Abstract. Vegetation plays a key role in the hydrological and biogeochemical cycles. It can influence soil water fluxes and transport which are critical for chemical weathering and soil development. In this study, we investigated soil water balance and solute fluxes in two soil profiles with different vegetation types (cushion-forming plants vs. tussock grasses) by measuring soil water content, flux, and solute concentrations and by modeling soil hydrology. We also analyzed the role of 20 soil water balance in soil chemical weathering. The influence of vegetation on soil water balance and solute fluxes is restricted to the A horizon. Evapotranspiration is 1.7 times higher and deep drainage is 3 times lower under cushion-forming plants than under tussock grass. Likewise, cushions transmit almost threefold less water from the A to lower horizons. This is attributed to the vertical distribution of soil properties associated with the root systems. Under cushion-forming plants, DOC and metals (Al, Fe) are mobilized in the A horizon. Solute fluxes that can be related to plant nutrient uptake (Mg, Ca, 25 K) decline with depth as expected from bio-cycling of plant nutrients. Dissolved silica and bicarbonate are minimally influenced by vegetation and represent the largest contributions of solute fluxes. Soil chemical weathering is higher and constant with depth below tussock grasses; while lower and declining with depth under cushion-forming plants. This difference in soil weathering is attributed mainly to the water fluxes. Our findings reveal that vegetation can modify soil properties in the uppermost horizon altering the water balance, solute fluxes, and chemical weathering throughout the soil 30 profile.

1 Introduction

Soil hydrology regulates the chemical weathering of primary minerals in the regolith (Maher, 2010; Maher and Chamberlain, 2014; Velbel, 1993). Soil water flux and transport depend on soil water content (Rodriguez-Iturbe, 2000), and both are

35   critical for chemical weathering and soil development (Brantley et al., 2011; Calabrese & Porporato, 2020). For a given availability of reactive weathering products, slow water flux and transport within the soil mantle facilitate the buildup of solute concentrations (up to saturation) and eventually the formation of secondary solid phases (Pope, 2015). In contrast, high soil water flux (e.g., during hydrological events) can flush out water-soluble products from the vadose zone, resulting in a reduction of concentrations of weathering products in the soil (Berner & Berner, 2012; Perdrial et al., 2015). In well-

40   drained soil systems (e.g., fluid residence times between 5 days to 10 years), chemical weathering rates are proportional to water fluxes (Berner, 1978; Lasaga et al., 1994; Maher, 2010).

The influence of soil hydrology on chemical weathering rates has mostly been assessed through proxy variables, like soil water availability or soil moisture (Daly and Porporato, 2005; Moore et al., 2015; White et al., 2005). Soil water availability

45   can be approached using the ratio of mean annual rainfall to potential evapotranspiration, as illustrated in studies of soil development along climatic gradients (Chadwick et al., 2003; Dixon et al., 2016; Schoonejans et al., 2016) and even at the global scale (Calabrese and Porporato, 2020). While these investigations have recognized the importance of water flux and transport in soil weathering, only a few of them directly assessed how soil water fluxes (Clow and Drever, 1996; Maher, 2010; White et al., 2009) and hydrological processes, like infiltration and storage (Cipolla et al., 2021; García-Gamero et al.,

50   2022), control weathering processes. Moreover, the effect of water balance on soil weathering can be elusive due to the potential influence of less-explored co-evolving soil formation factors, notably lithological and climatic settings (Schoonejans et al., 2016).

Soil weathering can be assessed from the solid and solute chemical distributions in the soil mantle. Changes in the solid-

55   phase soil mass derived from elemental mass balances are measures of long-term weathering (White, 1995; White et al., 1998, 2009), whereas contemporary solute fluxes reflect weathering rates at short time scales (White & Buss, 2014; White, 1995). Soil weathering processes vary with depth, chemical weathering is more pronounced near the surface (A, E horizons) and decreases with depth through the B horizon to the less weathered C horizon (White, 1995). The depth gradient in weathering extent is associated with the solution pH, dissolved Al, and organic and carbonic acids influencing dissolution

60   reactions, as well as with the hydraulic conductivity that affects water flux and transport (Anderson et al., 2007). The water residence time plays a critical role in the depth variation of the soil weathering extent, as it increases with depth in the soil leading to a longer time for reaction between water and the surfaces of soil particles (Pope, 2015).

Vegetation plays a key role in the hydrological cycle at different spatial and temporal scales by extracting water from the soil and influencing water pathways and fluxes (Brantley et al., 2017; Drever, 1994; Kelly et al., 1998; Moore et al., 2015). The soil water availability and seasonal water balance can, in turn, determine the distribution of vegetation types (Tromp-van Meerveld and McDonnell, 2006; Berghuijs et al., 2014). Vegetation development can co-evolve with soil weathering extent by vegetation adapting to and transforming its environment through biogeochemical weathering (Sivapalan, 2018). Soil-vegetation-water interactions are not fully understood. For instance, the influence of soil type and properties can overrule the effects of vegetation type on dynamic soil water storage change and residence time in conditions of low precipitation seasonality and low evaporation (Geris et al., 2015). Conversely, soil structure and hydraulic properties associated with vegetation (e.g., distance from trees) can control the spatial patterns of soil water content (Metzger et al., 2017). Moreover, the presence and architecture of root systems can increase soil porosity and saturated hydraulic conductivity affecting water infiltration (Jiang et al., 2018) and also explain the variability in evapotranspiration at a given climatic condition (Hunt, 2021).

Vegetation can directly influence biogeochemical processes and facilitate soil weathering in several ways. For example, by (i) root and microbial respiration, increasing concentrations of carbon dioxide in the soil and thus, lowering soil solution pH, (ii) root penetration, enhancing pathways for subsurface flow, (iii) production of organic acids and compounds from the decay of organic matter or root exudation, resulting in lower pH and in chelates that mobilize soluble metal complexes as well as alter nutrient exchanges, (iv) uptake of water and solutes in the rhizosphere, resulting in changes of ion concentrations in soil solution (v) cycling nutrients (e.g., Ca, Mg, K) through litter and roots, which can result in higher concentrations in soil solution in the upper horizons (Brantley et al., 2012; Hinsinger et al., 2006; Kelly et al., 1998; Pope, 2015). Likewise, biota effects on weathering can also be present in chemical gradients (e.g., pH, solute concentrations) along with soil depth even at millimetric scales (Chorover et al., 2007).

Here, we take advantage of the mosaic-like distribution of vegetation types in the high Andes ecosystem, changing over short distances and allowing other factors (i.e., climate, geology, soil age, and topography) to remain constant (Molina et al., 2019). We hypothesize that vegetation type has an impact on water and solute fluxes and further on soil chemical weathering at the soil profile scale. The main research questions addressed in this study are: (i) what are the effects of vegetation type and associated soil properties on soil water balance?; (ii) to what extent do soil-vegetation associations alter solute fluxes?; (iii) how does vegetation alter contemporary soil weathering through soil water balance? The HYDRUS-1D model was used to simulate soil hydrological processes at daily timesteps, including evapotranspiration, deep drainage, and soil water storage. Simulated water fluxes at soil horizons were validated with independent field measurements. Soil solutions were sampled at biweekly intervals, and their compositions served to estimate solute fluxes. The influence of the infiltrated water fluxes on solute fluxes and soil chemical weathering was analyzed. Overall, this study assesses the influence of vegetation

type and associated soil properties on soil water balance, solute fluxes, and contemporary soil chemical weathering at the soil profile scale.

2 Páramo Ecosystem

100   The high Andean ecosystem, known as *páramo,* is a cold and humid Neotropical alpine region with high solar radiation and low-intensity rainfall. It is situated between forest and snow lines and is characterized by soils of volcanic origin (Aparecido et al., 2018) covered by a highly diverse mosaic of endemic plants adapted to extreme climatic conditions (Myers et al., 2000; Körner, 2003). Soils are characterized by high porosity, high organic matter content, low bulk density as well as high hydraulic conductivity. Subsurface water flow is dominant (Correa et al., 2017; Mosquera et al., 2022), and overland rainfall

105   runoff is only reported in anthropogenically degraded *páramo* soils (Harden, 2006). Chemical weathering has been reported to exceed physical erosion in *páramo* catchments (Tenorio et al., 2018), similar to what was observed in other alpine environments (Dixon & Thorn, 2005). In the total solute load of *páramo* stream waters, the fluxes of bicarbonate, dissolved silica and dissolved organic carbon are dominant (Arízaga-Idrovo et al., 2022; Tenorio et al., 2018).

110   Previous work mostly focused on vegetation effects on individual components of the soil water balance, like interception, evapotranspiration, or soil weathering. Carrillo-Rojas et al. (2019) showed that the actual evapotranspiration can represent half of the annual rainfall in tussock grasslands, and Ochoa-Sánchez et al., (2018) pointed to the importance of vegetation interception that can vary between 10 – 100 % depending on the total rainfall. Significant differences in soil chemical weathering were associated with vegetation patterns (Molina et al., 2019), but it is not yet clear how vegetation can influence

115   contemporary weathering rates through its effect on soil water fluxes and transport.

This study contributes to filling this knowledge gap by examining the differences in soil hydrology and chemical weathering rates in two pedons with different vegetation cover, located at summit topographic positions. The soil profiles covered by tussock grass and cushion-forming plants consist of polygenetic, young volcanic ash soil; and are located in the northern

120   Ecuadorian *páramo*.

3 Materials and methods

3.1 Study Sites

The *páramo* ecosystem supplies drinking water to more than half a million inhabitants of Ecuador's capital, Quito (EPMAPS and FONAG, 2018). The study sites are located on the western slopes of the Antisana volcano within the Antisana´s Water

125   Conservation Area (Antisana's WCA; Fig. 1b). The area is managed by the Fondo de Protección del Agua (FONAG) and since 2011 all anthropogenic activities and extensive grazing have been prohibited. Two soil profiles with distinct vegetation

types, i.e. cushion-forming plants (CU-UR) and tussock grass (TU-UP), were excavated (Fig. 1a). Due to the location of the soil profiles at the crest of a headwater sub-catchment in Jatunhuayco watershed and their low slope gradients (≤ 6.5 %), we posit that vertical downward water flow is dominant in the soil profiles. The mean annual meteorological variables as recorded in 2019-2020 at the JTU_AWS station (Fig. 1a) are summarized as follows: rainfall 723.3 ± 7.4 mm, air temperature 4.3 ± 0.5 ºC, incoming shortwave radiation 169.2 ± 9.1 W m^{-2}, relative humidity 92.9 ± 0.9 %, wind speed 3.4 ± 0.3 m s^{-1}, and predominant wind direction from east to west. Vegetation species on the TU-UP and CU-UR profiles are dominated by *Calamagrostis intermedia* and *Azorella pedunculata*, respectively. Rooting depth is 70 cm at TU-UP and 30 cm at CU-UR. The soils in the upper 1 m are polygenic vitric Andosols (Calispa et al., 2021) developed from Holocene ash depositions (Hall et al., 2017). Four horizons have been identified, the upper organic-rich A horizon on top of a buried 2A horizon, and below two mineral horizons 2BC and 3BC (Table 1). These horizons are characterized by a decreasing gradient with depth of organic carbon, hydraulic saturated conductivity, and water retention (Páez-Bimos et al., in rev.). The recent soils are developed on top of a ~27 m thick sequence of paleosols and tephra layers that are overlaying scoria-rich layers and glaciofluvial sediments (Hall et al., 2017).

