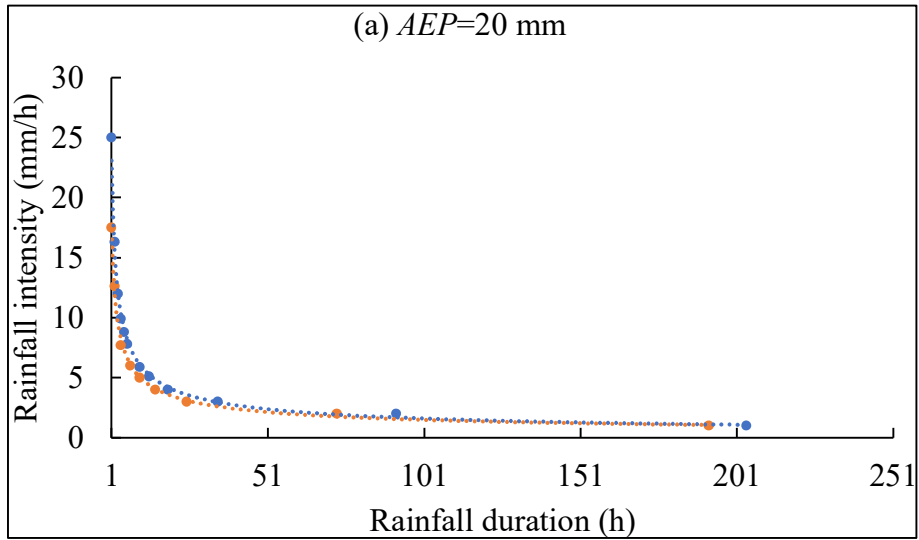

278 Dens-ID yields the upper and lower boundary lines of the ID threshold in each condition of a  
 279 preset AEP, and these two boundary lines are characterized by different debris flow density and  
 280 listed in Table 1. It can be seen from Table 1 that the maximum density corresponding to the ID  
 281 threshold curve cannot reach 2.2, when AEP is less than 15 mm. A small AEP indicates the supply  
 282 rate of solid resources in JJG is far less than the runoff generation rate during a subsequent rainfall

283 process. In this situation, runoff is dominated in the water-soil coupling process yielding a water-  
 284 soil mixture with low density value.

