13
14 **Abstract:** Preferential flow induced by desiccation cracks (PF-DC) has been proven to be an important hydrological effect
15 that could cause various geotechnical engineering and ecological environment problems. Investigation on the PF-DC remains
16 a great challenge due to the soil shrinking-swelling behavior. This work presents an experimental and numerical study of the
17 PF-DC considering the dynamic changes of DC. A soil column test was conducted under wetting-drying cycles to investigate
18 the dynamic changes of DC and their hydrological response. The ratio between the crack area and soil matrix area (crack
19 ratio), crack aperture and depth were measured. The soil water content, matrix suction and water drainage were monitored. A
20 new dynamic dual-permeability preferential flow model (DPMDy) was developed, which includes physically-consistent
21 functions in describing the variation of both porosity and hydraulic conductivity in crack and matrix domains. Its performance
22 was compared to the single-domain model (SDM) and rigid dual-permeability model (DPM) with fixed crack ratio and
23 hydraulic conductivity. The experimental results showed that the maximum crack ratio and aperture decreased when the
24 evaporation intensity was excessively raised. The self-closure phenomenon of cracks and increased surficial water content
25 were observed during low evaporation periods. The simulation results showed that the matrix evaporation modeled by the
26 DPMDy is lower than that of the SDM and DPM, but its crack evaporation is the highest. Compared to the DPM, the DPMDy
27 simulated a faster pressure head building-up process in the crack domain and higher water exchange rates from the crack to
28 the matrix domain during rainfall. Using a fixed crack ratio in the DPM, whether it is the maximum or the average value from
29 the experiment data, will overestimate the infiltration fluxes of PF-DC but underestimate its contribution to the matrix domain.
30 In conclusion, the DPMDy better described the underlying physics involving crack evolution and hydrological response with
31 respect to the SDM and DPM. Further improvement of the DPMDy should focus on the hysteresis effect of the soil water
32 retention curve and soil deformation during wetting-drying cycles.

33 **Keywords:** Desiccation cracks; preferential flow; dynamic changes; dual-permeability model; wetting-drying cycles

34 **1. Introduction**

35 Desiccation cracks are prevalent in clay-dominated soils due to water loss, which often lead water to bypass the surface soil
36 matrix and rapidly infiltrate into subsoil as preferential flow (Davidson, 1984; Weiler, 2005). Positively, the preferential flow
37 induced by desiccation cracks (PF-DC) can promote the migration of farmland organic matter (Vervoort et al., 2003) and
38 reduce surface runoff (Pei et al., 2020; Zhang et al., 2021a). Negatively, it also has proven to be an important hydrological

mechanism that could lead to geotechnical engineering and ecological environment problems, such as dike and slope instability (Jamalinia et al., 2020; Zhang et al., 2021b), shallow landslides (Bogaard and Greco, 2015; Caris and Van Asch, 1991; Luo et al., 2021), groundwater pollution (Chaduvula et al., 2022; Chen et al., 2002; Mooney and Morris, 2008; Schlögl et al., 2022) and reduction of irrigation efficiency (Greve et al., 2010; Smith et al., 2005; Wang et al., 2018; Wang et al., 2022). Under the current background of frequent extreme flood-drought climate events, its negative effects will be more prominent (Tichavsky et al., 2019). Investigation on the PF-DC are of great significance in guiding scientific research and practical design in the above disciplines.

A unique characteristic of the desiccation cracks is their dynamic features, often causing instantaneous variation of crack proportion, depth and connectivity with moisture content. Previous efforts have attempted to reveal the effects of crack dynamics on the PF-DC through experimental studies, but most of them focused on short-term wetting process and obtained only qualitative results and debates remained. For instance, Favre et al. (1997) and Liu et al. (2003) stated that crack closure due to wetting can cause a significant reduction or even disappearances in the preferential flow. However, other studies found that the PF-DC also leads water to rapidly infiltrate into deep soil even when desiccation cracks are nearly closed (Baram et al., 2012a; Greve et al., 2010; Luo et al., 2021; Tuong et al., 1996; Sander and Gerke, 2007). Cheng et al. (2021) conducted a series of constant-head permeability tests with the hydraulic head gradient of 15 kPa. They stated that 4% of surface crack ratio could be a critical value for determining whether desiccation cracks cause a significant increase in the infiltration rate or not. However, this value may vary with different soils, rainfall patterns and sample scales, and thus lacks general applicability. Indeed, PF-DC has long-term and complex spatiotemporal variability due to crack dynamics during wetting-drying cycles. Therefore, short-term and small-scale infiltration tests (i.e. laboratory permeability tests) are not enough to reveal the complex hydrological process induced by PF-DC. Meanwhile, it is also difficult to quantitatively study PF-DC only through experiments. An improve understanding of the PF-DC combined with theoretical methods is also needed.

Regarding the theoretical methods, explicit crack models (EMs) (Hendrickx. and Flury, 2001; Khan et al., 2017; Xie et al., 2020)), dual-porosity (DPoM) (Van Genuchten, 1980; Van Genuchten and Wierenga, 1976) and dual-permeability (DPM) (Aguilar - López et al., 2020; Gerke and Van Genuchten, 1993b, 1993a) models were developed to simulate preferential flow in cracked clay soils. EMs were constructed based on the single-domain (or single-permeability) framework, which require to define the details involving the geometry, spatial distribution and hydrological properties of each crack. Such requirement may be conceptually correct but makes them difficult for simulating network-distributed desiccation cracks due to considerable computational burden (Aguilar - López et al., 2020). The DPoM and DPM concepts belong to the dual-domain framework that assumes the soil pore system can be represented as two overlapping interacting regions, one which represents the matrix domain with micropores and the other one represents the crack domain with meso-macro pores (Šimůnek et al., 2003). Those models represent the cracks in the soil as implicit form which need not to prescribe geometrical and spatial features of the desiccation cracks. The DPoM concept holds the simplifying stipulation that water only flows through the shrinkage cracks rather than the soil matrix, which is unrealistic in many cases. To remedy this shortcoming, classical DPM was developed, where, the water flow in soil matrix and crack domain was simulated using the Richards' equation (Aguilar - López et al., 2020; Coppola et al., 2012; Gerke and Maximilian Köhne, 2004; Gerke and Van Genuchten, 1993a) or Green-Ampt model (Davidson, 1984; Stewart, 2019; Weiler, 2005) building on Darcy's law. However, some critics emerged that the Richards' equation building on the capillarity, not existing in large PF paths (e.g. tensile cracks and biological holes), is not suitable to simulate the PF (Larsbo and Jarvis, 2003; Nimmo, 2010; 2021). Consequently, some improved DPMs were developed, where, water flow in the crack domain was simulated by the Navier-Stokes equation (Germann and Karlen, 2016; Nimmo, 2010), kinematic wave equation (Greco, 2002; Larsbo and Jarvis, 2003) and Poiseuille model (Lepore et al., 2009). Although these improved DPM models better captured the characteristics of the water flow in the crack domain, the classical DPM concept has still been widely accepted and used in simulating preferential flow in soils due to its easily available

parameters, reasonably satisfactory prediction to the measurements and high computation efficiency (Jarvis et al., 2016). Most importantly, a recent numerical study conducted by Aguilar - López et al. (2020) proved that effective parameter selection in the DPM models can achieve similar modeling results to the EMs.

Nevertheless, classical DPM models often adopt the assumption that crack volume and hydrological properties remain constant in both time and space, which is unfeasible to capture the full dynamics of PF-DC. Some attempts have been made to incorporate the dynamic nature of desiccation cracks into DPM including the SWAP family of models, i.e. LEACHM, which simulates PF-DC using a shrinkage characteristic and water loss (Kroes et al., 2000), but neglects water exchange process occurring at the interface between two domains. Such a process has widely been confirmed to be significant in cracked soils (Greve et al., 2010; Krisnanto et al., 2016; Tuong et al., 1996). A later modification of SWAP incorporated the aforementioned process, but at the cost of neglecting shrink-swell behavior of soil. The VIMAC model developed by Greco (2002) solved previous problems but against the cost of inducing many parameters which are difficult to determine from experiments or measurements. Coppola et al. (2012); (2015) took another step forward to allow crack volume and/or hydrological properties to vary as a function of soil shrinkage. However, the relationship proposed in the model, an empirical natural logarithm function involving the suction head and crack proportion, is not directly transferable to other types of soil. Stewart et al. (2016b) deduced a shrinking-swelling model, with relatively clear physical meaning and high consistency, and recently incorporated it into a Green-Ampt based DPM (Stewart, 2018). While an analytical solution was obtained, the intrinsic limitation of the Green-Ampt approach (i.e. hypothesis of the wetting front and request for a constant boundary condition) hindered the further application of this model in complicated scenarios.

The objective of this research was to investigate the PF-DC from the experimental perspective in combination with an effective modelling approach. Hence, a soil column test was conducted to investigate the dynamic changes of desiccation cracks and hydrological response. The variation of crack geometry, including crack ratio, width and depth were measured. The soil moisture content, matrix suction and water drainage were also monitored. Meanwhile, we developed a dynamic dual-permeability preferential flow model by incorporating the shrinking-swelling model proposed by Stewart et al. (2016b). The performance of the model was evaluated by comparing the simulated results with measured data.