3.2 Soil hydro-physical and chemical properties

Undisturbed soil samples (100 cm^3) were collected in duplicate (next to each other) at 9 vertical positions (15, 25, 35, 45, 55, 65, 75, 85, 95 cm) for both profiles. For the TU-UP profile, the first sample was taken at 10 cm. We determined water retention at high matric potentials (0, -3, -6, -10, -24, and -46 kPa) on the undisturbed samples by the multi-step apparatus (van Dam et al., 1994). Afterward, these samples were dried and weighed to calculate the bulk density (BD), expressed in g cm^{-3}. We determined water retention at lower matric potentials (-100, -300, and -1500 kPa) on saturated disturbed samples

160 by the Eijkelkamp pressure membrane apparatus (Klute, 1986). A total of 36 undisturbed and 18 undisturbed samples were measured at the Hydro-physics laboratory, Universidad de Cuenca. Water retention is reported as the volumetric water content (θ, cm^3 cm^{-3}) for a given matric potential ψ_m (kPa) and was determined for saturation (θ_{SAT}) at 0 kPa, field capacity (θ_{FC}) at -10 kPa, and wilting point (θ_{WP}) at -1,500 kPa. The total available water (θ_{TAW}) is calculated as the difference between water retention at field capacity and wilting point. The saturated hydraulic conductivity (K_{SAT}) was measured in

165 replicates per soil horizon by the Guelph Permeameter (Soilmoisture Equipment Corp) using the two heads method (5 and 10 cm) (Reynolds and Elrick, 1985). The replicates were taken at > 3 m from each other (Table S1 in Supplementary material 1). A total of 17 K_{SAT} measurements were taken at both soil profiles. Soil texture was determined by the laser diffraction particle sizing analyzer (LS 13 320, Beckman Coulter) at the Geo-Institute of KU Leuven. Sample preparation consisted in grinding and sieving (2 mm) the dry soil samples, removal of carbonates (if any) with 10% HCl, and organic

170 matter with 35% hydrogen peroxide. The soils were then treated with ultrasonics to disperse clays. A total of 10 disturbed samples corresponding to one sample per soil horizon were used for the texture analysis. The texture is expressed as a percent of the bulk soil (%) and classified based on the following particle size ranges: sand (2000 – 50 µm), silt (50 – 2 µm), and clay (< 2 µm).

175 Soil chemical properties were determined at the MOCA platform, Earth and Life Institute, UCLouvain based on 10 disturbed samples taken at mid-height of each horizon for both profiles. The soil organic carbon (SOC) was measured on 5-day air-dried soil samples, which were sieved through a 2 mm mesh and crushed using a vibratory disk mill (Retsch RS200). SOC was measured by dry combustion with an Elementar Variomax elemental analyzer (< 0.1% precision) and is expressed in % of dry weight soil. Soil pH was measured in a 1:5 soil-to-water (w/v) suspension with a glass electrode. Cation exchange

180 capacity (CEC, cmol$_c$ kg^{-1}) was measured by the ammonium acetate method (Pansu and Gautheyrou, 2006).

3.3 Hydrometry and water fluxes

An automatic weather station (JTU_AWS) recorded rainfall, air temperature and relative humidity, incoming solar radiation, and wind speed. To exclude potential field-scale variability in meteorology, we also measured at the TU-UP and CU-UR

185 locations rainfall, air temperature, and relative humidity. Soil moisture, expressed as the volumetric water content (VWC, in cm^3 cm^{-3}), was measured at three depths in each profile (Table 1) using water content reflectometers. Reflectometers were installed on the upslope facing wall of the soil pits in a horizontal direction (Fig. 2b, 2e). They were calibrated for each horizon and vegetation type (for ±1% accuracy, Supplementary Material 2) following earlier work in páramo soils (Iñiguez et al., 2016; Ochoa-Sánchez et al., 2018). All variables were recorded at 5-min intervals and were further aggregated to daily

190 values.

Water fluxes were measured in the 2A horizon of each soil profile using a suction (with wick, FXW) and non-suction (without wick, FX) fluxmeter (Fig. 2a, 2d). Although wick lysimeters have been extensively used to measure water fluxes (Singh et al., 2018), they may overestimate fluxes when compared to non-suction lysimeters (van der Velde et al., 2005; Weihermüller et al., 2007). The design of both fluxmeters was based on Gee et al., (2009) and van der Velde et al., (2005). They consisted of PVC tubes of 20 cm diameter inserted into the soil to a depth of 50 cm. Their lower end is in contact with a funnel filled with soil and covered with a nylon mesh of 20 µm at the bottom. For the FXW fluxmeter, one round fiberglass wick (1381 Pepperell Braiding Company) was unbraided and placed below the nylon mesh of the funnel and extended to a total length of 50 cm. The lowest part of the funnel was connected to a 1-gallon plastic container to collect water draining from the soil. The water volume was recorded biweekly with a resolution of 1 ml and converted into flux by dividing it by the internal cross-sectional area of the PVC tube (283.5 cm^2).
Figure 2: Photos of the soil pits under cushion-forming plants (CU-UR, (a), (b)) and tussock grasses (TU-UP, (c), (d)) showing the fluxmeters (a) and (c); water content reflectometers (red rectangles) and suction cups (red circles) (b) and (d).

3.4 Water flux modeling

Simulation of soil hydrology at the profiles was conducted using the one-dimensional HYDRUS-1D model (Šimůnek et al.,
2018) for the period between December 2018 to March 2021. we used the bimodal van Genuchten model (Durner, 1994) to
represent the water retention and hydraulic conductivity functions (Priesack and Durner, 2006; Dettmann et al., 2014) of the
soil. The upper boundary condition was set to an atmospheric boundary with surface runoff and the lower boundary to free
drainage. The model was set to run at a daily timestep with a calibration (22/12/2018 to 05/03/2020) and validation
(06/03/2020 to 12/03/2021) period. To reduce the number of soil hydraulic parameters, we performed a global sensitivity
analysis using the variance-based Sobol method (Sobol, 2001). Using the sensitive parameters, we carried out an inverse
numerical modeling for the calibration period by the Marquardt-Levenberg algorithm (Šimůnek and Hopmans, 2002) based
on the observed and simulated soil volumetric water content (VWC) at three depths. Supplementary Material 3 describes the
model setup, sensitivity analysis, and calibration. The goodness-of-fit was assessed by the coefficient of determination (R^2),
root mean square error (RMSE), and Kling-Gupta efficiency (KGE). Apart from the validation of the model simulations, an
independent validation was performed using the field-based water flux measurements at the 2A horizon from the FXW and
FX fluxmeters. These values were collected over 24 field visits during the period April 2019 to March 2020 and compared to
the simulated water flow at 50 cm depth that was aggregated at the same time interval (Table S3 in Supplementary Material
1). Simulated and measured water fluxes were analyzed by Spearman correlation since most water flux variables did not
show normality.

To examine the influence of vegetation on the water partitioning, we established a soil water balance ($\Delta S = P – ETa - D$) for
the upper 1-m of the soil profiles, and derived the following soil water balance components at daily and annual timescales:
the rainfall (P), the actual evapotranspiration (ETa), the soil water storage (ΔS), and the deep drainage (D). ETa was derived
from potential evapotranspiration (ETp) according to the surface pressure head and soil moisture.

3.5 Characterization of soil solutions

3.5.1 Soil solution collection and pre-treatment

Soil pore water was sampled with suction cup samplers at three depths per profile as detailed in Table 1. The samplers are
0.50 m in length with a porous ceramic cup of max. 1 μm pore size. We installed the suction lysimeters sub-horizontally
(with a 5% downward inclination) on the upslope-facing wall of the soil pit (Fig. 2b, 2e). Soil solutions were collected in
500-ml glass bottles wrapped in aluminum paper, closed with rubber stoppers, and placed inside plastic containers. All
tubing was shielded from sunlight. Suction cup samplers were installed between November and December 2018, and soil

pore water samples were analyzed over the period from April 2019 to March 2020. This left ample time for the porous cups to equilibrate with the soil conditions (Dere et al., 2019). Soil pore water was collected biweekly and a vacuum of 45-50 kPa

240   was applied after every collection. Soil solutions were filtered through 0.45 μm mixed cellulose ester filters of 47 mm (S-PAK® Membrane Filter). The material was pre-washed by passing > 150 ml of ultrapure water through the filter to avoid leachate of dissolved organic carbon from the cellulose (Khan and Subramania-Pillai, 2007). Filtered samples were split into two 30 ml plastic bottles, which were previously washed with a 0.5 M HNO_3 solution and rinsed with ultrapure water three times before use. One split was left unpreserved for analyses of anions and dissolved organic carbon (DOC), and the other

245   split was acidified to pH < 2 by adding three drops of concentrated (68 %) nitric acid for cation analysis. All samples were refrigerated at ~4 ºC during storage.

3.5.2 Water chemical analyses

In the field, electric conductivity, water temperature, and pH of all samples were measured. The alkalinity was determined in a field laboratory setup at 4010 m a.s.l. on the same day of collection using the ASTM D1067-16 (2016). For a selection of

250   13 sample collects (from a total of 24), the cation, anion, and dissolved organic carbon were determined at the MOCA platform, Earth and Life Institute, UCLouvain (Table S3 in Supplementary Material 1). Cation concentrations (total Ca, Mg, Na, K, Al, Fe, and dissolved silica (DSi)) were determined by inductively-coupled plasma optical spectroscopy (ICP-OES, Thermo Fisher iCAP 6000 Series, limit detection < 1ppb). Dissolved organic carbon (DOC) concentrations were determined by the combustion catalytic oxidation/NIR method (TOC-L Series, SHIMADZU) with a detection limit of 4 ppb. Anion

255   concentrations (Cl^-, NO_3^-, SO_4^{2-}) were determined by ion chromatography (Dionex ICS 2000, Thermo Fisher) with a detection limit of 200 ppb. All solute concentrations are reported in mg L^{-1}. We removed outliers by eliminating concentrations larger (smaller) than two standard deviations above (below) the average (Dere et al., 2019). The charge balance error (CBE) was calculated for each available sampling time. Only two soil solutions out of 66 with more than two ion concentrations equal to NA were discarded for CBE calculation.