285 Table 1 ID threshold curve database under different AEP

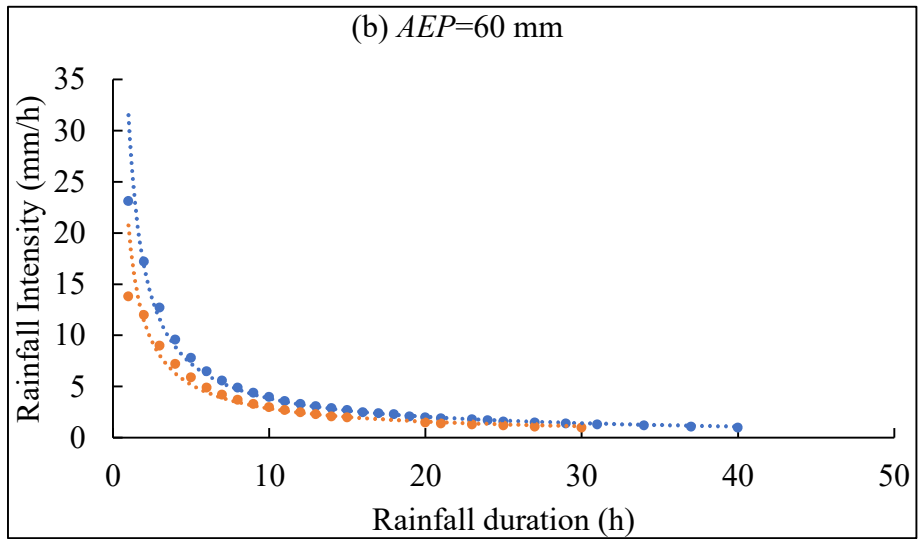

AEP (mm)	ID threshold curve function for JJG	
	1.2 g/cm <sup>3</sup>	2.2 g/cm <sup>3</sup>
10	$I_{1.2} = 19.85D^{-0.54} D \in [1, 269] (R^2 = 0.991)$	$I_{1.8} = 15.85D^{-0.48} D \in [1, 263] (R^2 = 0.990)$
15	$I_{1.2} = 21.69D^{-0.55} D \in [1, 236] (R^2 = 0.993)$	$I_{2.0} = 16.10D^{-0.50} D \in [1, 229] (R^2 = 0.995)$
20	$I_{1.2} = 23.22D^{-0.58} D \in [1, 203] (R^2 = 0.996)$	$I_{2.2} = 17.20D^{-0.53} D \in [1, 192] (R^2 = 0.995)$
25	$I_{1.2} = 24.47D^{-0.60} D \in [1, 171] (R^2 = 0.997)$	$I_{2.2} = 16.92D^{-0.53} D \in [1, 160] (R^2 = 0.998)$
30	$I_{1.2} = 26.24D^{-0.64} D \in [1, 143] (R^2 = 0.996)$	$I_{2.2} = 18.09D^{-0.57} D \in [1, 132] (R^2 = 0.995)$
35	$I_{1.2} = 35.47D^{-0.65} D \in [1, 123] (R^2 = 0.958)$	$I_{2.2} = 19.55D^{-0.58} D \in [1, 112] (R^2 = 0.985)$
40	$I_{1.2} = 40.59D^{-0.78} D \in [1, 103] (R^2 = 0.966)$	$I_{2.2} = 22.15D^{-0.64} D \in [1, 92] (R^2 = 0.984)$
45	$I_{1.2} = 41.12D^{-0.78} D \in [1, 83] (R^2 = 0.932)$	$I_{2.2} = 23.19D^{-0.69} D \in [1, 72] (R^2 = 0.981)$
50	$I_{1.2} = 41.26D^{-0.86} D \in [1, 65] (R^2 = 0.981)$	$I_{2.2} = 23.50D^{-0.74} D \in [1, 55] (R^2 = 0.980)$
55	$I_{1.2} = 38.63D^{-0.88} D \in [1, 53] (R^2 = 0.950)$	$I_{2.2} = 23.31D^{-0.70} D \in [1, 42] (R^2 = 0.932)$
60	$I_{1.2} = 31.49D^{-0.92} D \in [1, 40] (R^2 = 0.992)$	$I_{2.2} = 20.73D^{-0.86} D \in [1, 30] (R^2 = 0.977)$
65	$I_{1.2} = 29.14D^{-0.95} D \in [1, 32] (R^2 = 0.957)$	$I_{2.2} = 18.10D^{-0.91} D \in [1, 22] (R^2 = 0.893)$
70	$I_{1.2} = 23.05D^{-0.96} D \in [1, 25] (R^2 = 0.998)$	$I_{2.2} = 13.04D^{-0.93} D \in [1, 15] (R^2 = 0.995)$
75	$I_{1.2} = 21.13D^{-0.97} D \in [1, 22] (R^2 = 0.994)$	$I_{2.2} = 10.90D^{-0.95} D \in [1, 12] (R^2 = 0.995)$
80	$I_{1.2} = 18.72D^{-0.98} D \in [1, 20] (R^2 = 0.997)$	$I_{2.2} = 9.96D^{-0.95} D \in [1, 11] (R^2 = 0.999)$
85	$I_{1.2} = 18.47D^{-0.99} D \in [1, 18] (R^2 = 0.999)$	$I_{2.2} = 8.17D^{-0.95} D \in [1, 9] (R^2 = 0.999)$

286 Under the condition of  $AEP < 10$  mm, Dens-ID cannot derive the threshold curve  
 287 corresponding to even the minimum density value of  $1.2 \text{ g/cm}^3$ , which indicates that the subsequent  
 288 rainfall can hardly trigger debris flow JJG. Table 1 also shows that the AEP ranging from 10 to 85  
 289 mm can significantly affect the ID threshold curve, because the parameters including  $\alpha$  and  $\beta$   
 290 regularly respond to the change in AEP.