2. Experimental study

2.1 Testing apparatus

To investigate the effects of dynamic changes of desiccation cracks on preferential flow, a soil column infiltration test was conducted under wetting-drying cycles (abbreviated as WD cycles hereafter). The testing apparatus consisted of a rainfall-evaporation system, environment monitoring device, a plexiglass column, HD camera, hydrological sensors and drainage measurement device (Fig. 1).

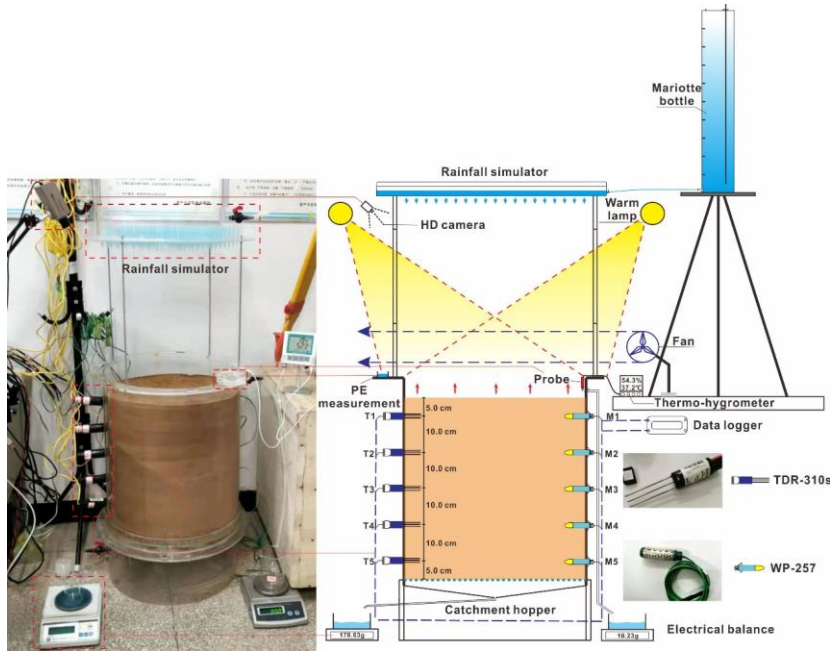

The rainfall-evaporation system included a rainfall simulator and two warm lamps as well as a small fan. The rainfall simulator was 0.5 m above the soil surface, which can produce rainfall with the intensity of 24-120 mm/h. The warm lamps and a small fan were put near the soil surface to accelerate water evaporation. The environment monitoring device consisted of a thermo-hygrometer that connected a probe above the soil surface to detect the environmental temperature and humidity, and a water container to measure the potential evaporation.

The plexiglass column was composed of a column (with a height of 60 cm and a diameter of 50 cm) placed on a catchment hopper which was used to collect and drain out water from the soil column.

HD camera (TTQ-J2, constant focal length: 35 mm) was fixed on the slope above the soil surface to take photos at regular intervals during the drying periods.

Hydrological sensors, including 5 soil moisture content/temperature sensors (Acclima, TDR-310s, with a measurement moisture content range of 0-100%, an accuracy of $\pm 2\%$; temperature range of $-40\text{ }^{\circ}\text{C}$ - $+60\text{ }^{\circ}\text{C}$, an accuracy of $\pm 0.2\text{ }^{\circ}\text{C}$) and 5

122 water potential sensors (Campbell, WP-257, with a measurement range of -200 kPa - 0 kPa, an accuracy of ± 0.5 kPa), were
 123 used to monitor the hydrological response during WD cycles. Five TDR-310s and five WP-257s were inserted into the soil
 124 column from the two opposite sides of the plexiglass column, respectively, with the same height spacing of 10 cm from top
 125 to bottom.
 126 Drainage measurement device, including two electronic balances, were used to record the cumulative water drainage from
 127 the soil column.

128
 129 **Fig. 1** Schematic design and photos of the soil column test

130 **2.2 Materials**

131 The soil used in the test was taken from Zongyang county Anhui, China. Table 1 shows the basic physical parameters and
 132 main mineral composition of the soil samples. The soil found in this study is classified as weak expansive soil. The saturated
 133 hydraulic conductivity was measured on reconstituted soil cores with a dry density of 1.55g/cm^3 (the same as the soil column).
 134 In addition, the shrinkage curve of the saturated soil core was also obtained using a similar method proposed in Wen et al.
 135 (2021). The difference is that we measured the vertical deformation in regular time intervals instead of continuous monitoring.
 136 Fig. 2 shows the variation of soil porosity with the volumetric water content.

137 **Table 1** Basic physical parameters of the soil sample

Gs (-)	ω_{opt}	$\rho_{d,max}$	L_l (%)	P_l (%)	δ_{ef} (%)	C_{Illite}	$C_{Kaolinite}$	C_{Quartz}	C_{Albite}	K_s
2.73	0.17	1.7	38.7	18.9	42.7	43-57	4-12	34-47	0-11	$8.3 \times 10^{-7} - 1.3 \times 10^{-6}$

Gs - specific gravity (-);
 ω_{opt} - optimal moisture content (g/g) which refers to the water content corresponding to the maximum dry density;
 $\rho_{d,max}$ - the maximum dry density (g/cm^3);
 L_l - liquid limit (%); P_l - Plastic limit (%);
 δ_{ef} - Free swelling ratio (%);
 C_{Illite} , $C_{kaolinite}$, C_{Quartz} and C_{Albite} - content of illite, kaolinite, quartz and albite, respectively (%);
 K_s - Saturated hydraulic conductivity (m/s)

138
139 **Fig. 2** Shrinkage curve of the test soil

140 To ensure the homogeneity of the soil column, soil samples were compacted in 10 layers, and each layer was 5 cm thick. Prior
141 to filling soil into the plexiglass column, the soil samples with the total weight required for each layer were prepared according
142 to the designed density (dry density of 1.55g/cm³) and gravimetric water content (10%). Then, the soil samples were
143 compacted in the plexiglass column using a rubber hammer. The soil column was constructed within one day. After that, the
144 soil column was allowed to stand for 3 days to obtain stable records of the hydrological sensors.

145
146 **2.3 Data collection**

147 In the soil column test, the following data was collected:

- 148 (1) Boundary conditions: rainfall intensity (r , mm/h), potential evaporation (PE , mm/h) at 1 h time interval, temperature (T , °C)
149 and relative humidity (RH , %) at 5 min time interval.
150 (2) Hydrological data: volume water content (θ_{exp} , %) and soil matrix suction (S_{exp} , kPa) in different depths at 5 min time
151 interval, cumulative drainage from the top (D_{top} , g) and bottom (D_{bottom} , g) of the soil column.
152 (3) Crack geometric data: crack ratio ($w_{c,exp}$), crack aperture ($w_{j,exp}$), and the maximum crack depth (d_{max} , mm). The $w_{c,exp}$
153 and $w_{j,exp}$ were obtained via processing the crack photos which were taken at 20 min intervals during drying periods. The
154 image processing method mainly includes two steps as shown in Fig. 3. The d_{max} was measured by thin wire before each
155 rainfall event.

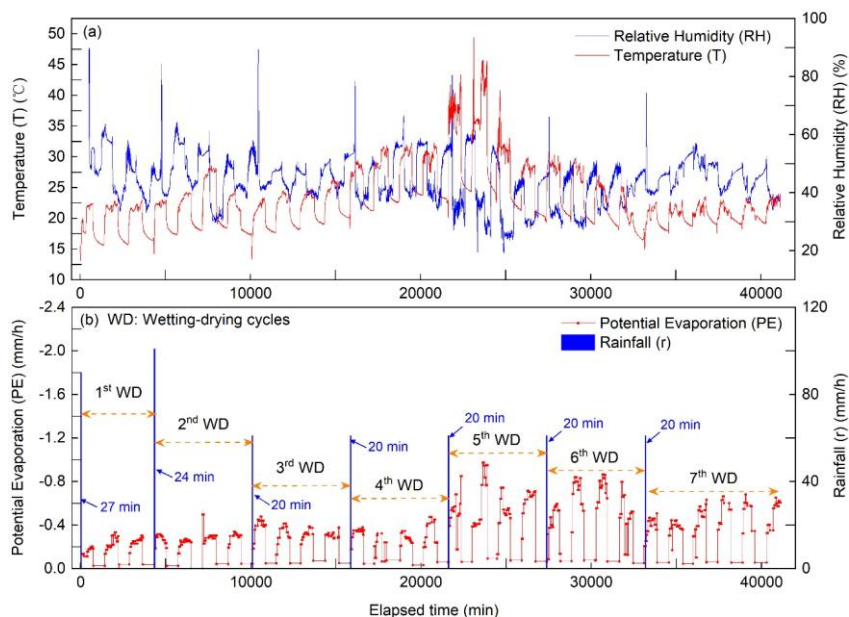

156
157 **Fig. 3** Process of crack image processing. (a) a photo obtained from the HD camera, 800 pixels × 1400 pixels; (b) crack
158 image after cropping and pixel enhancement, 1044 pixels × 1005 pixels; (c) crack image after binarization and denoise, and
159 the crack ratio was calculated as the crack area divided by the overall area of interest, the crack aperture was calculated as the
160 average value of crack aperture from three different positions.

161
162 **2.4 Test procedure**

163 The overall experimental process included two stages of WD cycles. The purpose of the first stage was to generate a relatively
164 stable surface pattern of the desiccation cracks. It started from 2022/01/05 15:00 to 2022/02/28 9:00, including thirteen WD
165 cycles.