260

Daily water fluxes simulated by the model were aggregated into biweekly intervals by addition. Biweekly solute fluxes were calculated by multiplying the solute concentrations by the biweekly water fluxes at the corresponding depth and time interval. To obtain annual solute fluxes, biweekly solute fluxes at all sampling times (n=24) were aggregated over the period 29/03/2019 to 04/03/2020. For sampling times with missing solute concentrations (n=11), we interpolated these

265   concentrations based on linear regressions between biweekly water fluxes and the available solute concentrations (Fig. S1 in Supplementary Material 1). Contemporary weathering fluxes are the sum of major cations (Ca^{2+}, Mg^{2+}, Na^+, K^+) and DSi fluxes (T.Cat.).

270

3.6 Statistical analysis

The Mann-Whitney U test was applied to test for changes in solute concentrations and solute fluxes between vegetation types (cushion vs. tussock). This test was applied for the A and 2A horizons, as these horizons correspond to the part of the

275 soil profiles where the root systems are mostly developed. To analyze the effects of seasonality on soil water balance and weathering, we separated dry, intermediate, and wet periods based on rainfall data. The dry period was defined as the months with rainfall values less than the 25th percentile of the annual average rainfall (Jan., Jul.-Sep. 2019 and Mar., Oct. 2020). The wet period was assumed to correspond to the months when the monthly rainfall exceeded the 75th of the annual average rainfall (Apr.-May., Oct.-Nov. 2019, Nov.-Dic.2020 and Feb. 2021). The remaining months were defined as being

280 "intermediate" (Fig. S2 in Supplementary Material 1). All statistical analyses and plots were carried out in the R programming language (R Development Core Team, 2010).

4 Results

4.1 Depth-variation of soil hydro-physical and chemical properties

285 There are clear differences in the properties of the A and 2A horizons between the CU-UP and TU-UP soils. The depth-variation of the mean total available water (θ_{TAW}) is different for the two vegetation types, with a maximum θ_{TAW} of 0.50 and 0.52 cm^3 cm^{-3} for the A horizon of CU-UR and 2A horizon of TU-UP, respectively (Fig. 3b). The depth variation of θ_{TAW} is inverse to the BD (Fig. 3c). The mean K_{SAT} is highest under cushion plants: the elevated values of 175 mm h^{-1} measured for the A horizon (Fig. 3a) are in contrast with the one order of magnitude lower value in the 2A horizon and two orders of

290 magnitude lower in the 2BC and 3BC horizons (15.6 and 1 mm h^{-1}, respectively). Under tussock grass, the depth-variation of K_{SAT} is more uniform, with values between 5 and 12 mm h^{-1} for the A, 2A, and 2BC horizons, and a decrease to 1 mm h^{-1} for the 3BC horizon. Mean K_{SAT} depth-variation resembles the vertical distribution of root diameter and abundance (Fig. 3e, 3f). Water retention at saturation and field capacity showed similar depth variation as θ_{TAW}, whereas water retention at wilting point showed negligible differences by vegetation type (Fig. S3, Table S1 in Supplementary Material 1).

295

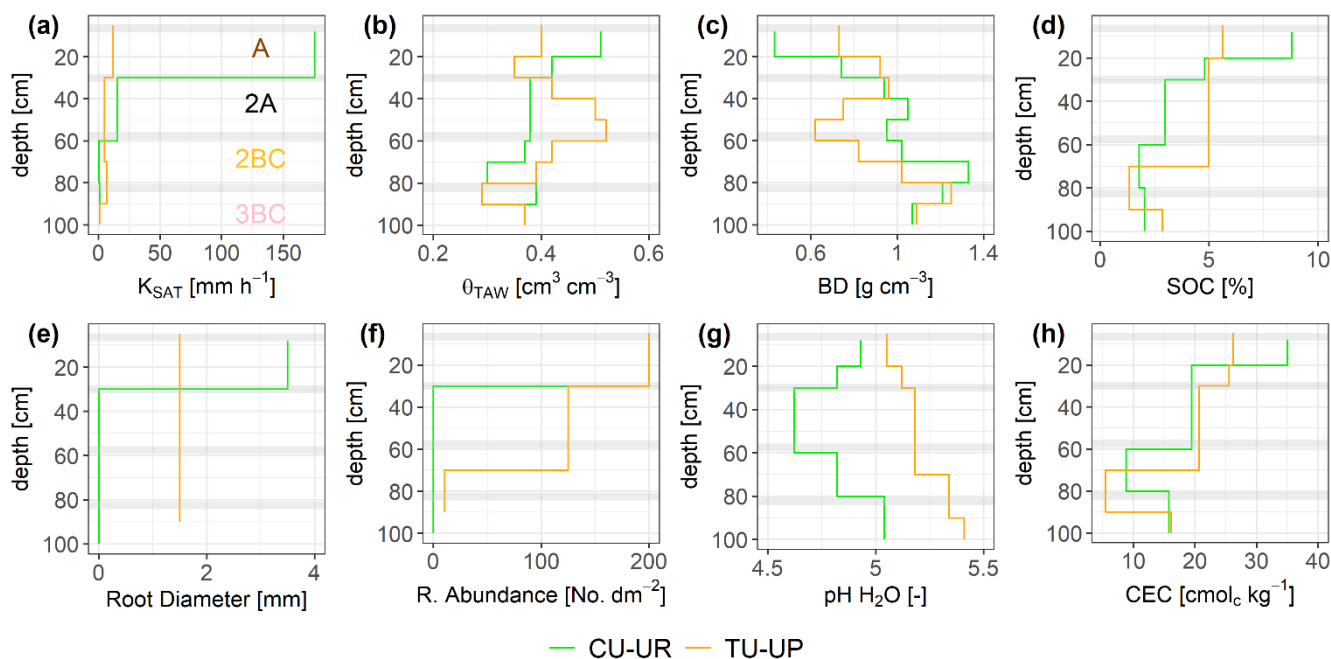
300


Figure 3: Depth-specific distribution of soil properties: (a) saturated hydraulic conductivity (K$_{SAT}$), (b) total available water (θ$_{TAW}$), (c) dry bulk density (BD), (d) soil organic carbon (SOC), (e) root diameter, (f) root abundance, (g) soil pH, and (h) cation exchange capacity (CEC).

The soil BD in the upper three soil horizons (A to 2BC) is different by vegetation type (Fig. 3c). Under cushion plants, the lowest value of 0.43 g cm^{-3} is measured in the topsoil, and values then systematically increase with depth to 75 cm. Under tussock grass, there is more local depth variation than under cushions: the lowest value (0.62 g cm^{-3}) is measured in the 2A horizon; whereas local maxima occur at 35 and 85 cm depth. The maximum BD (~1.25 g cm^{-3}) of both profiles is situated at the 2BC/3BC interface (70 – 90 cm depth). The soil texture of the three upper horizons is similar under both vegetation types: the sand and silt fraction are dominant (35 to 63%), while the clay content is less than 8%. In the 3BC horizon, a higher silt and clay content is observed under tussock grasses (Fig. S3, Table S2 in Supplementary Material 1).

In the topsoil, SOC and CEC are highest and decrease with depth. In the A horizon, SOC and CEC are higher under cushion plants. Under cushion plants, SOC decreases strongly from 9 to 2%; whereas below tussocks, it decreases from 6 to 3% with a local minimum (1%) at the 2BC horizon (Fig. 3d, Table S2). Soil pH is acidic and lower (4.6 to 5) under cushion plants compared to tussock grass in the entire profile (Fig. 3). Also, the depth variation differs: under cushion plants, the pH decreases from the topsoil to the 2A horizon and then increases to lower depths; whereas under tussock grasses there was a

consistently increasing pH with depth (Fig. 3g, Table S2). In the A horizon, CEC is highest (35 cmol$_c$ kg^{-1}) under cushion plants, compared to 26 cmol$_c$ kg^{-1} under the tussock profile. The highest cation exchange capacity at the upper horizon decreased with depth until the 2BC horizon, and then, it slightly increased at the 3BC horizon for both soil profiles. Details on soil properties are included in Supplementary Material 1 (Table S2).

4.2 Model simulations and independent validation

After calibration of the Hydrus-1D model with the bimodal van Genuchten approach, based on observed and simulated soil volumetric water contents, the model performance for the calibration period resulted in R^2 values of 0.63 to 0.90, RMSE ≤ 0.02 cm^3 cm^{-3}, and KGE values of 0.39-0.86 for the A and 2A horizons, and 0.07-0.12 for the 2BC and 3BC horizons (Fig. 4). For the validation period, the model performance is slightly higher than for the calibration (R^2: 0.49-0.91, RMSE ≤ 0.02 cm^3 cm^{-3}, KGE: 0.35-89 for the A and 2A horizons and 0.08-0.71 for the 2BC and 3BC horizons), indicating that the soil hydrological processes are well represented. Model performance decreases in the lower horizons when measured by KGE for both profiles. For the cushion plant profile, the fitted soil hydraulic parameters are related to the slope of the water retention function (*n*) along with soil profile depth; whereas for the tussock grass profile most fitted parameters are related to the soil hydraulic properties in the A horizon. The standard errors of the fitted hydraulic parameters were one order of magnitude lower than their mean value for most cases (except for parameter *n* at 35, 55 and 65 cm depth at CU-UR). This indicates that the inverse approach gave in general stable estimates (Table S6 in Supplementary Material 1). The mass balance error in the numerical solution of the model was lower than 1% for both profiles.