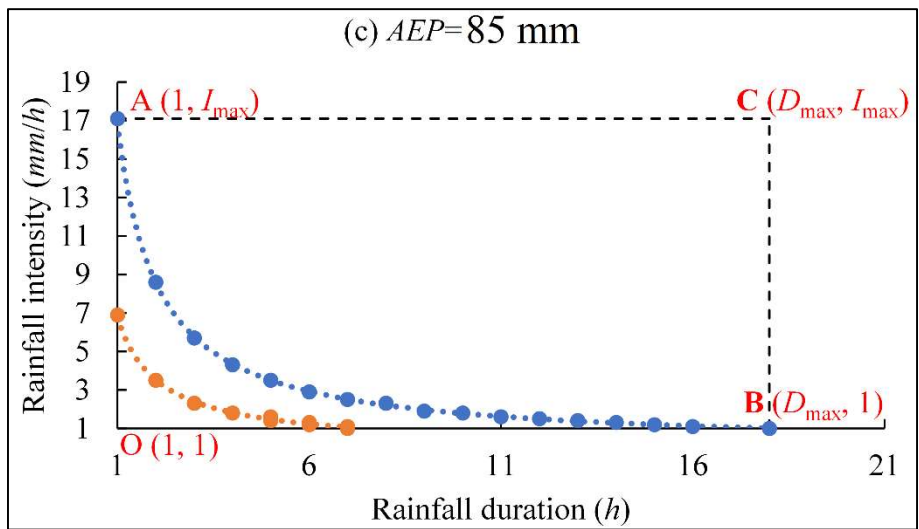

291

292

293

294

295

296 Fig.2 ID threshold curves derived by Dens-ID (the blue dotted line corresponds to  $1.2 \text{ g/cm}^3$ , and

297 the orange dotted line corresponds to  $2.2 \text{ g/cm}^3$ )

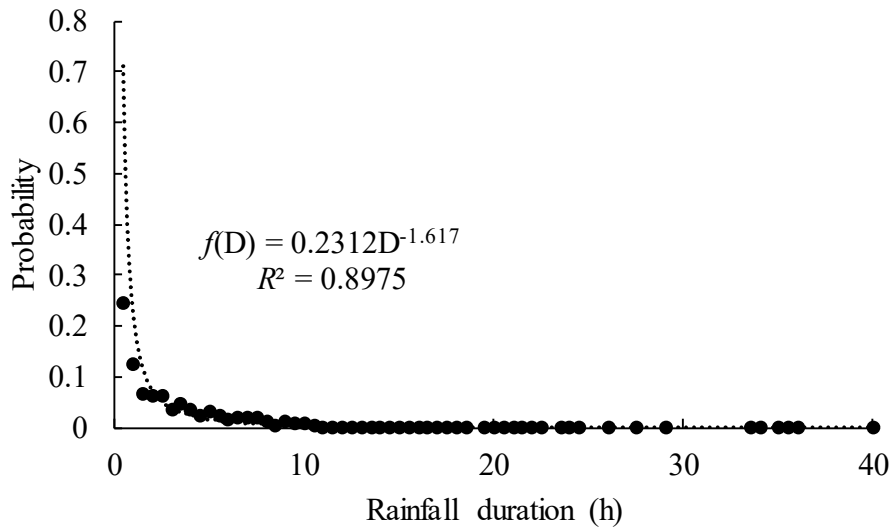

298 There are two ID threshold curves in each subplot of Fig. 2, which correspond to  $1.2 \text{ g/cm}^3$  and  
299  $2.2 \text{ g/cm}^3$ , respectively. Because the debris flow density in JJG varies within a certain range from  
300  $1.2\text{--}2.3 \text{ g/cm}^3$ , the two ID threshold curves shown in each subplot can be regarded as the upper and  
301 lower boundary lines for determining the occurrence of debris flow (Zhang et al., 2020). Within the  
302 ID coordinate system, the two derived curves together with the I- and D-axes delineate a closed area  
303 shown in Fig.2c. Any subsequence rainfall represented by the combination of I and D falling into  
304  $W_{ID}$  may trigger a debris flow. As shown in each subplot, the threshold curve can be represented by  
305 the power function  $I=\alpha D^\beta$ . The variation intervals of the independent (D) and dependent (I) variables  
306 of the power function are  $[1, D_{\max}]$  and  $[1, I_{\max}]$ , respectively, where  $D_{\max}$  represents the rainfall  
307 duration required to trigger debris flow when  $I= 1 \text{ mm/h}$ , and  $I_{\max}$  represents the rainfall intensity  
308 required for debris flow formation for  $D=1 \text{ h}$ . As shown in Fig.2c, independent variable D and  
309 dependent variable I can delineate a larger rectangular area (AOBC) in the ID plane than  $W_{ID}$ , which  
310 is denoted as  $R_{ID}$ . The coverage area of  $R_{ID}$  is much larger than that of  $W_{ID}$  indicating that the  
311 proportion of rainfall conditions that can trigger debris flows is low. Therefore, even for AEP=85  
312 mm, the occurrence probability of debris flows remains low. As shown in each subplot, each AEP  
313 corresponds to a different  $W_{ID}$  and  $R_{ID}$ , which provides basic data for the quantitative evaluation of  
314 the effect of different AEPs on the occurrence probability of debris flows.