166 The second stage started from 2022/02/28 9:00 to 2022/03/28 22:30, including seven WD cycles. Fig. 4 presents the variation
 167 of rainfall, evaporation, temperature and relative humidity in the entire experiment process. Because the two warm lamps and
 168 fan were closed during the night, two kinds of evaporation intensity can be observed during the drying periods. In addition,
 169 the average environment temperature in the 5th WD cycle was higher because we turned up the power of the two warm lamps.
 170 In this current study, we mainly focus on the second stage of WD cycles.

171
 172 **Fig. 4** Environmental conditions of the experiment. (a) time series of temperature and relative humidity; (b) rainfall intensity
 173 and potential evaporation.
 174

175 3. Model Description

176 3.1 Dual-permeability model (DPM)

177 The DPM concept used in this study corresponds to the one developed by Gerke and Van Genuchten (1993a). The model
 178 divides the flow domain into two overlapping and interacting continua according to the volumetric ratios of each domain,
 179 where two coupled 2-D Richards' equations are used to describe the matrix flow and preferential flow as

$$180 C_c(h) \frac{\partial h_c}{\partial t} = \nabla [K_c(h) \nabla (h_c + z)] - \frac{\Gamma_w}{w_c} \quad (1)$$

$$181 C_m(h) \frac{\partial h_m}{\partial t} = \nabla [K_m(h) \nabla (h_m + z)] + \frac{\Gamma_w}{w_m} \quad (2)$$

$$182 \Gamma_w = \alpha_w K_a (h_c - h_m) \quad (3)$$

$$183 w_c + w_m = 1 \quad (4)$$

184 where subscript "c" and "m" indicate the crack and matrix domains, respectively; h (m) is the pressure head; C represents the
 185 specific water capacity, $d\theta/dh$ (1/m); θ (-) is the volumetric water content; K (m/s) is the isotropic hydraulic conductivity;
 186 z (m) is the elevation head; w (-) is the volumetric ratio of the crack domain or matrix domain over the bulk soil volume;
 187 Γ_w is the water exchange term (1/s) between the two domains; α_w (1/m²) is the effective water transfer coefficient; K_a

188 (m/s) is the interface hydraulic conductivity.
 189 The hydraulic properties of the two domains are parameterized based on the Mualem-van Genuchten soil-water retention
 190 curves (SWRC) (Mualem, 1976; Van Genuchten, 1980) as

$$191 S_e(h) = \frac{\theta - \theta_r}{\theta_s - \theta_r} = [1 + (\alpha h)^n]^{-m} \quad (5)$$

$$192 K(S_e) = K_s K_r(S_e) = K_s S_e^{0.5} [1 - (1 - S_e^{1/m})^m]^2 \quad (6)$$

193 where S_e (-) is the effective saturation; θ_s (-) and θ_r (-) are the saturated and residual volumetric water content, respectively;
 194 α (1/m), n (-) and m (-) are fitting parameters; K_s (m/s) is the saturated hydraulic conductivity; K_r (-) is the relative
 195 hydraulic conductivity.

196 According to Gerke and Van Genuchten (1993a), the total porosity ε (-), total volume water content θ (-), total hydraulic
 197 conductivity K (m/s) and total volumetric flux (m/s) in terms of the volume ratio of each domain can be expressed as

$$198 \varepsilon = w_c \varepsilon_c + w_m \varepsilon_m \quad (7)$$

$$199 \theta = w_c \theta_c + w_m \theta_m \quad (8)$$

$$200 K = w_c K_c + w_m K_m \quad (9)$$

201 Note that the total porosity ε is define as the total pore volume (V_p) divided by total soil volume (V), while ε_m (or ε_c) is
 202 defined as the pore volume in matrix ($V_{p,m}$) (or crack, $V_{p,c}$) domain divided by the volume of that domain (V_m or V_c). The total
 203 volume water content has the same definition.

204 In the case of a DPM model, specified flux i is divided between the matrix and crack domains as

$$205 i = w_c i_c + w_m i_m \quad (10)$$

206 where i_c and i_m are the effective boundary fluxes into each domain (m/s).

207 Considering a rainfall condition, the effective boundary fluxes of the two domains are initially equal to rainfall intensity (r)
 208 due to the infiltration capacity of each domain is larger than r (Dusek et al., 2008), and therefore the boundary fluxes of each
 209 domain can be written as

$$210 i_c = r \quad (11)$$

$$211 i_m = r \quad (12)$$

212 As the soil keeps wetting, the decrease of the pressure head gradient may firstly lead to the infiltration capacity of matrix
 213 domain dropping to a value less than r . Then, ponding occurs on the surface of the soil matrix and the boundary condition
 214 changes to a specified pressure head boundary. This transformation can be achieved in COMSOL, a multi-physic solver and
 215 simulation software package building on finite element method, by using a combined type of boundary (Dirichlet and
 216 Neumann) proposed by Chui and Freyberg (2009). Once ponding occurs on the matrix domain, the surplus water from that
 217 domain infiltrates into the crack domain and its effective flux increases to

$$218 i_c = (r - w_m i_m) / w_c \quad (13)$$

219 when the retained water volume in the cracks exceeds its storage capacity, water will pond on the surface of the crack domain.

220 Considering an evaporation condition, the Wilson-Fredlund-Barbour-Penman experimental function model (Wilson et al.,
 221 1997) was used to calculate the actual evaporation of each domain

$$222 AE / PE = \exp\left(\frac{-Sg\omega_w}{\xi(1-h_a)\gamma_w R(T_s + 273.15)}\right) \quad (14)$$

223 where AE is the actual evaporation; PE is the potential evaporation measured in the experiment; S (kPa) is total matric suction
 224 at the soil surface; g (m/s²) is the gravitational acceleration constant; ω_w is molecular mass of water, 0.018kg/mol; ξ is

225 a dimensional empirical parameter with a suggested value of 0.7; h_a is relative humidity of overlying air; γ_w is unit mass
 226 of water, 9.807 kN/m³; R is universal gas constant, 8.314J/(mol·K); T_s (°C) is the soil surface temperature.

227
 228 3.2 Dynamic dual-permeability model (DPMDy)
 229 3.2.1 Porosity description

230 In Stewart et al. (2016a); (2016b) and Stewart (2018), the total porosity (ϕ_{max}) of a cracked soil was divided into three domains:
 231 aggregates (or soil matrix), cracks (voids from horizontal deformation induced by desiccation cracks) and subsidence (voids
 232 from vertical deformation induced by desiccation cracks). In Stewart et al. (2016a), the distributions of these domains change
 233 as a function of a unified water content, U

$$234 \phi_{max} = \phi_{matrix}(U) + \phi_{crack}(U) + \phi_{sub}(U) \quad (15)$$

235 where the subscripts matrix, crack and sub refer to the aforementioned three domains. In this study, we assume that the
 236 horizontal deformation dominates the formation of desiccation cracks, thus $\phi_{sub}(U)$ can be neglected.

237 Stewart et al. (2016a) then deduced the porosities of each domain as:

$$238 \phi_{matrix}(U) = (\phi_{max} - \phi_{min}) \left(\frac{p+1}{p+U^{-q}} \right) + \phi_{min} \quad (16)$$

$$239 \phi_{crack}(U) = (\phi_{max} - \phi_{min}) \left(\frac{1-U^q}{1+pU^q} \right) \quad (17)$$

240 where p and q are functional shape parameters; ϕ_{max} is the maximum porosity of a soil core prior to shrinkage and thus also
 241 represents the total porosity; ϕ_{min} is the minimum porosity of the matrix domain; U is a unified water content (defined as
 242 water content u divided by its saturated value u_{max}), which can be approximately estimated to be the saturation degree ($S_{e,m}$)
 243 in an SWRC function of the soil matrix (Stewart et al., 2016a). Indeed, Eq. (16) represents a shrinkage curve function in which
 244 four parameters can be obtained through a shrinkage test.

245 Substituting $S_{e,m}$ as U and incorporating Eq. (5) into Eq. (16) and Eq. (17), we can obtain the porosity of the two domains as
 246 a function of pressure head h

$$247 \phi_{matrix}(h) = (\phi_{max} - \phi_{min}) \left(\frac{p+1}{p+S_{e,m}^{-q}} \right) + \phi_{min} = (\phi_{max} - \phi_{min}) \left(\frac{p+1}{p + \left(\left[1 + (\alpha_m h_m)^{n_m} \right]^{-m_m} \right)^{-q}} \right) + \phi_{min} \quad (18)$$

$$248 \phi_{crack}(h) = (\phi_{max} - \phi_{min}) \left(\frac{1-S_{e,m}^q}{1+pS_{e,m}^q} \right) = (\phi_{max} - \phi_{min}) \left(\frac{1 - \left(\left[1 + (\alpha_m h_m)^{n_m} \right]^{-m_m} \right)^q}{1 + p \left(\left[1 + (\alpha_m h_m)^{n_m} \right]^{-m_m} \right)^q} \right) \quad (19)$$