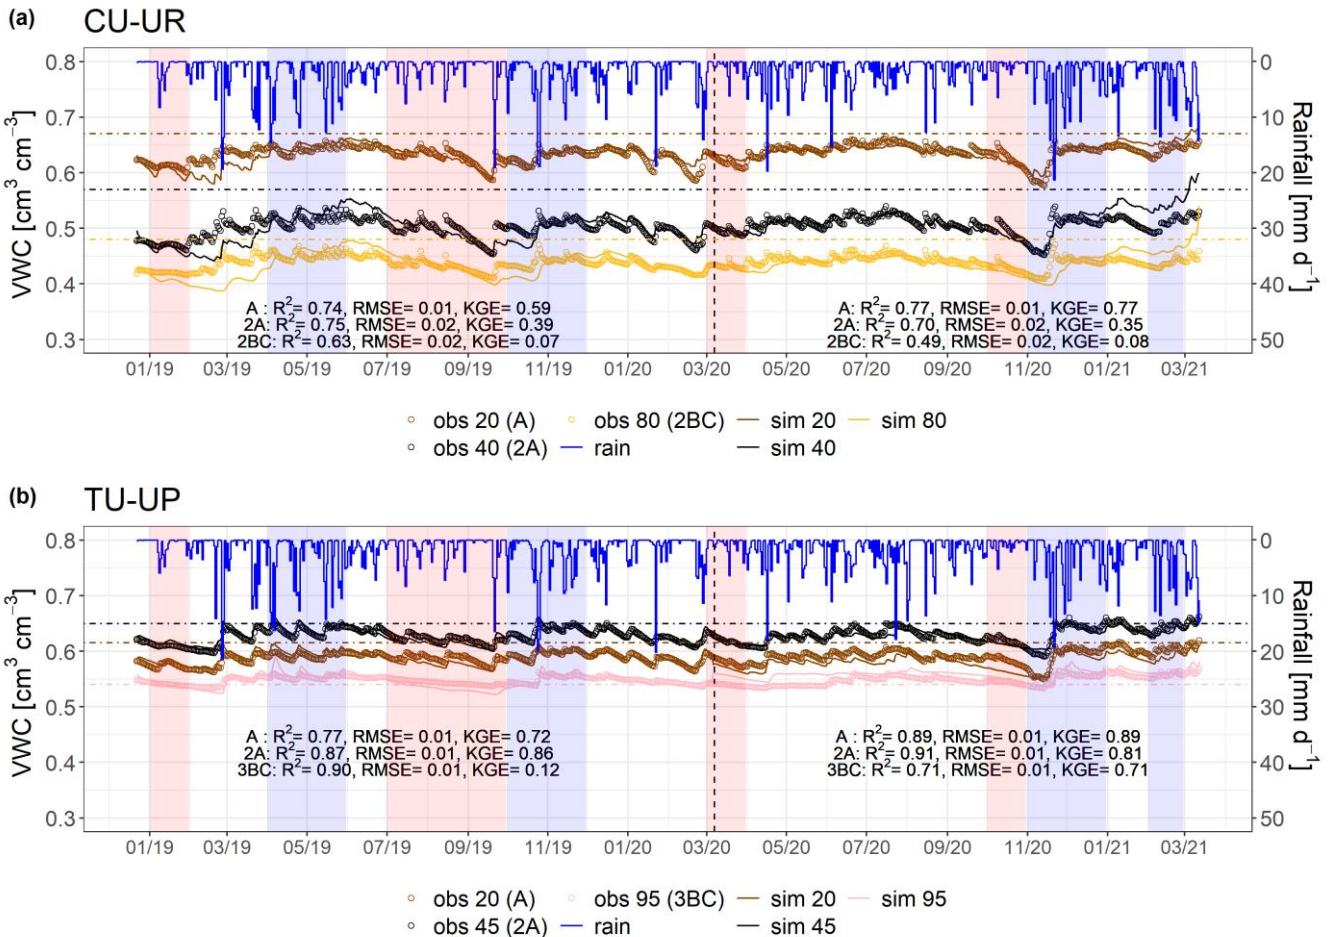
Soil moisture (volumetric water content, VWC) varied in depth by vegetation type (Fig. 4, Table 3). Mean annual soil moisture is highest in the A horizon (0.63 cm^3 cm^{-3}) and declines strongly with depth to the 2BC horizon (0.40 cm^3 cm^{-3}) below cushion plants; whereas it is highest in the 2A horizon (0.63 cm^3 cm^{-3}) and decreases slightly to the upper (0.59 cm^3 cm^{-3}) and lower (0.55 cm^3 cm^{-3}) horizons below tussock grasses. Soil moisture response to rainfall events and dry periods is more dynamic under cushion vegetation throughout the soil profile (Fig. 4a).


Figure 4: Simulated (thin line) and observed (dots) volumetric water content (VWC) for (a) CU-UR profile and (b) TU-UP profile. The rainfall is represented by the blue line. Brown and black colors represent the A and 2A horizons for both soil profiles. The yellow and pink lines represent the 2BC and 3BC horizons for the CU-UR and TU-UP profile, respectively. The vertical dashed line separates the calibration and validation periods. Horizontal dot-dashed lines indicate filed capacity (θ_{FC} = -10 kPa) at corresponding depth. Red stripes represent months defined as dry periods, while blue stripes represent months defined as wet periods.

Besides the internal calibration and validation with daily volumetric water contents, the model performance was also evaluated with biweekly independent observations obtained from the two water flux meters installed at 50 cm depth (2A horizon) of each profile (Fig. 5). Simulated and observed water fluxes under tussock grass are systematically higher than fluxes under cushion plants over the study period (Fig. 5a, c). There is a significant correlation between the simulated and observed water fluxes in the 2A horizon, as all Spearman correlation coefficients are > 0.73 with p < 0.001 (Fig. 5b, d). Notwithstanding, the comparison also shows that the simulations tend to underestimate water fluxes at higher rates (> 20 mm d^{-1}).

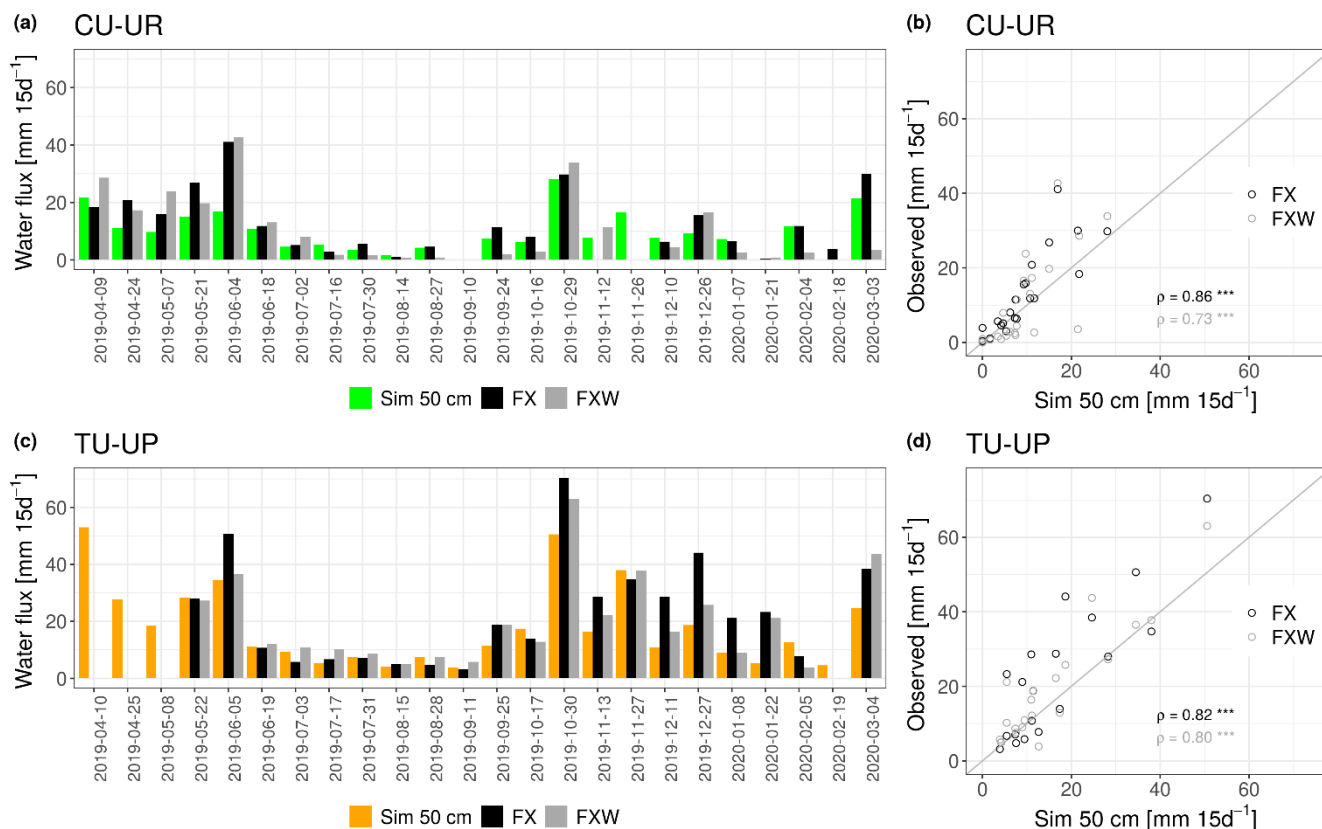
365


Figure 5: (a, c) Left panels show the biweekly temporal series of simulated (Sim) and observed water fluxes (FX, FXW), (b, d) right panels show the correspondence between the simulated and observed water fluxes. Water fluxes were measured by the two flux meters (FX = without wick, FXW = with wick) installed at 50 cm depth in each profile. Spearman correlation coefficients (ρ)
370 **and their significance (p-value), with levels of significance *, **, *** corresponding to p<0.05, p<0.01, p<0.001.**

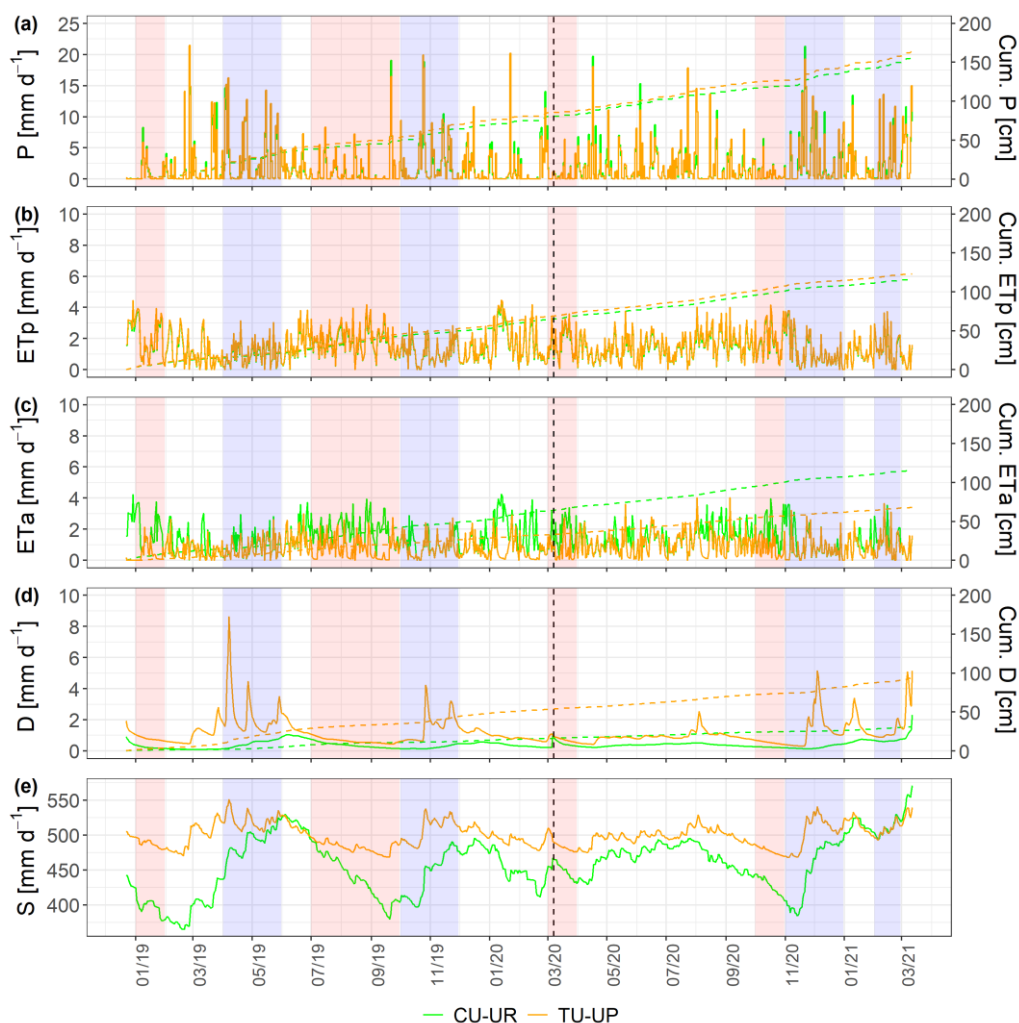
4.3 Soil water dynamics under different vegetation covers