#### 315 **4.2 Occurrence probability of debris flow under different AEP**

316 Based on the Monte Carlo method of calculating the definite integral, it is necessary to explore  
317 the probability density function of rainfall duration (D) to calculate the occurrence probability of  
318 debris flow under different AEP conditions. For the 1094 rainfall events listed in Appendix 1, we

319 found that the probability distribution of rainfall duration  $D$  in JJG can be described by a power  
 320 function (Fig. 3). As shown in Fig.3, the number of samples with  $D < 1$  accounted for 37.7%,  $1 < D < 3$   
 321 for 23.5%,  $3 < D < 5$  for 14.7%, and  $5 < D < 10$  for 16.9%; the number of rainfall events with  $D$   
 322 exceeding 10 h accounted for only 6.7%.

323

324 Fig. 3 Probability density function of  $f(D)$

325 Based on the probability density distribution function  $f(D)=0.2312D^{-1.617}$ , the cumulative  
 326 probability function  $cdf(D)$  can be obtained through integration. In  $cdf(D)$ , denoted as Equation 13,  
 327 the integration constant  $C$  needs to be determined.

328 
$$cdf(D) = \int_{-\infty}^D f(D) dD = -0.3747 * D^{-0.617} + C \quad (13)$$

329 The range of 0–40 h is evenly divided into 56 statistical intervals (the second column in  
 330 Appendix 2, titled “appendix 2-f(D)and CFD(D).xlsx”), and each statistical interval is separated by  
 331 0.5 h. The proportion of the sample size in each interval among the 1094 samples can be calculated  
 332 and listed in the second column in Appendix 2; the cumulative proportion that increases with  $D$  is  
 333 also derived and listed in the third column in Appendix 2. The data in the first and third columns of  
 334 Appendix 2 are substituted into Equation 13 to calculate  $C$ . The results show that  $C$  increases with  
 335  $D$  but gradually stabilizes at approximately 1.04 (the fifth column in Appendix 2). Therefore,  $C$  is

336 set to 1.04.

337 Based on the process of calculating  $P_{df}$  under different AEP conditions in Section 3.4, the  $P_{df}$   
338 corresponding to each AEP in Table 1 is obtained, and the function  $P_{df} = f(AEP)$  for describing  
339 their relationship has been fitted using the AEP and  $P_{df}$  data.

$$340 \quad P_{df} = 0.3442e^{0.0457AEP} \quad (14)$$

341 As shown in Equation 14, the relationship of AEP and  $P_{df}$  obeys the rule of exponential function  
342 as AEP changes from 10 to 85 mm, whereas  $P_{df} = 0$  when AEP is less than 10 mm. The evolution  
343 of  $P_{df}$  with AEP variation can be divided into two stages (Fig. 4). Two key issues must be stated  
344 before discussing the two stages in depth: (1) Based on the calculation results of the Dens-ID model,  
345 an upper limit volume of the rainfall-induced solid material supply is derived in JJG, which is the  
346 basic condition for determining the scale of debris flow in JJG (Zhang et al., 2020). (2) Based on  
347 the principle of water balance, AEP is defined as the rainfall that is preserved in the soil before the  
348 triggering rainfall process (Kohler and Linsley, 1951); field observations in JJG show that the AEP  
349 is positively correlated with the soil water content (Cui et al., 2007), and the field observations of  
350 the Liudaogou catchment in the northern Loess Plateau of China have the same result (Zhu and  
351 Shao, 2008); therefore, the AEP is typically used to estimate soil water content (Crozier, 1986; Chen  
352 et al., 2018; Zhao et al., 2019b). The water soil content before the triggering rainfall process can be  
353 characterized by AEP (Thomas et al., 2019; Schoener and Stone, 2020).