249 With these porosity equations in mind, we can rewrite Eq. (4) and Eq. (7) as:

$$250 \phi_{max} = w_c \varepsilon_c + (1 - w_c) \varepsilon_m \quad (20)$$

251 Because the crack domain is mainly composed of voids, we here assume that $V_{p,c}$ equals to V_c , and thus $\varepsilon_c = 1$. Through this
 252 assumption, we obtained a physically-consistent definition of how the porosity and crack volume vary as functions of
 253 saturation degree as follow

$$254 w_c \varepsilon_c = w_c = \phi_{crack}(S_{e,m}) = (\phi_{max} - \phi_{min}) \left(\frac{1-S_{e,m}^q}{1+pS_{e,m}^q} \right) \quad (21)$$

$$255 \varepsilon_m = \frac{\phi_{matrix}(S_{e,m})}{1-w_c} = \left[(\phi_{max} - \phi_{min}) \left(\frac{p+1}{p+S_{e,m}^{-q}} \right) + \phi_{min} \right] / \left[1 - (\phi_{max} - \phi_{min}) \left(\frac{1-S_{e,m}^q}{1+pS_{e,m}^q} \right) \right] \quad (22)$$

256

3.2.2 Water content and hydraulic conductivity

In terms of Eq. (8), the total water content of the soil volume can be expressed as:

$$\theta = \phi_{crack}(h)\theta_e + (1 - \phi_{crack}(h))\theta_m \quad (23)$$

Regarding the hydraulic conductivity of each domain, the classical DPM often assumed it equals to the product of a fixed K_s and the relative hydraulic conductivity K_r of the corresponding domain. In the DPMDy model, VG-Mualem equation is adopted in the matrix domain, while in the cracks, where capillarity has little effect on water flow, we set $K_r=1$. Hence, the following equations are obtained

Regarding the hydraulic conductivity of each domain, the classical DPM often assumed it equals to the product of a fixed K_s and the relative hydraulic conductivity of the corresponding domain. The following equations are obtained according to Eq. (6):

$$\begin{cases} K_m = K_{m,s} K_r(S_{e,m}) = K_{m,s} S_{e,m}^{0.5} [1 - (1 - S_{e,m}^{1/m_m})^{m_m}]^2 \\ K_c = K_{c,s} K_r(S_{e,c}) = K_{c,s} S_{e,c}^{0.5} [1 - (1 - S_{e,c}^{1/m_c})^{m_c}]^2 \end{cases} \quad (24)$$

~~$$K_c = K_{c,s} K_r(S_{e,c}) = K_{c,s} S_{e,c}^{0.5} [1 - (1 - S_{e,c}^{1/m_c})^{m_c}]^2 \quad (24)$$~~

$$K_c = K_{c,s} K_r(S_{e,c}) = K_{c,s} S_{e,c}^{0.5} [1 - (1 - S_{e,c}^{1/m_c})^{m_c}]^2 \rightarrow K_c = K_{c,s} \quad (25)$$

where $K_{c,s}$ and $K_{m,s}$ refer to the saturated hydraulic conductivity in crack and matrix domains, respectively.

However, the $K_{c,s}$ and $K_{m,s}$ are transient variables that changes with the crack geometries in crack domain and porosity in matrix domain, which should be taken into consideration in a shrinking-swelling soil. To solve this issue, Stewart et al. (2016b)

further deduced models that describe the relationships between $K_{m,s}$, $K_{c,s}$ and $S_{e,m}$.

$$K_{m,s}(S_{e,m}) = K_{m,max} \left(\frac{p+1}{p+S_{e,m}^{-q}} \right) \quad (26)$$

$$K_{c,s}(S_{e,m}) = K_{c,max} \left(\frac{1-S_{e,m}^q}{1+pS_{e,m}^q} \right)^2 \quad (27)$$

where $K_{c,max}$ is the maximum saturated hydraulic conductivity of the crack domain (at $S_{e,m} = 0$) when the crack aperture achieves the maximum value; $K_{m,max}$ is the maximum saturated hydraulic conductivity of the matrix domain (at $S_{e,m} = 1$) when the radius of cylindrical pores in that domain achieves the maximum value (See Eq. (25) and Eq. (27) in Stewart et al. (2016b)). The assumption $K_r(S_{e,c}) = 1$ means that the magnitude of K_c only depends on the crack area or the saturated degree of the soil matrix domain. ~~In the DPMDy model, we here set $K_r(S_{e,c}) = 1$ in Eq. (25). This modification means that the magnitude of K_c only depends on the crack area or the saturated degree of the soil matrix domain.~~

$$K_c = K_{c,s} = K_{c,s}(S_{e,m}) = K_{c,max} \left(\frac{1-S_{e,m}^q}{1+pS_{e,m}^q} \right)^2 \quad (28)$$

Incorporating Eq. (26) and Eq. (27) into Eq. (9) obtains:

$$K_s = \phi_{crack}(h) K_{c,max} \left(\frac{1-S_{e,m}^q}{1+pS_{e,m}^q} \right)^2 + (1 - \phi_{crack}(h)) K_{m,max} \left(\frac{p+1}{p+S_{e,m}^{-q}} \right) \quad (29)$$

Note that $K_{m,max}$ can be obtained by laboratory-based infiltration test through a saturated soil core prior to shrinkage. Then,

带格式的: 下标

域代码已更改

286 Eq. (29) can be used to fit the $K_{c,max}$ through the overall saturated hydraulic conductivity (measured K_s) under different
 287 crack volume or ratio. Alternatively, $K_{c,max}$ can also be approximately calculated as

$$288 \quad K_{c,max} = \frac{w_{j,max}^2 g}{12\nu} \quad (30)$$

289 where $w_{j,max}$ stands for the maximum crack aperture measured in experiment (m), g is the gravity acceleration constant
 290 (m/s^2), and ν is the water kinematic viscosity (m^2/s). This equation is a relation to the cubes of the aperture of a crack with
 291 respect to the crack inner flux, which is based on the derivation of laminar flow between parallel plates for Hagen-Poiseuille
 292 type of flow (Snow, 1965).

293 Eventually, we can simulate the hydrological process with considering the dynamic changes of desiccation cracks by
 294 incorporating Eq. (19), Eq. (21), Eq. (26), Eq. (27) and Eq. (28) into the DPM.

295

296 4. Experimental results

297 4.1 Crack dynamic changes

298 Fig 5 presents typical images of crack evolution during each WD cycle. Intuitively, it seems that the crack area and width did
 299 not show an obvious increasing trend with the WD cycles as expected. Conversely, during the 1st to 4th WD cycles, the cracks
 300 at the same moment after rainfall (Fig 5b2-4) and the final state (Fig 5c2-4) decreased significantly even though the
 301 environmental temperature (T) and the potential evaporation (PE) increased in these periods. The cracks increased
 302 significantly since the 5th WD cycle, but most of them were finer than before. Overall, cracks in the 1st WD cycle are wider
 303 than those formed in other cycles.

304

305 **Fig. 5** Typical images of crack evolution in seven wetting-drying cycles. (a1-7) water ponds on the soil surface after rainfall;
 306 (b1-7) crack images at the 2135th min after each rainfall; (c1-7) crack images at the end of the final high evaporation period
 307 during each wetting-drying cycle

308

309 Fig 6 quantitatively shows the variation of crack ratio ($w_{c,exp}$) and crack aperture ($w_{j,exp}$) in the experiment. Overall, the
 310 variation curves corresponded to the intuitive descriptions mentioned above. Especially, an unexpected result was that the T
 311 and PE in the 5th and 6th WD cycles were higher than in previous cycles, but their maximum $w_{c,exp}$ and $w_{j,exp}$ became
 312 smaller. During a single WD cycle, the $w_{c,exp}$ and $w_{j,exp}$ have a similar trend, which shows a dramatic decrease during
 313 rainfall, rapid increase in high evaporation periods and slow increase or even decrease in low evaporation periods. More
 314 specifically, during the rainfall periods, the crack closure process was not significant until the water ponded on the soil matrix,

315 then ponded water flowed into the cracks, leading to acceleration of the crack closure. Note that cracks were not completely
 316 closed even when they were full of water (Fig 5a1-7). The minimum crack ratio under such conditions is approximately 0.1%.
 317 In the evaporation periods, the maximum crack ratio reaches 2.87% and the maximum crack aperture reaches 2.6 mm. In
 318 addition, Fig 7 shows the maximum crack depth (d_{max}) measured after each cycle. It can be seen that d_{max} increased
 319 substantially after the 1st WD cycle and then slightly increased in the last six cycles, with a maximum value of 23.8 cm.

320
 321 **Fig. 6** Time series of crack geometries. (a) crack ratio; (b) crack aperture

322
 323 **Fig. 7** The maximum crack depth measured after each wetting-drying cycle

324
 325 **4.2 Hydrological response**

326 Table 2 presents the manually recorded results of external hydrological responses involving ponding and drainage during each
 327 WD cycle. It can be seen that the ponding occurred on the soil surface within 5 min after each rainfall. The ponding duration
 328 in each rainfall mainly decreased with WD cycles. Note that the ponding depth in each rainfall was below the upper drainage
 329 outlet. Regarding the water drainage, approximately 1.4 kg of water (the total water mass was 8 kg) was leaked during the 1st
 330 rainfall due to the interspace between the soil and the plexiglass column and the hydrological sensors. Then, we sealed the

interspace using clay powder and polyurethane cement (soft materials without constrain effects on the soil swelling) after each drying process, and subsequently, no water drainage was observed at the bottom outlet.