The soil water dynamics of both profiles were compared based on the time series (Dec. 2018 – Mar. 2021) of rainfall (P), actual evapotranspiration (ETa), drainage (D), and soil water storage (S) at a daily scale (Fig. 6). Rainfall was evenly
375 distributed over the study period and the mean annual values (2019-2020) did not differ significantly between the two sites (687 ± 6 for CU-UR and 726 ± 34 mm TU-UP). The daily rainfall intensity reached up to 21 mm day^{-1}. There exist clear differences in mean annual water partitioning and soil water balance between soils under cushion-forming plants and tussock grasses (Table 2). Mean annual actual evapotranspiration (ETa) is higher for cushion plants (522 ± 37 mm) than for tussock

grass (308 ± 33 mm). The difference is highest during the dry periods (Jan. 2019; Jul.-Sep. 2019; Mar.2020; Oct.2020),

380   when the ETa under cushion plants is two times higher than under tussock grasses (Fig. 6c, Table S7).

Deep drainage (D) is - on an annual average - three times higher under tussock grasses (405 ± 92 mm) than under cushion
plants (127 ± 6 mm). The largest differences occur during the rainy periods (Apr.-May 2019; Oct.-Nov. 2019; Nov.-Dec.
2020; Feb.2021) when deep drainage under tussock grasses can be up to 13-fold higher than under cushions (Table S7, Fig.

385   6d). In contrast to the tussock grass, the deep drainage under cushion-forming plants is steady over time and less reactive to
rainfall inputs. Furthermore, the soil water storage in the soil profile (S) is more dynamic under cushion plants than under
tussock grasses (Fig. 6e) showing a larger range for the cushion plants profile (34 ± 22 mm) compared to tussock grass (9 ±
15 mm).


390

Figure 6: Soil water balance at a daily scale (a) rainfall (P), (b) potential evapotranspiration (ETp), (c) actual evapotranspiration (ETa), (d) deep drainage (D), and (e) soil water storage (S) (vertical dashed line separates calibration and validation periods). The green and brown lines represent the CU-UR and TU-UP profile, respectively. Red stripes represent months defined as dry periods, while blue stripes represent months defined as wet periods.

395

Table 2: Mean annual water balance (Jan.-Dec.2019- Jan.-Dec.2020) and corresponding percentage of rainfall input (mean ± standard deviation).

Soil profile	P [mm]	ETp [mm]	ETa [mm]	D [mm]	ΔS [mm]	ETa [mm d⁻¹]
CU-UR	686.6 ± 5.5	526.0 ± 31.8 (76.6 ± 5.2 %)	522.1 ± 37.3 (76.0 ± 6.0 %)	127.0 ± 6.3 (18.6 ± 0.6 %)	34.1 ± 21.6 (5.0 ± 3.1 %)	1.43 ± 0.09
TU-UP	726.3 ± 34.2	558.5 ± 35.3 (77 ± 8.6%)	308.3 ± 32.7 (42.5 ± 6.6 %)	404.8 ± 91.7 (55.4 ± 9.9 %)	9.4 ± 14.8 (1.3 ± 2.1 %)	0.84 ± 0.09

400 The mean annual water fluxes below tussock grasses are higher than under cushion plants for all horizons (Table 3). Under cushion plants, the mean annual water flux is highest in the A horizon (357 ± 22 mm) and decreases with depth to the 3BC horizon (127 mm). In contrast, the mean annual water fluxes are more constant with depth under tussock grasses (420 to 405 mm). Under cushion plants, the A horizon is highly responsive to rainfall input (Fig. 7b) showing high infiltration capacity; conversely, the lower horizons show an attenuated response. In contrast, under tussock grass, water flux at the uppermost

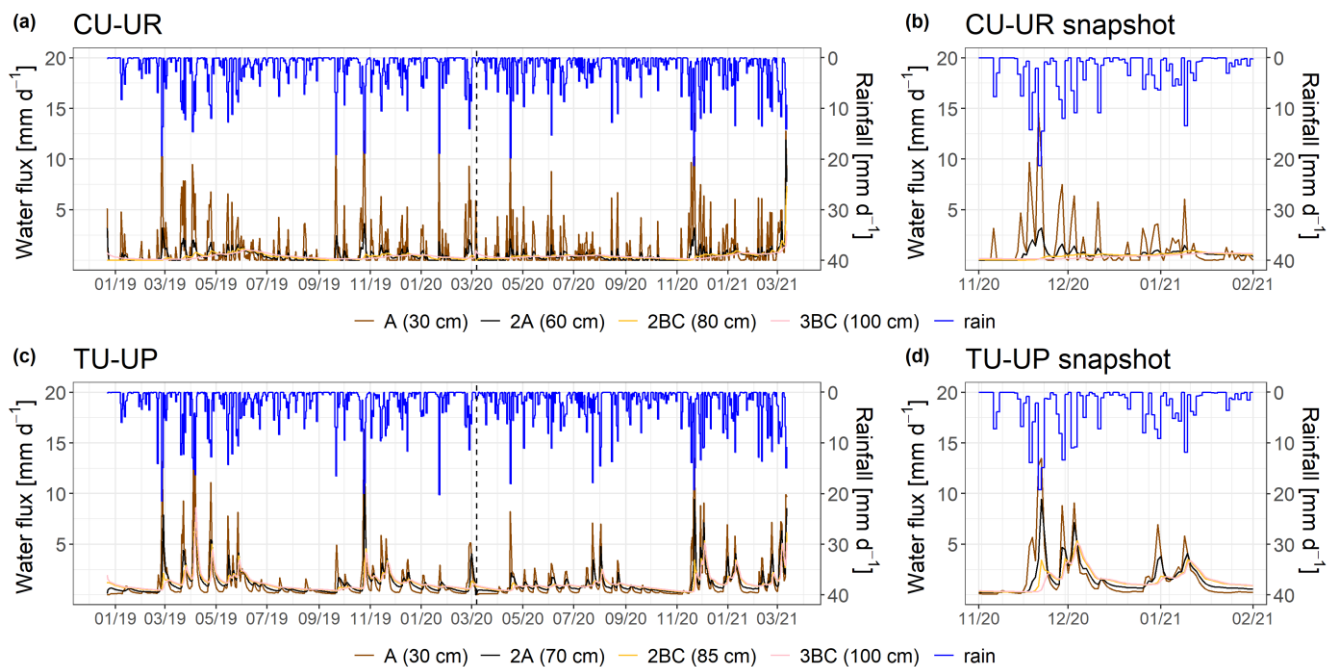
405 horizon is higher but less responsive to rainfall events and shows larger recessions once rainfall stopped (Fig. 7d). Moreover, water fluxes below tussock grass show similar responses in all horizons in depth.


Figure 7: Simulated water fluxes over the period 2018/12-2021/03 (a, c) for the two soil profiles. A snapshot is shown in (b, d) to highlight the response during rainfall events. The rainfall is represented by the blue line. Brown and black colors represent the A and 2A horizons for both soil profiles. The yellow and pink lines represent the 2BC and 3BC horizons for the CU-UR and TU-UP profile, respectively. The water fluxes are derived from the bottom of the soil horizons.

Table 3: Mean annual water fluxes and volumetric water content (Jan.-Dec.2019- Jan.-Dec.2020) by soil horizon (mean ± standard deviation).

Soil horizons	Water flux [mm]	Soil moisture [cm³ cm⁻³]	Water flux [mm]	Soil moisture [cm³ cm⁻³]
	CU-UR		TU-UP	
A	356.7 ± 22.2	0.63 ± 0.00	420.2 ± 80.4	0.59 ± 0.00
2A	157.0 ± 29.5	0.50 ± 0.00	407.0 ± 88.0	0.63 ± 0.00
2BC	124.5 ± 14.9	0.43 ± 0.00	404.8 ± 90.9	-
3BC	127.0 ± 6.3	-	404.7 ± 91.7	0.55 ± 0.00