363

364

365

366

367

368

369

Stage 1: The probability of debris flow occurrence in JJG is equal to 0 when the AEP is < 10 mm. Dens-ID estimates the solid material volume by simulating rainfall-induced shallow landslides. According to Equation 4, the key hydrological process that triggers shallow landslides is the continuous increase in soil water content caused by rainfall infiltration. The increase in soil moisture content reduces soil matrix suction and eventually contributes to shallow landslides. The soil water content of the loose soil mass in JJG is low when the AEP < 10 mm (Long et al., 2020), and a long duration of rainfall infiltration is needed to increase the soil water content. However, based on the infiltration border of Dens-ID (Equation 1), limited by the infiltration capacity of the topsoil in JJG, the portion of precipitation that exceeds the infiltration capacity is be converted into runoff; therefore, when the water content of the soil layer in JJG is low, the surface runoff can be rapidly generated. Therefore, the runoff generation rate can be much higher than the supply rate of solid material in the condition of AEP < 10 mm. In this hydrological scenario, Dens-ID determines that even a soil-water mixture with a density of 1.2 g/cm<sup>3</sup> is difficult to generate in JJG; thus, the probability of debris flow is 0.

370 Stage 2: When AEP varies within the interval of 10 mm-85mm, the subsequent rainfall is  
371 capable of triggering debris flow in JJG. Compared to AEP < 10 mm in Stage 1, the soil water  
372 content within JJG increased significantly. Therefore, the solid material from shallow landslides can  
373 be immediately ready without a long rainfall infiltration duration, and a large water content of  
374 topsoil is beneficial to the rapid generation of runoff (Jones et al., 2017; Hirschberg et al., 2021).  
375 When there is a sufficient supply of solid material and runoff, the probability of debris flow  
376 occurrence in Stage 2 is significantly increased by the increasing AEP. The relationship between  
377  $P_{df} \sim AEP$  can be described by an exponential function of  $P_{df} = 0.3442e^{0.0457AEP}$ . The exponential  
378 function and its boundary show that the increasing tendency of  $P_{df}$  is a little sluggish before AEP is  
379 equal to 50 mm. The occurrence probability of debris flow in JJG is only 15.88% even when AEP  
380 is equal to 85 mm.

## 381 **5 Discussions**

### 382 **5.1 Correlation analysis of the two curves derived from Dens-ID and observation data**

383 The AEP in Appendix 1 varied from 0–87.9 mm, according to this range, we can test the  
384 reasonability of the relationship between  $P_{df} \sim AEP$  shown in Fig. 4. We introduce how to use the  
385 rainfall and debris flow data recorded in Appendix 1 to calculate  $P_{df}$ : (1) The original AEP value is  
386 rounded to one decimal place, and the rounded AEP are listed in the 8<sup>th</sup> column of Appendix 1,  
387 which were sorted from largest to smallest; (2) the maximum AEP<sub>i</sub> was set to 85 mm, and [AEP<sub>i</sub>,  
388 AEP<sub>i</sub>-5] was used as the search window to collect the rainfall events and debris flow events; and (3)  
389 we count the number of debris flow events  $N_{df}$  and the number of rainfall events  $N_{rain}$  in each search  
390 window and then calculate  $P_{df} = N_{df}/N_{rain}$ . Based on the above steps, the collected data and calculated