Table 2 Manual readings of external hydrological responses

Wetting-drying cycles	1 st	2 nd	3 rd	4 th	5 th	6 th	7 th
t_p (min)	4.1	1.8	1.2	1.2	1.2	2.2	2.8
Ponding duration (min)	70	160	68	47	34	25	23
Drainage (g)	1412	-	-	-	-	-	-
* t_p (min) – beginning of ponding after each rainfall							

Fig 8 shows the internal hydrological responses recorded by the soil moisture and water potential sensors. Because the M2 and M4 were damaged during soil compaction, no matric suction data was obtained at their depths. Overall, water content at all depths increased during rainfall and decreased during evaporation, where T1 showed the most sensitive responses to the WD cycles. During rainfall, the time for water content to respond to each rainfall increased with depths, but the time difference among all depths decreased significantly since the 2nd WD cycle. During the drying periods, an interesting phenomenon was that the water content at 5 cm depth showed an overall decline trend, but transient increases of water content frequently appeared during low evaporation periods. Such transient increases seem to be related to the slow decrease of crack ratio as mentioned in section 4.1. Regarding the matric suction, its variation trend was similar to the water content but showed more delayed responses to the environmental conditions, especially in the last three WD cycles. Additionally, Fig 8b also implies that soil at 5 cm depth reached saturation during each rainfall, while soil below the 25 cm depth was in the unsaturated state in the whole experiment process.

Fig.8 Time series of volume water content (a) and matric suction (b) at different depths.

5. Numerical simulation

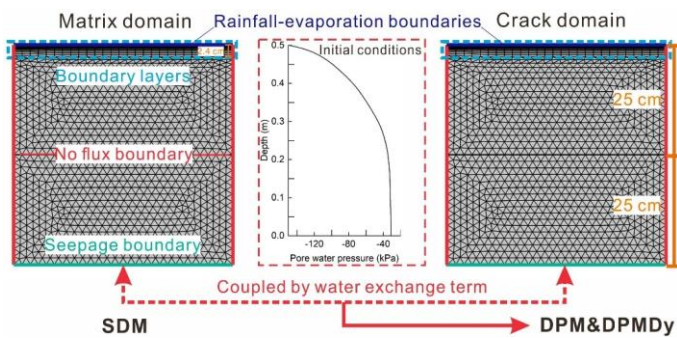

5.1 Set-up of numerical model

The single-domain model (SDM), dual-permeability model (DPM) and dynamic DPM (DPMDy) were implemented in a finite

351 element solver for Richards' equation as part of the COMSOL Multiphysics software (Comsol 5.6). As shown in Fig 9, they
 352 have the same 2-D size, boundary conditions, mesh structure and initial condition. The model domain is 0.5 m by 0.5 m, same
 353 as the soil column. Because the measured maximum crack depth was 23.8 cm, we specified the crack domain existing within
 354 the upper 25 cm depth of the soil column.

355 The boundary conditions at the top were set as combined type of boundary conditions (as mentioned in section 3.1) for
 356 representing the rainfall, ponding and evaporation process recorded in the experiment; the bottom side is a seepage
 357 condition; the left and right sides of the model are no-flux boundaries.

358 Because the pressure head in the surface area may change frequently and drastically during WD cycles, a refined mesh
 359 structure with dense boundary layers was used to capture the transient hydrological conditions. The boundary layers included
 360 15 layers of rectangular grid, with the minimum and maximum thick of approximately 0.04 cm and 0.3 cm, respectively. A
 361 coarser free-triangle mesh (average length of 1.8 cm) was defined below the boundary layers. The initial condition both in
 362 matrix and crack domains was set as the distribution of pore water pressure measured from the experiment prior to the 1st WD
 363 cycle.

364 **Fig. 9** Set-up of the 2-D numerical model for the SDM, DPM and DPMDy
 365

367 5.2 Parameters

368 5.2.1 Shrinkage parameters

369 As shown in Fig 10, using Eq. (18) to fit the measured shrinkage curve in Fig. 2, we obtained the four shrinkage parameters
 370 as $\phi_{\min}=0.22$, $\phi_{\max}=0.30$, $p=8.8 \pm 4.84$, $q=2.71 \pm 0.85$. Then, the variation of porosity in crack domain (or crack ratio
 371 w_c) and matrix domain (ε_m) could be obtained using Eq. (21) and Eq. (22), respectively. Note that the minimum w_c calculated
 372 by Eq. (21) was set as 0.001 considering the incomplete closure of cracks during rainfall.

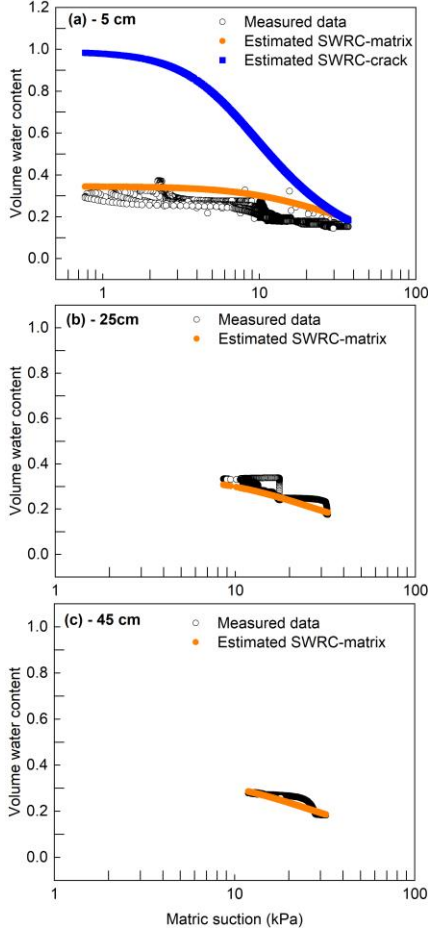

373

374 **Fig. 10** Fitted shrinkage curve (solid line) and modeled porosity variation of matrix (dash line) and crack domains (dash-dot
375 line)

376
377 5.2.2 Soil water retention parameters

378 **Fig 11** shows the measured matric suction versus volume water content at different depths. The SWRCs were estimated using
379 best fitting of the van Genuchten-Mualem equation to measured soil water retention data. It can be seen that the WD cycles
380 lead to hysteretic curves in the SWRC at 5 cm and 25 cm depths, while that at the 45 cm depth rarely show hysteretic curves.
381 This result may also indicate that most of the cracks exist within the upper 25 cm depth of the soil column. In this study, we
382 simply estimated an approximate single SWRC of the soil matrix through experiment data instead of incorporating the
383 hysteretic curves into the model. For instance, the estimated SWRC curve in **Fig 11a** lies between the wetting SWRC and
384 drying SWRC to capture the overall characteristics of wetting-drying SWRC as far as possible. Note that the shape parameter
385 n in the upper matrix domain is slightly smaller than the lower one considering the upper soil matrix may become denser after
386 long-time WD cycles (13 times, 54 days). Regarding the SWRC of the crack domain, as we assume the crack domain does
387 not contain any solids, the
388 saturated water content ($\theta_{c,s}$) and the residual water content ($\theta_{c,r}$) of that domain was set to be 0.99 and 0.01, respectively.
389 Meanwhile, because SWRC of the crack domain cannot be experimentally determined, we assigned the other two SWRC
390 parameters ($a=1.5$ and $n_c=2$) to mimick coarse textured soil like behavior, and to be consistent with Poiseuille law-, which
391 implies little effects of capillarity on flow through the cracks~~which implies that we neglect capillarity in the cracks.~~

392
393 **Fig. 11** Measured and estimated SWRC at different depths. (a) 5 cm; (b) 25 cm; (c) 45 cm

394
395 5.2.3 Hydraulic conductivity

396 As mentioned in Eq. (29), the maximum saturated hydraulic conductivity of matrix domain ($K_{m,max}$) equals the saturated
397 hydraulic conductivity (K_s) measured in laboratory. Here, we set $K_{m,max} = 1.16 \times 10^{-6}$ m/s. Regarding the $K_{c,max}$, it was
398 calculated using Eq. (30), where the $w_{j,max}$ was set to 2.6 mm obtained from Fig 6b. Then, the variation curve of transient
399 saturated hydraulic conductivity of the matrix domain ($K_{m,s}$) and the crack domain ($K_{c,s}$) could be obtained using Eq. (27)
400 and Eq. (28), respectively. Note that here we slightly modified Eq. (28) as follow.

401
$$K_{c,s}(S_{e,m}) = K_{c,max} \left(\frac{1 - S_{e,m}^q}{1 + p S_{e,m}^q} \right)^2 + K_{c,min} \quad (28-b)$$

402 This modification not only avoided the $K_{c,s}$ dropping to zero thus benefits the numerical convergence, but also was
403 reasonable when considering the incomplete closure of cracks during rainfall. The $K_{c,min}$ was also estimated using Eq. (30)
404 with a suggested $w_{j,max} = 0.01$ mm. Further, the variation of K_m and K_c with the pressure head (h) in the DPMDy could
405 be calculated by combining Eq. (24), Eq. (26) and Eq. (28). **Fig 12** presents K_m and K_c in the three models. Note that the

406 pressure head in $K_c(h_m)$ of the DPMDy refers to that of the matrix domain (h_m), while h in $K_c(h_c)$ of the DPM refers to
 407 that of the crack domain (h_c).
 408

409 5.2.4 Water exchange between and pore domains

410 In the dual-permeability concept, another important parameter is the hydraulic conductivity of the interface between matrix
 411 and crack domains (K_a). Generally, K_a was often estimated as the arithmetic mean of hydraulic conductivity of the two domains
 412 (Arora et al., 2011; Coppola et al., 2012; 2015; Gerke and Van Genuchten, 1993b; Laine-Kaulio et al., 2014; Shao et al., 2015).
 413 However, this approximation may overestimate the K_a when the hydraulic conductivity of the crack domain is much higher
 414 than that of the matrix domain, especially in cracked clays. In our current study, a K_a function reformulated by (Gerke et al.,
 415 2013) was adopted.

$$416 K_{a_{min}} = \begin{cases} \min\{K_m(h_c), K_c(h_c)\} & h_c \geq h_m \\ \min\{K_m(h_m), K_c(h_m)\} & h_c < h_m \end{cases} \quad (31)$$

417 This formulation represents that the flow occurs from the highest head toward the lowest head but regulated by the less
 418 permeable of the two subsystems in that instant of time (Aguilar - López et al., 2020).