4.4 Solute concentrations and fluxes

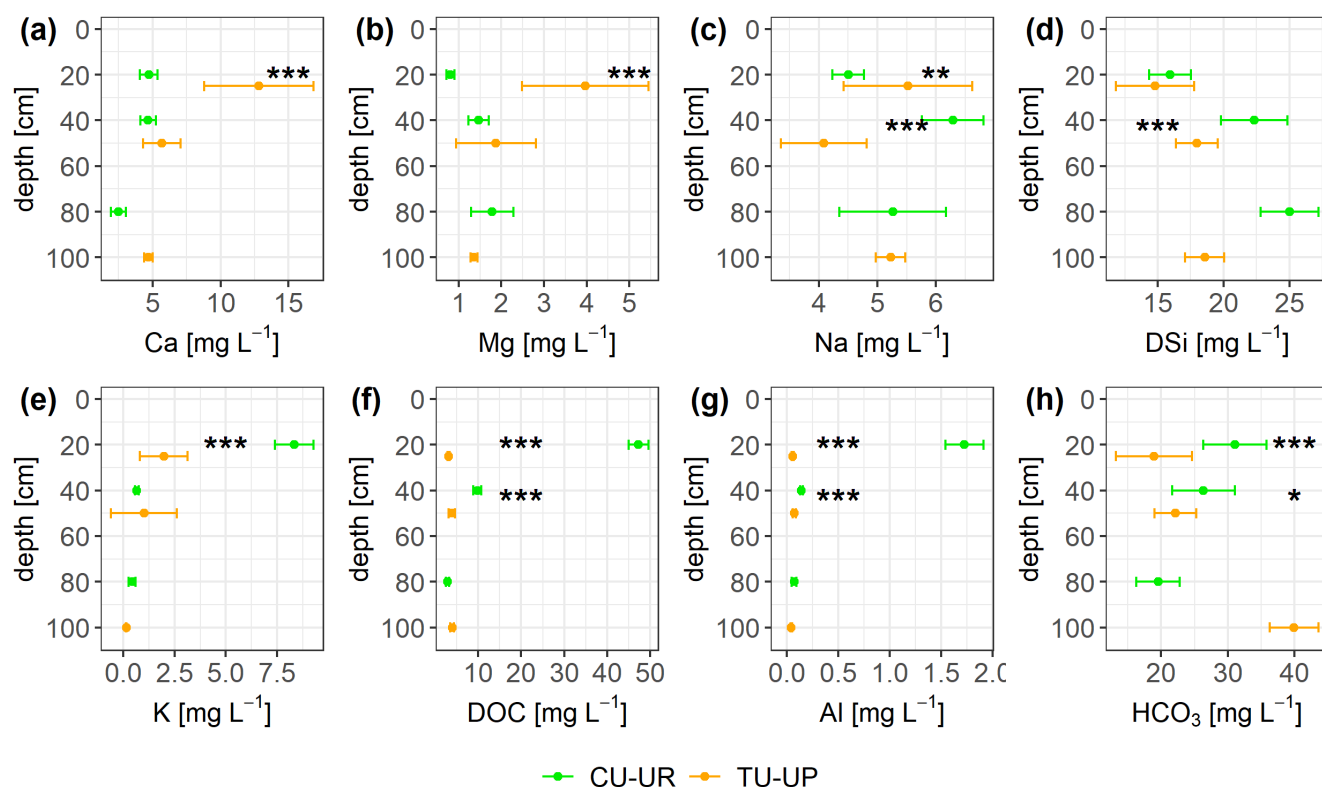
The solute concentrations at both soil profiles generally decrease in the order $HCO_3^- > DSi > NO_3^- > DOC > Ca \approx SO_4^{2-} > Na > Mg \approx K \approx Cl^- >> Al \approx Fe$ (Fig. 8, Table S8). The mean charge balance error was negative from -5.9 ± 6.8 to -11.9 ± 7.3 %, except at CU-UR in the A horizon (12.9 ± 7.7 %). The mean DOC and Al concentrations are one order of magnitude higher ($p \leq 0.001$) in the A horizon below cushion plants (resp. 47 and 2 mg L^{-1}) than under tussock grass (resp. 3 and 0.1 mg L^{-1}). In the 2A horizon, the differences in mean DOC and Al concentrations ($p \leq 0.001$) are less pronounced with concentrations under cushions (resp. 10 and 0.14 mg L^{-1}) being higher than under tussock grass (resp. 3 and 0.07 mg L^{-1}; Fig. 8f-8g). While the DOC and Al concentrations further decrease in the soil water extracts of the 2BC horizon under cushion plants, they remain stable with depth under tussock grass (Table S8 in Supplementary Material 1). In the A horizon, Ca and Mg concentrations are higher ($p \leq 0.001$) under tussock grass than under cushion plants; conversely, K concentration is higher for cushion plants. Below 30 cm, there are no significant differences by vegetation type (Fig. 8a, 8b, 8e).


Figure 8: Solute concentrations (mean ± standard deviation) integrated over biweekly intervals for both soil profiles. The Mann-Whitney U test was applied for differences between vegetation types, with levels of significance *, **, *** corresponding to p<0.05, p<0.01, p<0.001.

Despite significant differences in HCO_3^-, Na, and DSi concentrations in the A and 2A horizons between the two vegetation types, they are not consistent with depth (Fig. 8c, 8d, 8h). DSi concentrations increase with depth for soils under both
440   vegetation types. Under CU-UR, bicarbonate concentrations seem to follow the depth distribution of the roots, that is, higher HCO_3^- values at the A horizon where roots are abundant, and rapidly decreasing $HCO3^-$ concentrations below the rooting zone. This trend is not clear for TU-UP. The Na concentration in the soil solutes varies only between 3 and 7 mg L^{-1}, and exhibits no clear trends with depth and no consistent influence of vegetation.

445

Table 4: Annual solute fluxes [g m^{-2} y^{-1}] for both study sites.

Soil profile	CU-UR			TU-UP		
Horizon	A	2A	2BC	A	2A	3BC
Ca	1.94	1.36	0.36	5.13	2.71	2.20
Mg	0.32	0.41	0.26	1.48	0.90	0.64
Na	1.76	1.77	0.75	2.29	1.88	2.43
K	3.30	0.18	0.07	0.78	0.71	0.07
HCO_3^-	11.08	7.29	3.13	9.60	9.07	20.32
DOC	19.92	2.67	0.41	1.51	1.51	1.77
Al	0.68	0.04	0.01	0.03	0.03	0.02
DSi	6.48	6.73	3.82	7.21	8.92	8.87
T.Cat.	13.80	10.46	5.24	16.89	15.13	14.21

T.Cat. = Sum of Ca, Mg, Na, K, and DSi fluxes

The annual solute fluxes of cations and DSi (T.Cat) are taken here as a proxy for contemporary soil chemical weathering
450   rates following Clow & Drever (1996), Guicharnaud & Paton (2006) and White et al. (2005). The annual fluxes below the TU-UP profile (14 – 17 g m^{-2} y^{-1}) are systematically higher than under CU-UR (5 – 14 g m^{-2} y^{-1}; Table 4). The dominant components are HCO_3^- (3 – 20 g m^{-2} y^{-1}) and DSi (4 – 9 g m^{-2} y^{-1}). Remarkably, the solute flux in the A horizon below the CU-UR profile is principally composed of DOC with an annual flux of 20 g m^{-2} y^{-1}. Under CU-UR, the annual solute fluxes decrease strongly with depth, while they remain constant with depth under TU-UP (Fig. S5 in Supplementary Material 1).
455   This depth variation of annual solute fluxes resembles the trends of mean annual water fluxes (Table 3).

Most solute fluxes differ by vegetation type in the uppermost A horizon, with exception of the Na and DSi fluxes (Fig. 9, Table S9). At the A horizon under the CU-UR profile, the mean biweekly solute fluxes of DOC and total Al are one order of magnitude higher (797 ± 644, 28 ± 20 mg m^{-2} d^{-1}, respectively) when compared to TU-UP (DOC = 60 ± 51, Al = 1 ± 1 mg

460 m^{-2} d^{-1}). In contrast, below the TU-UP profile, the mean biweekly fluxes of Ca and Mg (205 ± 143, and 59 ± 39 mg m^{-2} d^{-1}, respectively) are higher than under CU-UR (Ca = 77 ± 62, Mg = 13 ± 10 mg m^{-2} d^{-1}), except K flux which is higher under the CU-UR profile (137 ± 98 mg m^{-2} d^{-1}) compared to TU-UP (31 ± 24 mg m^{-2} d^{-1}). The mean biweekly HCO$_3^-$ is higher under the CU-UR profile (472 ± 220 mg m^{-2} d^{-1}) than under TU-UP (300 ± 278 mg m^{-2} d^{-1}). At the 2A horizon, similar but no significant differences by vegetation occur for Ca, Mg and K fluxes, except for DOC. In addition, there is no significant

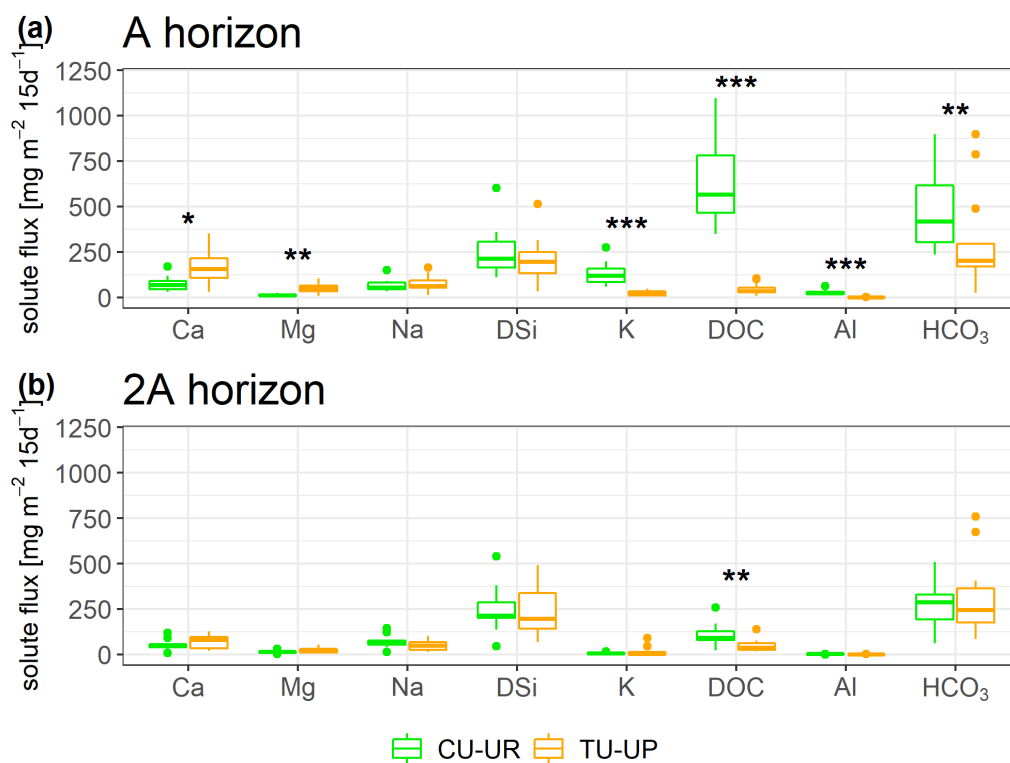
465 difference in Na and DSi fluxes between the vegetation types.


Figure 9: Biweekly solute fluxes in the two upper horizons of the CU-UR and TU-UP profiles. The Mann-Whitney U test was applied for differences between vegetation types, with levels of significance *, **, * corresponding to p<0.05, p<0.01, p<0.001.**

470

5. Discussion

5.1 Soil water dynamics under cushion-forming plants and tussock grasses

Overall, the good agreement between water fluxes from simulations and independent fluxmeter observations as well as
475 between the observed and simulated soil moisture at three horizons indicates that the soil-water processes are reasonably
well represented by the HYDRUS-1D model. The outcomes of the model show that the soil water partitioning is different by
vegetation type. The largest differences are attributed to the actual evapotranspiration (ETa) which is 1.7 times higher under
cushion plants compared to tussock grasses (Table 2). During dry periods ETa under cushion plants is 2.5-fold higher than
under tussocks. The higher solar radiation (1.3-fold) and wind speed (1.6-fold) during dry periods compared to wet periods
480 (Table S7, Fig. S6 in Supplementary Material 1) can promote conditions for higher evapotranspiration, as reported for alpine
ecosystems (Knowles et al., 2015; Ochoa-Sánchez et al., 2020).

The higher ETa under cushion-forming plants compared to tussock grasses is consistent with a recent study in the same sites
based on water stable isotopes (Lahuatte et al., in rev.). The authors found that soils under cushion plants are more prone to
485 evapotranspiration than under tussock grass. This difference was attributed to the direct exposure of cushion plants' topsoil
to solar radiation, whereas tussock grasses limit this exposition by producing a shadow effect with their leaves. The mean
annual percentage of ETa in relation to rainfall below the tussock grass (43 ± 7%) is slightly lower than in the southern
Ecuadorian páramo grasslands (51%; Carrillo-Rojas et al., 2019), and lower than other high altitudinal alpine tundra in USA
(59%; Knowles et al., 2015) and alpine meadows on the Qinghai-Tibetan Plateau in China (60%; Gu et al., 2008). The mean
490 annual percentage of ETa in relation to rainfall below the cushion-forming plants (76.0 ± 6.0%) is higher than under páramo
grasslands. This occurs despite the fact that the mean annual potential evapotranspiration (ETp) is 1.06 higher under tussock
grass than under cushion plants (Table 2).