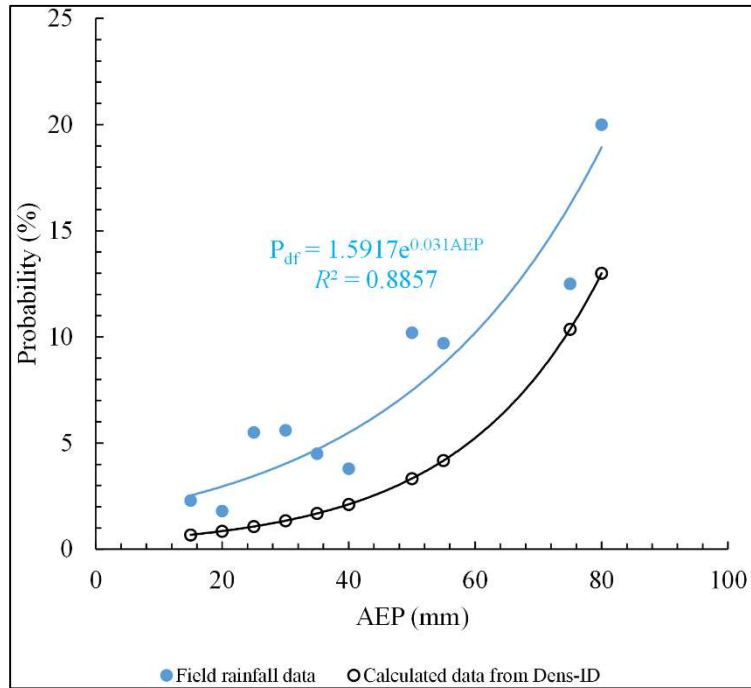

391  $P_{df}$  are listed in Table 2. As shown in Table 2, a positive correlation between the probability of debris  
 392 flow occurrence and AEP in JJG was determined. When AEP < 10 mm, a total of 205 rainfall  
 393 processes were recorded; however, no debris flow events were observed, and the debris flow  
 394 occurrence probability was 0, which is consistent with the results of Stage 1 derived from Dens-ID.

395

Table 2 Collected and calculated  $P_{df}$  in each search window

	Field observation data and calculated $P_{df}$										
AEP	10	15	20	25	30	35	40	45	50	75	80
$N_{df}$	0	3	2	7	7	4	4	5	3	1	1
$N_{rain}$	205	133	111	127	124	106	106	49	31	8	5
$P_{df}(\%)$	0	2.3	1.8	5.5	5.6	3.8	3.8	10.2	9.7	12.5	20

396 Based on  $P_{df}$  and AEP listed in Table 2, their relationship can be described by the exponential  
 397 function denoted as  $P_{df} = 1.5917e^{0.031AEP}$ , which is similar to Equation 14 drawn in Fig.4. The  
 398 two curves were nearly parallel. Equation 12 was used to analyze the correlation of the two curves,  
 399 and  $r$  is equal to 0.93, suggesting they have a very high correlation. Therefore, the function of  $P_{df} =$   
 400  $f(AEP)$  derived from Dens-ID, which is used to describe the evolution trend of debris flow  
 401 occurrence probability with AEP variation, is reasonable.

402

403 Fig.5 Relationship of AEP and  $P_{df}$  obtained from field observation data and Dens-ID model (the blue line is

404 derived from field observation data, and the black line is derived from Dens-ID)

405 We can also see from Fig.5 that although the variation tendencies of the two curves are

406 consistent, a significant bias existed between them. Basically, the probability value derived from the

407 field observation data is larger than that from the Dens-ID model in the condition of a given AEP.

408 As shown in Fig.5, the blue line fitted through the observation data is above the black line derived

409 from Dens-ID, indicating that Dens-ID underestimated the probability of debris flow occurrence if

410 the observation data were used as the reference. Taking the probability value in the 6<sup>th</sup> row of Table

411 2 as references, the error of the Equation 14 was calculated using the AEP in Table 2 as inputs and

412 listed in Table 3.

413 Table 3 Error estimation on the Equation 14

AEP	15	20	25	30	35	40	45	50	75	80
Error	0.70	0.53	0.81	0.76	0.63	0.44	0.67	0.57	0.17	0.35