419 Regarding the α_w , experimental results presented by Song et al. (2018) showed that the saturated K_a may be 1 order of
 420 magnitude larger than the $K_{m,s}$ which will represent an enlarging coefficient ranging from 10 to 18. Hence, the α_w was set
 421 as 10 m^{-2} considering the saturated $K_{a_{min}}$ determined by Eq. (31) equals to the $K_{m,s}$.

422
 423 **Fig. 12** Modeled hydraulic conductivity of each domain in the three models. (a) Saturated hydraulic conductivity of the matrix
 424 domain; (b) saturated hydraulic conductivity of the crack domain; (c) transient hydraulic conductivity of the matrix domain;
 425 (d) transient hydraulic conductivity of the crack domain
 426

427 All parameters and parametric methods for the SDM, DPM and DPMDy are listed in **Table 3**.

Table 3 Summary of parameters and parametric methods for the SDM, DPM and DPMDy

Model	Symbol	Parameter name	Units	Upper layer	Lower layer	Parameterization
SDM	$\theta_{m,s}$	Saturated water content of matrix domain	(-)	0.345	0.345	Fitting to data
	$\theta_{m,r}$	Residual water content of matrix domain	(-)	0.01	0.01	Fitting to data
DPM	α_m	SWRC fitting parameter of matrix domain	(1/m)	0.6	0.6	Fitting to data
DPMDy	n_m	SWRC fitting parameter of matrix domain	(-)	1.65	1.8	Fitting to data
	$K_{m,max}$	The maximum K_s of matrix domain	(m/s)	1.16×10^{-6}	1.16×10^{-6}	Measured
DPM	$\theta_{c,s}$	Saturated water content of crack domain	(-)	0.99	-	Assigned
	$\theta_{c,r}$	Residual water content of crack domain	(-)	0.01	-	Assigned
DPMDy	α_c	SWRC fitting parameter of crack domain	(1/m)	1.5	-	Assigned
	n_c	SWRC fitting parameter of crack domain	(-)	2	-	Assigned
	$K_{c,max}$	The maximum K_s of crack domain	(m/s)	5.9	-	Measured
	K_a	Hydraulic conductivity of the interface	(m/s)	K_{amin}	-	Assigned
	a_w	Mass transfer coefficient	(1/m ²)	10	-	Assigned
DPMDy	ϕ_{max}	The maximum porosity of a soil core	(-)	0.3	-	Fitting to data
	ϕ_{min}	The minimum porosity of a soil core	(-)	0.22	-	Fitting to data
	p	Shape parameter of soil shrinkage curve	(-)	10	-	Fitting to data
	q	Shape parameter of soil shrinkage curve	(-)	3.5	-	Fitting to data
DPM	w_c	Constant crack ratio using in DPM	(-)	0.01; 0.03	-	Assigned

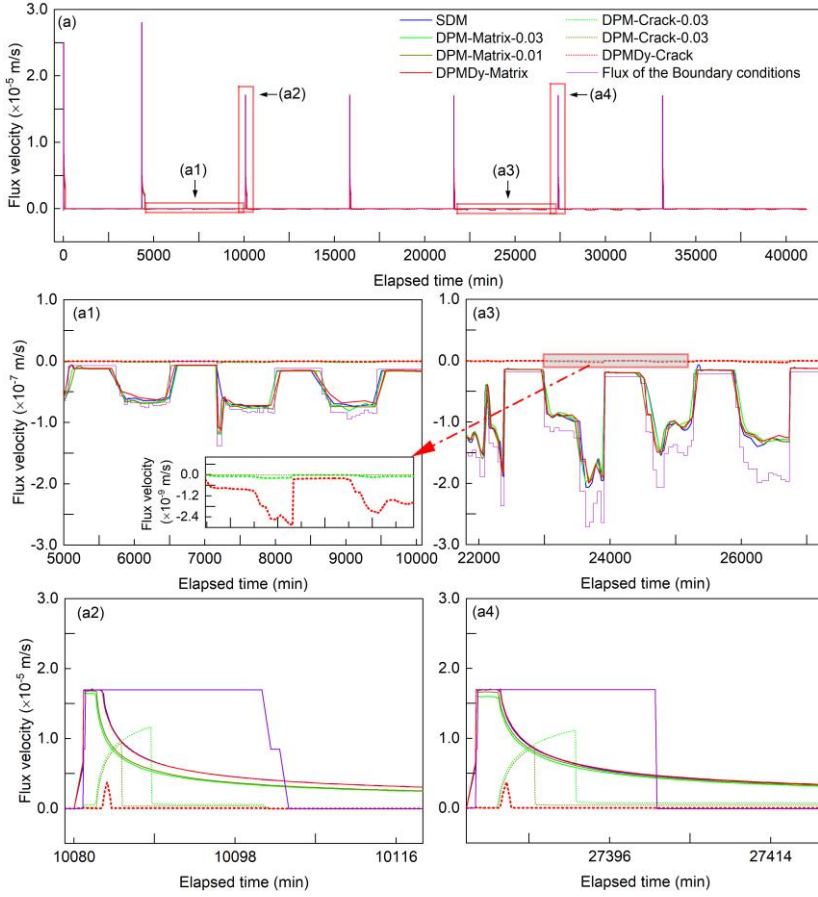

* SDM: single-domain model; DPM: dual-permeability model neglecting crack dynamic changes; DPMDy: Dynamic DPM; $w_c = 0.01$ and 0.03 refers to the average and the maximum value of the measured crack ratio, respectively.

430 5.3 Simulation results

431 5.3.1 Boundary flow

432 **Fig. 13** shows the temporal evolution of the boundary flow velocity simulated by the SDM, DPM and DPMDy. As shown in
433 **Fig. 13a1 and a3**, during drying periods, the matrix domain dominates the soil evaporation process and was responsible for
434 97%-99% of the total evaporation in all the dual-permeability models. The matrix evaporation rate (e_m) simulated by the
435 DPMDy was overall lower than that of the SDM and DPM during high-intensity evaporation periods, but the crack
436 evaporation rate (e_c) simulated by the DPMDy, especially during the last three drying periods, was approximately one to two
437 orders of magnitude larger than that of the DPM (see the enlarged image in Fig. a1).

438 With regard to the wetting process, **Fig. 13a2 and a4** represent two typical infiltration patterns before and after the 5th drying
439 period (with significantly increased evaporation intensity). Overall, matrix flow still dominated the infiltration process in all
440 the dual-permeability models due to the relatively small crack ratio and depth. For the SDM, all the rainfall infiltrates into the
441 soil during the beginning of rainfall events. When the soil surface gets saturated, water ponding occurred and the soil infiltration
442 rate gradually decreased. In the DPM and DPMDy, the surplus water after matrix ponding infiltrates into the crack domain as
443 preferential flow, and water will pond on the overall soil surface when the crack domain reached its storage capacity. Recall
444 that the crack volume in the DPMDy decreases with the matrix getting moist, while that in the DPM keeps constant.
445 Consequently, the ponding time of the crack domain simulated by the DPMDy in the 3rd rainfall event (inflection point of the
446 red dash line in Fig. 13a2) was 1.6 and 4.8 min earlier than that of the DPM-0.01 and DPM-0.03, respectively. The cumulative
447 preferential flow simulated by the DPMDy was 87.4% and 95.2 % less than that of the DPM-0.01 and DPM-0.03, respectively.
448 Similar rainfall pattern was obtained during the 6th rainfall event.

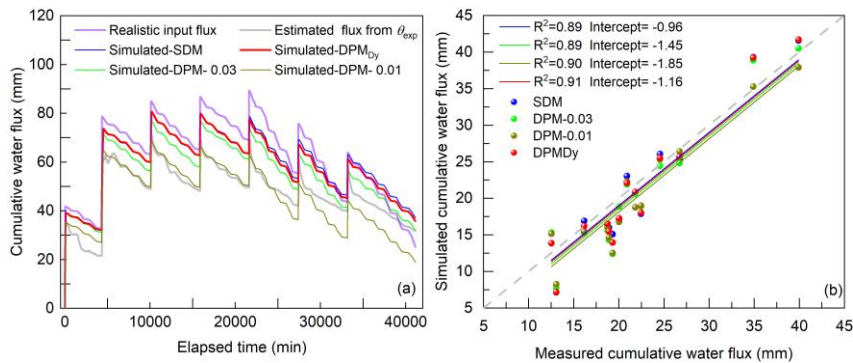

449 **Fig. 13** Boundary flow simulated by the SDM, DPM and DPMDy. (a) Flow velocity of the boundary conditions and simulated
 450 results; (a1) and (a2) are the enlarged images of the flow velocity during the 2st drying and 3rd wetting process, respectively;
 451 (a3) and (a4) are the enlarged images of the flow velocity during the 5th drying and 6th wetting process, respectively. The
 452 positive value is for infiltration and negative for evaporation.
 453
 454

455 5.3.2 Water balance

456 By integrating the boundary flow velocity in Fig. 13a, the total cumulative flux for the experiment and the three models were
 457 obtained (**Fig 14a**). In the experiment, the variation of water flux was estimated by calculating the sum of the difference
 458 between θ_{ini} (initial volume water content) and $\theta_{t=i}$ (volume water content at any time) in the five monitoring depths.
 459 Meanwhile, the water evaporation during water ponding was also estimated and added to the total flux volume. Regarding
 460 the numerical model, the water balance was obtained by integrating all flow components along the upper and lower boundaries.
 461 The steep increase stage of each curve represents cumulative input water flux during wetting periods and the gradual decrease
 462 stage represents cumulative output water flux during drying periods. To evaluate the performance of each model on the water
 463 balance, the measured cumulative input and output water fluxes in each wetting and drying stage were compared to the
 464 simulated ones (Fig. 14b).