There is approximately 3-fold less water flux transmitted from the A to the underlying horizons under cushion plants (Table
495 3, Fig. 7b). Likewise, deep drainage is also about threefold lower under cushion plants than under tussock grass (Table 2),
especially during wet periods (Table S7, Fig. 6d). We attribute the differences in vertical water fluxes and deep drainage to
the difference in the vertical distribution of soil water storage. The limitation of soil water transmission (e.g., by a reduction
in vertical hydraulic conductivity) can result in saturation even at low rainfall intensities during prolonged precipitation
events (Burt and Butcher, 1985). Thus, under tussock grass in the A horizon, the soil water storage capacity is limited by
500 lower θ_{TAW} and K_{SAT} than under cushion plants (Fig. 3a-3b). This results in soil conditions near saturation (soil moisture
closer to field capacity) and higher transmission of water downwards (Fig. 4). In contrast, under cushion plants in the A
horizon higher θ_{TAW} and K_{SAT} increase soil water storage capacity, which then can be used for evapotranspiration. This
higher soil water storage along with cushion topsoil prone to evapotranspiration results in the dynamic range in soil moisture
in the A horizon under cushion plants, which reflects the filling and emptying caused by low-intensity rainfall and

505   evapotranspiration (Fig. 4a). Under cushion plants, the coarser root system and lower BD in the A horizon result in higher K_{SAT} and θ_{TAW} compared to tussock grass (Fig. 3c, 3e), as previously reported (Páez-Bimos et al., in rev.).

Soil moisture is decisive for the actual evapotranspiration (Vereecken et al., 2015). When evapotranspiration is not limited by water availability, the ETa can be ultimately controlled by the available energy (Quiring et al., 2015; Seneviratne et al.,
510   2010). This is reflected in the relationship between ETa and ETp by vegetation type. Under cushion plants, the mean annual ETa (522 mm) is similar to ETp (526 mm) regardless of rainfall conditions (Table 2, Table S7) indicating there is water available for evapotranspiration during the whole study period. The strong decrease in soil moisture in the A and 2A horizons during the dry season as well as the steep increase in soil moisture during the first rainfall events after long dry periods (e.g., Sep. 2019 and Nov. 2020; Fig. 4a) are evidence of the high evapotranspiration and surface infiltration capacity
515   in soils under cushion-forming plants. Under tussock grass, the soil moisture variation is less pronounced during dry periods and rainfall events (Fig. 4b): the mean annual ETa (308 mm) is well below the ETp (559 mm), and the transmission of water towards deeper soil horizons is high. The fact that the highest soil moisture is observed in the 2A horizon under tussocks, is an indication of the higher soil water storage capacity of that layer. Under tussock grass at 95 cm depth, the mean annual soil moisture (0.55 cm^3 cm^{-3}) is higher than the soil water retention at field capacity (0.54 cm^3 cm^{-3}), indicating that the soil under
520   tussocks is under saturation conditions at this depth over most of the study period.

The soil hydrology' simulations show that surface runoff is not occurring, similar to what is observed in other regions characterized by high infiltration and low rainfall rates (Blume et al., 2009; Mosquera et al., 2022; Tobón and Bruijnzeel, 2021). Interception is considered negligible for cushion plants since their leaves are placed directly on the ground (Fig. 2b-
525   2c). For tussock grass, we analyzed the interception loss influence by adapting a method, developed for 100 % of vegetation cover (Ochoa-Sánchez et al., 2018). We reduced the vegetation cover to 55.8% (*Calamagrostis intermedia*; Table 1) as observed in the TU-UP profile to estimate the effective rainfall (rainfall – interception loss), and simulated the soil hydrological processes. This resulted in a 30% reduction in effective rainfall that led to a severe reduction of simulated water content at 2A and 3BC horizons, especially during the dry periods (Fig. S7 in Supplementary Material 1). We consider that
530   by applying the adapted model for interception loss for the TU-UP profile, the rainfall reduction is overestimated since it eliminates most small rainfall events during dry periods. This is in line with the decreasing non-linear interception rate in alpine grasslands when they lose vegetation cover (Genxu et al., 2012). Therefore, we consider that tussock canopy interception plays a minor role in the soil water balance of the TU-UP profile. The complete analysis of interception can be found in Supplementary Material 4.

535

5.2 Solute fluxes under soil-forming cushion plants and tussock grasses

Bicarbonate and DSi were observed as the dominant soil solute fluxes, while the DOC flux was highest in the A horizon of the soil profile covered by cushion plants (Table 4, Fig. S5). The dominance of bicarbonate (3 - 20 g m^{-2} y^{-1}) and DSi (4 – 9

540   g m^{-2} y^{-1}) in the soil weathering fluxes is in line with the existing data on river chemical loads from paramo environments (Arízaga-Idrovo et al., 2022; Tenorio et al., 2018) where fluxes of 9 to 30 and 2 to 4 g m^{-2} y^{-1} were reported for bicarbonate and DSi, respectively. For Andean basins, the solute fluxes show similarly high contributions of HCO$_3^-$, DSi, and also Ca (61, 13 and 18 g m^{-2} y^{-1}, respectively) (Moquet et al., 2016).

545   Vegetation type imposed a significant influence on solute fluxes in the upper A horizon, while the influence was lower and less significant in the lower 2A horizon (Fig. 9, Table 4). Annual DOC fluxes (1.5 - 2.7 g m^{-2} y^{-1}) are in line with the values reported from similar Andosols (0.9 – 8.4 g m^{-2} y^{-1}) as detailed in Table S11, except in the A horizon under cushion plants (20 g m^{-2} y^{-1}). The high DOC fluxes in the A horizon below cushion plants compared to tussocks can be attributed to a high concentration (47 mg L^{-1}) rather than to water flux, since water flux is lower under cushions in the A horizon (Table 3).

550   Besides cushion plants in the A horizon, mean DOC concentrations in our study (3.1 – 4.0 mg L^{-1}) are close to the range of values measured in Andosols grasslands: 4.7 mg L^{-1} (by wick samplers, Pesántez et al., 2018) and 5 – 7 mg L^{-1} (by lysimeters, Ugolini et al., 1988). DOC concentrations present a larger range when measured in soil solutions collected by lysimeters for Andosols under other vegetation covers (2 – 28 mg L^{-1}, Aran et al., 2001; Chen et al., 2017; Fujii et al., 2011). Extraordinary high DOC concentrations (up to 60 mg L^{-1}) have been reported for marshes, bogs, and swamps, related to

555   large plant net primary productivity and slow-moving streams (Thurman, 1985).

We argue that the high DOC concentration under cushions in the A horizon can be partially explained by a high water residence time attributed to low downward water fluxes below the A horizon (Table 3, Fig. 7b), and to the filling and emptying of the soil water storage as a result of low-intensity rainfall (Padrón et al., 2015) and high ETa (Fig. 6c). The high

560   DOC concentration is related to the high SOC (9%) content in the A horizon under cushion plants that decreases strongly with depth (Fig. 3d). DOC might be attributed to SOC from roots/leaf litter decay (Kalbitz et al., 2000). High SOC and low pH (< 5) in the rooting zone (Fig. 3d-3g) under cushion-forming plants can point to a release of organic acids that contribute to the observed rise in DOC concentration (Molina et al., 2019; Takahashi and Dahlgren, 2016; Ugolini et al., 1988). For tussock grass, no consistent trends with depth can be found between DOC concentrations and any soil property.

565

The values of Al fluxes follow the behavior of DOC and Fe fluxes in both soil profiles. Under cushion plants, they decrease from the A horizon to the lower horizons, while, under tussock grass, they are lower but constant with depth (Table 4). DOC, Al, and Fe concentrations in soil solutes are significantly higher under cushion plants compared to tussocks at the 2A horizon (Fig. 8g, Table S8). This is also reflected in the higher DOC flux under cushion plants at the 2A horizon (Fig. 9b) despite

570   much lower water fluxes. Leaching of DOC, Al, and Fe from the A horizon to the lower horizons has been reported in volcanic ash soils (Ugolini et al., 1988), however we did not observe an accumulation of OC in the interface between the A and 2A horizons under cushion plants. Sampling DOC, Al, and Fe solutes at shorter time intervals, and soil material at higher depth resolution, could help to better understand the transport and remobilization of organic carbon below cushion plants.

575

Solute concentrations and fluxes of Ca, Mg, and K are influenced by the vegetation type in the A horizon (Fig. 9a, Table 4). In our sites, annual Ca fluxes (0.3 - 5 g m^{-2} y^{-1}), Mg fluxes (0.3 - 2 g m^{-2} y^{-1}), and K fluxes (0.1 – 3 g m^{-2} y^{-1}) lie in the range of observed soil solute fluxes in other ecosystems (Table S11). Under tussock grass, Ca and Mg fluxes decrease with depth, while the same occurs for K under cushion plants (Fig. S5 in Supplementary Material 1). The 3 to 5-fold higher fluxes of

580   these nutrients in the A horizon can be attributed to the corresponding 3 to 5-fold higher element concentrations in the soil water solutions (Fig. 8a-8b, 8e) rather than to the water fluxes (Table 3). The high concentrations and fluxes of Ca, Mg (for tussocks), and K (for cushions) in the near-surface horizons might reflect their uptake and cycling by plants (Amundson et al., 2007; Kelly et al., 1998; Lucas, 2001; White & Buss, 2014; White et al., 2009).

585   Vegetation type has no significant effect on Na and DSi fluxes (Fig. 9, Table 4). Annual DSi fluxes in our sites (4 - 9 g m^{-2} y^{-1}) are within the range of DSi fluxes in other ecosystems (0 - 27 g m^{-2} y^{-1}; Table S11). For cold environments low values of 0.04 to 1.1 g m^{-2} y^{-1}were reported (Clow & Drever, 1996; Guicharnaud & Paton, 2006), whereas higher values up to 26 g m^{-2} y^{-1} were found for tropical warmer settings (Hedin et al., 2003). The solute fluxes of DSi and Na follow closely the variation of water fluxes with depth (Table 4, Table 3). Although not significant, the systematically higher DSi concentrations under

590   cushion plants in comparison to tussock grass (Fig. 8d) can be a result of higher evapotranspiration and lower water fluxes as shown by White & Buss) (2014) and Berner & Berner (2012). The increase of DSi with depth under both vegetation types can be related to the longer water transit time at depth: (Lahuatte et al., in rev.) estimated water transit times for the A horizons at ~ 6 months, and for the 2A horizons at ~ 1 year. Bicarbonate concentrations seem to follow the vertical distribution of SOC content, root properties, and rooting depth, especially under cushion plants (Fig. 3d-3f, Fig. 8h). Higher

595   root and microbial respiration can enhance carbonic acid formation, which then dissociates into HCO$_3^-$ (Amundson et al., 2007; Perdrial et al., 2015; Ugolini et al., 1988). The fact that we observed the highest concentration of HCO$_3^-$ at the greatest depth (3BC) under tussock grass cannot be explained by the root network or SOC and needs further investigation (Fig. 8h).