414 It can be seen that very large bias of Equation 12 is listed in Table 2. However, we cannot

415 conclude that there is a precision problem in the calculation results of the Dens-ID. Because (1)  
416 Although 1094 rainfall processes and 37 debris flow events are the field observation data, there are  
417 many uncertain factors in Equation 7 for calculating AEP using these rainfall data (Kim et al., 2021),  
418 such as the subjectivity existing in  $K$  and  $n$  of Equation 7, which render uncertainty in the calculated  
419 AEP. In this case, if the data in Appendix 1 are used as the real value for evaluating the precision of  
420 Dens-ID, the error evaluation result may be unfair to Dens-ID. In this case, it is unfair to evaluate  
421 the Dens-ID error by using the calculated AEP in Appendix 1 as the true value. However, this  
422 uncertainty can show consistent directional deviations because of the fixed values of  $K$  and  $n$  in  
423 Equation 7; therefore, the uncertainty has no effect on the correlation analysis. (2) To establish the  
424 functional relationship between  $P_{df}$ -AEP, many rainfall scenarios were simulated using the Dens-ID  
425 model. Dens-ID simulated 3376, 3182, 2677, and 2677 rainfall processes with AEP = 20, 40, 45,  
426 and 50 mm, respectively. The total number of simulated rainfall processes was significantly larger  
427 than that of the 1094 observed rainfall events. The collected 1094 rainfall events still cannot fully  
428 reflect all rainfall conditions in nature; that is, the amount of the observed 1094 rainfall data is still  
429 inadequate when used as the denominator for calculating the probability of debris flow occurrence  
430 in JJG. Therefore, the  $P_{df}$  calculated using the field observation data may be generally higher than  
431 that calculated using Dens-ID. With the accumulation of rainfall observation data of JJG, it is  
432 believed that the Pdf derived from field observation data will gradually decrease until it is close to  
433 the calculated value of Dens-ID model. (3) Dens-ID cannot fully and accurately describe the  
434 formation process of the debris flow in JJG because of the simplification in theory and boundaries.  
435 Dens-ID is also affected by the accuracy of the input parameters (Zhang et al., 2020), which may  
436 eventually lead to deviations between the simulation results and field observations.

437 5.2 Potential application and limitation

438 Deriving a quantified functional relationship of  $P_{df}$  and AEP would be more conducive to  
439 examining the correspondence between these two parameters. Using mathematical physics method,  
440 the function of  $P_{df} = f(AEP)$  was firstly derived which can help us to learn more from the derived  
441  $P_{df} = f(AEP)$ .

442 Firstly, AEP is indeed an important factor affecting debris flow. Generally, there is the  
443 following consensus in the field of debris flow: the greater the AEP, the higher the probability ( $P_{df}$ )  
444 of subsequent rainfall triggering the debris flow (De Vita et al., 2000; Bel et al., 2017). However,  
445 this fuzzy qualitative description cannot explain the influence degree of AEP on the probability of  
446 debris flow induced by subsequent rainfall. It can be seen from  $P_{df} = f(AEP)$  that there are two  
447 key value nodes of AEP affecting  $P_{df}$ : (1) point 10 mm: the case of  $AEP < 10$  mm indicates that  
448 any subsequent rainfall cannot trigger debris flow in JJG. Because the supply rate of solid material  
449 is much lower than the runoff generation rate during subsequent rainfall in JJG, the water-soil  
450 mixture within tends to be a hyperconcentrated flow rather than a debris flow (Long et al., 2020);  
451 (2) Point 50 mm: the case of  $10 \text{ mm} \leq AEP \leq 50 \text{ mm}$  means that the soil water content increases  
452 significantly compared to  $AEP < 10$  mm, but a necessary infiltration time to increase it to the critical  
453 state for triggering shallow landslides is still required. Therefore, limited by the supply rate of the  
454 solid material, the increasing rate of  $P_{df}$  is sluggish. The case of  $50 \text{ mm} < AEP \leq 85 \text{ mm}$  represents  
455 the soil water content is relatively larger, the solid material from shallow landslides can be  
456 immediately ready without a long rainfall infiltration duration, and a large soil water content of  
457 topsoil is beneficial to the rapid generation of runoff (Jones et al., 2017; Hirschberg et al., 2021).  
458 When there is a sufficient supply of provenance and runoff, the probability of debris flow occurrence

459 in this subprocess is significantly enhanced by the increasing AEP.