465 In Fig. 14a, the results show that the total infiltration ($I_{t,inf}$) and evaporation flux ($E_{t,eva}$) estimated from measured θ_{exp} were

466 171 mm and 138.95 mm, respectively. The $I_{t,inf}$ was 5.86 % less than the supplied water (183.44 mm) due to the water leakage.
 467 The $E_{t,eva}$ was 16.48 % less than the cumulative PE (166.36 mm) because of the limit of the soil actual evaporation. Regarding
 468 the simulation results, the coefficient of determination (R^2) and intercept were used to evaluate the errors made by the three
 469 models. As shown in Fig. 14b, the slope of each fitting curve was fixed as 1. The SDM and DPMDy have relatively smaller
 470 intercepts and slightly higher R^2 than that of the DPM-0.01 and DPM-0.03, indicative of a better coincidence to the measured
 471 data. Overall, the errors in water balance caused by the three models were acceptable in this study.

472 **Fig. 14.** Water balance for the measured and simulated results (a) Temporal evolution of total water flux calculated from the
 473 measured water content, SDM, DPM and DPMDy; (b) measured versus modeled cumulative flux during each drying and
 474 wetting stage
 475
 476

477 5.3.3 Crack dynamic changes and hydrological response

478 **Fig. 15** shows part of the comparison results between the measured data and the three models. Detailed descriptions of all the
 479 comparison results are presented in **Appendix A**. Overall, all models show similar response trends with the measured data.
 480 Divergences among the three models mainly appeared during drying.

481 In **Fig. 15a**, the simulated surficial $w_{c,sim}$ was not only generally close to the $w_{c,exp}$ in value and trend, but also it captured
 482 the transient slow decrease of $w_{c,exp}$ during low evaporation periods. Notably, significant overprediction appeared in the 6th
 483 and 7th wetting-drying cycles.

484 In **Fig. 15b**, the matric suction (S_{sim}) at the 25 cm depth simulated by SDM and DPMDy was close to each other and had an
 485 average divergence 2.26 kPa to the measured data. The S_{sim} simulated by DPM had a greater average divergence of 3.4 kPa
 486 to the measured data. They showed systematic underprediction compared to the S_{sim} simulated by SDM and DPMDy, but
 487 their differences became smaller with the increasing WD cycles.

488 In **Fig. 15c**, the total volumetric water content θ_{sim} simulated by SDM was much lower with respect to the DPMDy and
 489 DPM. The θ_{sim} simulated by DPM-0.01 and DPM-0.03 overpredicted the volumetric water content. The DPMDy provided
 490 better prediction results but also showed slight underprediction to the measured data at the last two WD cycles.

491 **Fig. 15** Temporal evolution of the measured and simulated crack ratio, matric suction and volumetric water content. (a)
 492 Measured and simulated crack ratio on soil surface; (b) Measured and simulated matric suction at 25 cm depth; (c) Measured
 493 and simulated total water content at 25 cm depth
 494

495 6. Discussions

496 6.1 Crack dynamic changes

497 Our experimental results demonstrated that the crack evolution is not always positively correlated to the increase of the WD
 498 cycles, T and PE . For instance, the 5 cm θ_{exp} at the end of the final three WD cycles was lower than that in the 1st WD cycle
 499 due to the increased T and PE , but the maximum $w_{c,exp}$ measured during the final three WD cycles was much less than that
 500 in the 1st WD cycle. From the energy-driven perspective, soil cracking and propagation can be regarded as a process that the
 501 shrinkage energy (or stress), built up from the evaporation and thermal radiation, was released until a critical moment when the
 502 tensile strength of soil is reached (Peron et al., 2009; Xu et al., 2022; Tian et al., 2022). If the environmental condition
 503 changes in a stable range, the desiccation cracks will vary within the crack pattern and the maximum $w_{j,exp}$ that were formed
 504 under the maximum shrinkage energy. In this case, new desiccation cracks will not appear in the remained soil matrix during
 505 WD cycles (**Fig 5b1-b4**). One reason is that the shrinkage energy can be fully released via previous cracks. The other reason
 506 is that the shrinkage energy is not high enough to split the soil matrix that has a denser structure (or higher tensile strength)
 507 than its initial state prior to shrinkage (Luo et al., 2021). However, once the evaporation rate and thermal radiation increase
 508 to exceed the stable range, higher shrinkage energy will lead to new cracks appearing in the soil matrix that will concurrently
 509 restrain the width increase of the previous cracks (Wang et al., 2018; Xu et al., 2021). This is the reason that cracks in the
 510 final three WD cycles are finer than the first four WD cycles. Our model describes the crack evolution mainly from the
 511 hydrological-driven perspective that assumed the surface crack pattern has become stable after undergoing 13 WD cycles and
 512 has a constant function relationship with the water content. Indeed, this assumption is reasonable for natural soils under
 513 atmospheric environmental conditions. However, our experiment not only used reconstituted soil but also intensely changed

514 the environmental conditions since the 5th WD cycle. Therefore, the model overpredicted $w_{c,exp}$ at the end of the 6th and 7th
515 WD cycles.
516 In addition, another interesting phenomenon is the transient decrease of $w_{c,exp}$ and increase of θ_{exp} measured at 5 cm depth
517 during low evaporation periods, which we called as ‘self-closure’ process. In light of Fig 6 and Fig 8, the self-closure process
518 appeared always accompanied by relatively high RH . From the insight of the experiment, it is natural and common to infer
519 that the moist air wetted the surface soil from top to bottom, resulting in the self-closure phenomenon. Interestingly, our model
520 does not incorporate the vapor flow into the boundary conditions, and also the evaporation boundary only involves the outflow
521 of water, but it still managed to captured the self-closure process. Fig 16 shows the crack images at $t = 3702$ and 4327 min as
522 well as the corresponding cloud chart of θ_{sim} . It can be seen that the soil surface became moist during the low evaporation
523 period, which is a typical external phenomenon reflecting the self-closure process. The simulation results show that θ_{sim}
524 near the surface soil increased during evaporation while θ_{sim} at deep soils decreased, indicative of evaporation inducing the
525 deep water move up and wet the surface soil from bottom to top. We further found that the process occurred because the water
526 flow driven by the soil water potential gradients, existing between the wet and dry soil layers, overcame the gravity. Indeed,
527 this kind of ‘hydraulic lift’ process frequently occurs in planted soils where root zone soil can force water flow from moist
528 deep soil layers to dry shallow soil layers (Richards and Caldwell, 1987; Bauerle et al., 2008), but was rarely reported in
529 homogeneous bare soil. We infer that the evaporation boundary conditions using Eq. (14) might play a positive role in leading
530 water move up and constraining it within the surficial soil depths when the evaporation intensity decreased. In any case, our
531 results provide an additional possible explanation to the self-closure phenomenon. Further quantitative analysis based on gas-
532 liquid two phase flow model is needed to compare the contribution of ‘hydraulic lift’ and moist air to the self-closure process
533 of cracks.

534
535 **Fig. 16** Crack images at $t = 3702$ and 4327 min (Photo at the top of the figures) as well as the vertical distribution of water
536 content in the numerical model (Lower part of the figures) during the low evaporation process. The left part is at the beginning
537 of the final low evaporation stage during the 1st drying periods, while the right part is at the end of the final low evaporation
538 stage during the 1st drying periods.
539

540 6.2 Water flow with dynamic changes of desiccation cracks

541 6.2.1 Water fluxes

542 As mentioned in section 5.3.1, during the drying process, the matrix and crack evaporation simulated by the DPMDy are
543 overall lower and higher than other models, respectively. It can be explained by looking at the variation of boundary K_m and

544 K_c in each model. Take the time span in **Fig. 13a2** as an example, because the DPMDy considers the effects of matrix shrinkage
545 on the K_m using Eq. (26), the $K_{m,DPMDy}$ is always approximately 20% and 30% lower than that of the SDM and DPM,
546 respectively (**Fig. 17a**). On the contrary, because the DPM links the K_c with the saturation degree of the crack domain (see
547 Eq. (25)), the $K_{c,DPM}$ is destined to decrease with the decreased saturation degree of the crack domain induced by drying, while
548 the $K_{c,DPMDy}$ increases with the crack development induced by drying in light of Eq. (28-b). The ultimate $K_{c,DPMDy}$ is 80%
549 higher than the $K_{c,DPM}$ (**Fig. 17b**). Indeed, the decrease of K_c with the drying process is an unrealistic and physically-
550 unreasonable results. We can image that after long-term drought, the $K_{c,DPM}$ will decline to nearly zero according to Fig. 12d,
551 which will greatly underestimate the propagation of the PF-DC in the subsequent storm event. However, many laboratory and
552 field experiments have observed that heavy rainfall following a long-term drought facilitated PF-DC (Baram et al., 2012a;
553 2013; Greve et al., 2010; Kurtzman and Scanlon, 2011; Schlögl et al., 2022). By contrast, the DPMDy has the potential to
554 capture this process for its increasing K_c with the enlarging desiccation crack during the long-term drought. In this study,
555 because the experiment scale (or crack volume) is small, the increment of PF-DC simulated by the DPMDy after high-intensity
556 evaporation is not significant (despite increment = 25%), but we believe the DPMDy will have a better performance in a
557 larger scale (i.e slope scale).