5.3 The effect of vegetation on contemporary soil weathering through soil water balance

Vegetation types associated with each soil profile showed differences in soil water balance and soil chemical weathering.

600   Fig. 10 depicts the conceptualization of our findings. The annual soil chemical weathering rates (T. Cat. fluxes) in this study (5 - 17 g m^{-2} y^{-1}) are within the range of the values reported for cold environments (2 -3 g m^{-2} y^{-1}; Clow & Drever, 1996; Guicharnaud & Paton, 2006) and tropical forests (22 g m^{-2} y^{-1}; White et al., 1998). The annual depth-integrated (sum over all

horizons) soil chemical weathering under tussock grass (46 g m^{-2} y^{-1}) is 1.5 times higher than under cushion plants (30 g m^{-2} y^{-1}) (Table 4). This reflects mainly the higher water fluxes through the soil profile since solute concentrations for most

605 elements are similar (Ca, Na and Mg) or higher (K and DSi) under cushion plants (Fig. 8). This illustrates the higher dependence of soil weathering rates on the transmission of water in the soil profile than on the solute concentrations. The soil weathering rate is highest in the A horizon regardless of vegetation type, showing the combined effect of higher water fluxes and higher Ca, Mg, and K concentrations. The soil weathering rate at the 2BC horizon corresponds to 0.4 times of the rate at the A horizon under cushion plants, whereas under tussock grass the weathering rate at the 3BC horizon is 0.84 times

610 the rate at the A horizon resembling the decline in water fluxes with depth by vegetation type (Fig. 10a). This can be also linked to the progressive neutralization of soil solution acidity in the upper horizons that leads to less weathering with depth. This direct relationship between soil weathering rates and water fluxes in our sites corroborates the earlier work by Maher (2010). She found weathering rates that were strongly controlled by hydrological fluxes when the water residence times are between 5 days and 10 years and the water flow rates are below 16 m y^{-1}. Our data fall within this range with soil water

615 residence times of approx. 0.5 to 1 year and water flow rates of 0.1 to 0.4 m y^{-1}.

Differences in soil hydraulic properties by vegetation type in the A horizon can influence soil water balance and soil chemical weathering for the entire soil profile (Fig. 3, Fig. 10). The higher ETa under cushion plants reduces substantially the mean annual water transmitted from A to the 2A and 2BC horizons (0.4 times, respectively), while under tussock grass,

620 this decrease is almost negligible (Table 3). We argue that the coarser and shallow (up to 30 cm depth) root system under cushion plants is partially responsible for this difference in soil water balance by modifying soil structure and changing soil hydraulic properties. This is consistent with a recent theoretical study that relates the variability in evapotranspiration at a given climatic condition to the root architecture (Hunt, 2021). Several studies have also pointed to vegetation as an important influence on chemical weathering by altering water fluxes, storage, evapotranspiration, and soil water residence time

625 (Brantley et al., 2017; Drever, 1994; Hunt, 2021; Kelly et al., 1998). Moreover, there is an intertwined and co-evolutionary relationship between infiltration and roots. Rooting depth has been associated with infiltration depth on a global scale and with soil water content at a local scale (Fan et al., 2017). On the other hand, rooting depth and root morphology can alter soil hydraulic properties and thus, soil infiltration by changing soil structure (Lu et al., 2020). In our study sites, shallower and coarser rooting under cushion plants resulted in lower transmission of water below the A horizon and further lower soil

630 chemical weathering rates, while under tussock grass a deeper and finer root system promoted steady water transmission with depth and higher soil chemical weathering.

In our study, soil water fluxes through the soil profile play a significant role in soil chemical weathering, while soil moisture measured in the field does not. In contrast, Cipolla et al., (2021) found a hysteric relationship between soil moisture and

635 weathering rates in a short-term study and attributed this non-linearity to a memory of past events (wet and dry periods). García-Gamero et al., (2022) found a positive relationship between soil moisture and soil weathering using a long-term

model. We attribute this difference to the weak soil moisture seasonality in our study sites (Fig. 4), typical in tropical páramo ecosystems (Mosquera et al., 2022), which results in small ranges (max-min) of soil moisture for cushion plants ($\leq$ 0.09 cm^3 cm^{-3}) and tussock grasses ($\leq$ 0.07 cm^3 cm^{-3}) in comparison with larger soil moisture ranges from the modeled soil profiles

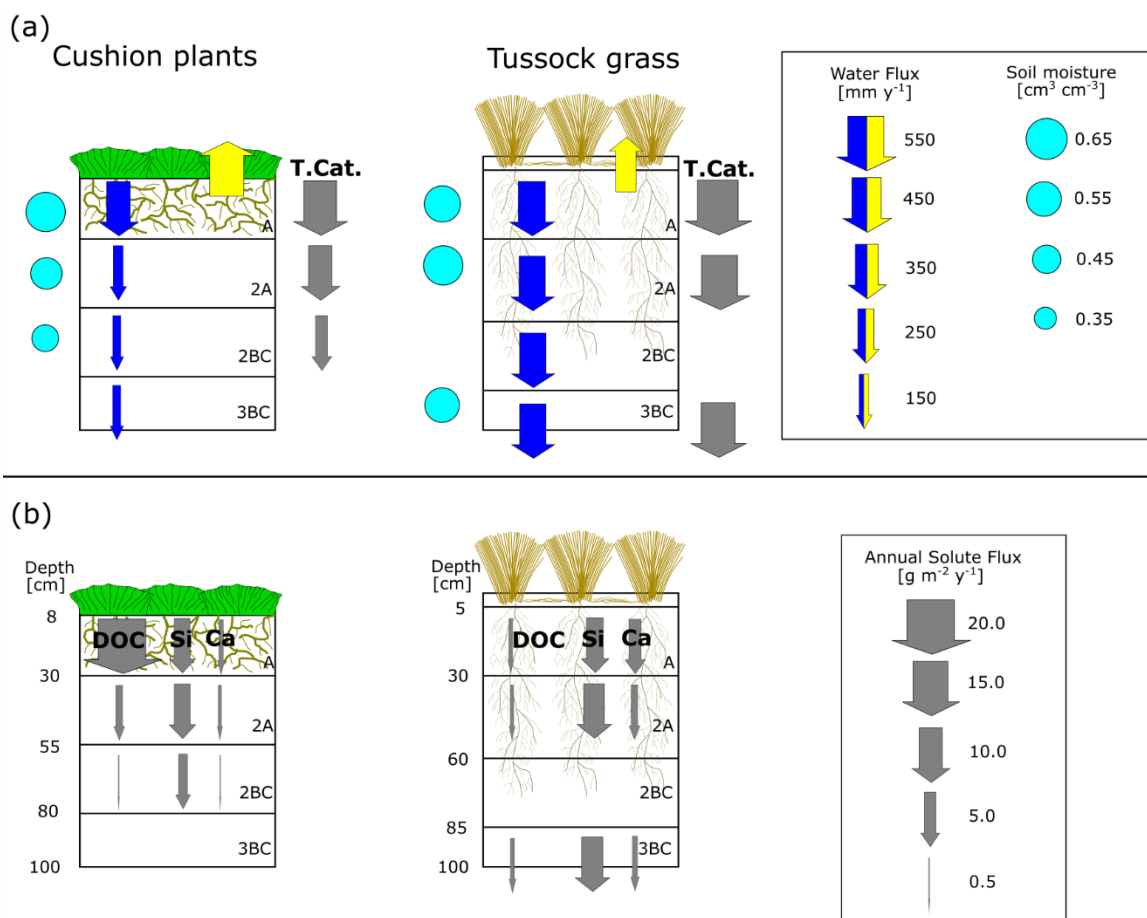
640   (0.35 cm^3 cm^{-3}) (Cipolla et al., 2021; García-Gamero et al., 2022).


Figure 10: (a) Mean annual water fluxes, contemporary soil weathering rates and soil moisture and (b) solute fluxes at different
645   **soil horizons under cushion-forming plants and tussock grass. The vertical arrows represent fluxes, of which size and direction indicate flux quantity and direction of flow. The blue and yellow arrows represent water fluxes: infiltration and actual evapotranspiration (ETa), respectively. The gray arrows represent soil chemical weathering rates (T.Cat.) and solute fluxes.**

6. Conclusions

We investigated the influence of soil-vegetation associations on soil water balance, solute fluxes and contemporary soil chemical weathering in two soil profiles under different vegetation types in the high tropical Andes. The soil water balance
655   in the soil profile under cushion-forming plants (dominated by *Azorella pedunculata*) describes a two-layer system, where the upper horizon stores water that is available for evapotranspiration, and where water transmission to the horizons below is low. In contrast, the tussock grass profile (dominated by *Calamagrostis intermedia*) represents a homogeneous system, that regulates and transmits water evenly through all soil horizons. In our study sites, we evidenced the role of root systems in regulating the soil water balance. Under cushion-forming plants, a shallower and coarser root system is related to a more
660   porous soil structure that leads to higher total available water (storage) and higher saturated hydraulic conductivity (infiltration capacity) in the top horizon. While under tussocks grass, a finer and deeper root system reflects a lower total available water and a lower but depth-constant saturated hydraulic conductivity, resulting in larger water fluxes being transmitted to lower horizons.

665   Vegetation type imposed a significant influence on solute fluxes in the upper A horizon, while the influence was lower and less significant in lower horizons. Particularly high DOC, Al and Fe fluxes are reported in the A horizon of soils under cushion-forming plants, despite relatively low water fluxes. Solute concentrations and fluxes of Ca, Mg, and K are 3 to 5-fold higher in the A horizon, and differ by vegetation type which can point to differences in plant biogeochemical fluxes between cushion-forming plants and tussock grasses. Other solutes like DSi, Na, HCO_3^- are only minimally influenced by
670   vegetation type.

Chemical weathering rates are more imprinted by the soil water fluxes than by the solute concentrations. In the young volcanic ash soils from the high Ecuadorian Andes, the vegetation type has an effect on contemporary soil chemical weathering by modifying soil hydraulic properties in the upper horizon, which in turn results in changes in soil water
675   balance. This evidences the importance of considering soil water fluxes when investigating the effect of hydrological conditions on soil weathering. Our findings reveal the role of the vegetation type in modifying the soil biogeochemical and hydro-physical properties of the uppermost soil horizon and, hence, in controlling water balance, solutes fluxes, and contemporary soil chemical weathering throughout the entire soil profile.