460 Secondly, Rainfall-induced debris flow is a small probability event compared with the rainfall  
461 frequency in nature. JJG is well-known due to its high-frequency debris flow event. However, the  
462 formation probability of debris flow in JJG induced by subsequence rainfall is only 15.88% even  
463 the AEP reaches to 85 mm. Therefore, debris flow induced by rainfall in JJG is a small probability  
464 event compared with the rainfall frequency. The figure of 15.88% means that the efficiency of rain-  
465 induced debris flow is extremely low, which also indicates that the formation of debris flow is an  
466 extremely complex physical process, in which rainfall is only one of the motivating factors, and  
467 there are other more important internal factors affecting the formation of debris flow, such as  
468 topography, source recharge and fluid characteristics of debris flow (Zhang et al., 2020). Thirdly, in  
469 practical application, when the AEP in JJG is calculated according to Equation 7, the derived  
470 exponential function can help us to assess the probability of debris flow in JJG triggered by  
471 subsequent rainfall, according to which debris flow warning information can be issued in advance  
472 to provide technical support for disaster prevention and reduction.

473 Our study also has its own limitations and needs to be listed for providing directions for  
474 subsequent investigation. (1) Long-term observation data should be used to deduce the functions of  
475  $P_{df} = f(AEP)$ , however, the number of debris flow gullies with long-term observational data  
476 worldwide is less than 10 (Hürlimann et al., 2019), accordingly, the function of  $P_{df} = f(AEP)$   
477 cannot yet be derived in other debris-flow gullies. (2) Dens-ID model assumes that the solid  
478 material mainly comes from shallow landslides. However, the formation mechanism and solid  
479 source supply mode of runoff-induced debris flow are different. Therefore, the functional of  $P_{df} =$   
480  $f(AEP)$  for runoff-induced debris flow still needs to be studied with the help of other physical

481 models. (3) The calculation result of  $P_{df} = f(AEP)$  derived from Dens-ID model has a large bias  
482 from the observation data, the authors think that the main reason is insufficient field observation  
483 data especially inadequate rainfall data. Basically, even for high-frequency debris flow gullies like  
484 JJG, the success rate of debris flow induced by rainfall is still very low. Continuous increase of  
485 rainfall and debris flow observation data will make the growth rate of  $N_{rain}$  in Table 2 much higher  
486 than that of  $N_{df}$ . Therefore, with the accumulation of rainfall observation data of JJG, it is believed  
487 that the  $P_{df}$  derived from field observation data will gradually decrease until it is close to the  
488 calculated result of Dens-ID model. Therefore, the authors will continue to collect field observation  
489 data of JJG in the later period, and constantly verify the accuracy of Equation 14 derived from Dens-  
490 ID.

## 491 **5 Conclusions**

492 The Dens-ID model and Monte Carlo integral equation is used to derive function of  $P_{df} =$   
493  $f(AEP)$ . The functional relationship is verified using a large amount of field observation data from  
494 JJG. The following conclusions are drawn as follows.

495 The positive relationship between  $P_{df}$  and AEP is now described by a clear mathematical  
496 equation in this study. the effective range of AEP that can affect debris flow formation verifies within  
497 10–85 mm. Based on the simulation results, the probability of debris flow occurrence in JJG is 0 in  
498 the condition of  $AEP < 10$  mm, and the relationship between  $P_{df}$  and AEP can be described by an  
499 exponential function when  $10 \text{ mm} \leq AEP \leq 85 \text{ mm}$ . The plausibility of the first two evolution stages  
500 of the  $P_{df}$ -AEP piecewise function is effectively confirmed by the field observation data because the  
501  $P_{df}$ -AEP relationship obtained from field observation data is highly correlated with the simulation  
502 results of Dens-ID. However, the reasonability of the last two stages of the  $P_{df}$ -AEP piecewise

503 function cannot be tested because of the lack of field observation data, and the errors of the  $P_{df}$ -AEP  
504 piecewise function cannot be verified because of the uncertainty of the AEP derived from the  
505 observation rainfall data.

506 This study mathematically confirms that "the greater the AEP, the higher the probability of  
507 subsequent rainfall triggering debris flow" and quantifies this qualitative conclusion using piecewise  
508 functions. This can effectively reveal the essential relationship between the two natural events of  
509 rainfall and debris flow, quantitatively describe the impact of different AEPs on the probability of  
510 debris flow occurrence, and provide key technical support for the early warning of debris flows.