558 **Fig. 17** Variation of boundary K_m and K_c in each model during the 5th drying periods. (a) K_m ; (b) K_c

561 6.2.2 Water exchange and distribution

562 For the dual-permeability model, the two domains are coupled by the water exchange term (Eq. 3) that is governed by the
563 pressure head difference between the two domains ($\Delta h = h_c - h_m$), water exchange coefficient (α_w) and the hydraulic
564 conductivity between the two domains (K_a). The higher the Γ_w , the quicker the two domains equilibrate. Generally, the
565 higher Γ_w leads to faster water exchange from the crack domain into the matrix domain and thus boosts the contribution of
566 preferential flow on the water distribution in the soil matrix. According to the previous studies, the commonly used magnitude
567 of the product of saturated $\alpha_w K_a$ in clay soils ranges from $10^{-5} \text{ m}^{-1}\text{s}^{-1}$ (Aguilar - López et al., 2020) to $10^{-6} \text{ m}^{-1}\text{s}^{-1}$ (Coppola
568 et al., 2012; 2015; Gerke and Maximilian Köhne, 2004; Vogel et al., 2000). In this study, the saturated $\alpha_w K_a$ is 1.16×10^{-5}
569 $\text{m}^{-1}\text{s}^{-1}$, which falls in the reasonable range. Building on the above statement, the Δh and water exchange rates (Γ_w / w_m) for
570 both the DPM and DPMDy at the 5 cm, 15 cm and 25 cm depths during the 6th rainfall event are graphed in **Fig. 18**.
571 As shown in **Fig. 18a1-a3**, Δh at all depths simulated by both the DPM and DPMDy rapidly reaches a positive peak value
572 and gradually decreases with the rainfall process. The rapidly increasing positive value is because the crack domain gets

573 saturation earlier than the surrounding soil matrix due to the influx of preferential flow and the small crack storage space in
574 this study. The decrease of the Δh is ascribed to the increase of h_m with water exchanging from crack to matrix domain.
575 Notably, the crack closure process during rainfall process leads to decrease of crack volume (or crack water storage space),
576 the ‘water table’ (saturated zone) in the shrinking cracks elevates faster than that in the constant larger crack volume, which
577 means the h_c simulated by DPMDy is higher than the DPM-0.01 and DPM-0.03. Consequently, the time for Δh reaching
578 the peak value simulated by the DPMDy is the earliest at all the three depths, then followed by the DPM-0.01 and DPM-0.03.
579 The Γ_w / w_m simulated by the DPMDy shows the similar trend to the Δh (Fig. 18b1-b3). During the 6th rainfall event, its
580 cumulative Γ_w / w_m at the 5 cm, 15 cm and 25 cm depths is (26%, 50%), (10%, 26%) and (3%, 14%) larger than that of the
581 DPM-0.01 and DPM-0.03, respectively.
582 This result means that the crack closure during wetting benefits the building-up process of the pressure head in the crack
583 domain and thus can promote water exchange from crack into matrix domain. It corresponds to some experimental results
584 that the PF-DC also exists and leads water to rapidly infiltrate into soils even if desiccation cracks are nearly closed (Baram
585 et al., 2012a; Greve et al., 2010; Luo et al., 2021; Sander and Gerke, 2007; Tuong et al., 1996). It also means using DPM may
586 overestimate the flux of PF-DC, but underestimate the water exchange coming from the PF-DC. Because the experimental
587 scale, crack ratio and depth in this study is small, the difference of simulation result involving the matric suction and water
588 content between the DPM and DPMDy is not very significant. However, we can image that the deviation caused by the DPM
589 at a larger scale will be more significant, especially in a typical shrinking-swelling soil slope under long-term WD cycles.

590
591 **Fig. 18** Pressure head difference (a1-a3) and water exchange rate (b1-b3) between the two domains at the 5 cm, 15 cm and
592 25 cm depths during the 6th rainfall event. The positive value of water exchange rate is for the water flowing from the crack
593 to the matrix domain, while the negative value for the opposite direction

594
595 **6.3 Model performance**

596 We evaluated the prediction errors of different models to the measured matric suction, water content and crack ratio using a
597 fixed slope line as the same in section 5.3.2 (see Fig. A3 and Table 4). Overall, the DPMDy, which incorporates the dynamic
598 changes of desiccation cracks and hydraulic conductivity into the dual-permeability model, has an overall better performance
599 than the SDM and DPM, as indicated by small intercept and high R^2 . With regard to the water flux, while the three models all
600 give a good fit with the measured data, the DPM overpredicted the water flux of PF-DC but underestimated the water exchange

from cracks to soil matrix compared to other models. It implies that adopting a constant crack volume in the DPM model, whether it is an average or a maximum value of the measured crack ratio, will overestimate the PF-DC, which may be unsuitable to evaluate the irrigation efficiency. With regard to the matric suction (or pore water pressure), although the SDM has good performance as the DPMDy does, it significantly underpredicted the volume water content and thus may overestimate landslide stability in a moisture-content-dependent threshold method. Further, we expect that the SDM may show much poorer performance if one applies it to scenarios where the cracks are deeper and the soil has a higher swelling-shrinking ability than that of our experiment. A comprehensive model sensitivity analysis will be conducted in our future work.

Table 4 Summary of fitting performance of different models to measured data

Models	SDM		DPMDy			DPM-0.03		DPM-0.01	
	S	θ	S	θ	w_c	S	θ	S	θ
Slope	1								
Confidence interval	95%								
Intercept	1.51	-1.88	1.35	0.45	1.02	3.91	2.19	3.74	1.79
R ²	0.34	0.53	0.38	0.50	0.47	-0.05	0.21	-0.03	0.13

Compared to other dynamic preferential flow models, the DPMDy developed in this study also has its unique advantages. Firstly, the variation of crack volume (or crack ratio) in our model is deduced from the changes of matrix porosity due to shrinkage and thus has a universal definition. Instead, Coppola et al. (2012); (2015) linked the crack ratio to the suction head with an empirical natural logarithm function, which is not transferable to other types of soils. ~~Secondly, Secondly, the results support the suitability, in the crack domain, where capillarity has little effect, of V-G SWRC with effective parameters and a constant relative hydraulic conductivity ($K_r=1$). In fact, a common defect in classical DPMs is that they often set the hydraulic conductivity of the crack domain (K_c) varies as a function of the saturated degree calculated from the SWRC of the crack domain (i.e Eq. (25)). This will lead to an unreasonable extremely low K_c in drying initial conditions (Aguilar - López et al., 2020). Setting $K_r=1$ ensures that the magnitude of a common defect in classical DPMs is that they often set the hydraulic conductivity of the crack domain (K_c) varies as a function of the saturated degree calculated from the SWRC of the crack domain (i.e Eq. (25)). This will lead to an unreasonable extremely low K_c in drying initial conditions (Aguilar - López et al., 2020). In our model, we set the relative hydraulic conductivity of the crack domain to unit ($K_r=1$). It ensures that the magnitude of K_c only depends on the crack area or the saturated degree of the soil matrix domain, which provides a potential solution for remedying the shortcoming mentioned above. Thirdly, compared to some dynamic preferential flow models neglecting the water exchange between the two domains (Jamalinia et al., 2020; Kroes et al., 2000; Luo et al., 2021; Stewart, 2018) or that ones adopting an arithmetic mean of hydraulic conductivity of the two domains (Coppola et al., 2012; 2015; Laine-Kaulio et al., 2014; Shao et al., 2018) that tends to overestimate the water exchange, our model tentatively adopts an improved exchange term proposed by Gerke et al. (2013), which we showed to be a logical and satisfactory improvement in simulating water exchange in our experiment.~~

However, in the current study, the hysteresis effect was neglected in both the soil deformation and SWRC because we assumed the soil shrinking-swelling behavior has less influence on the pore-size distribution (or SWRC shape) but more influence on the porosity (or hydraulic conductivity). This assumption inevitably caused some errors when compared to the measured water content, especially for the surficial soil layer that has been significantly affected by the WD cycles. Our future work will try to incorporate the hysteresis effect into the current model to further improve the prediction strength. Besides, we have to remind again that because the shrinking-swelling model in our method is developed based on the hydrological-driven perspective, it may be more suitable in the natural soil layer where the crack pattern already has a stable state after long-term WD cycles.

638 7. Conclusions

639 This study combined an experimental study and a numerical simulation to quantify the preferential flow induced by dynamic
640 changes of desiccation cracks (PF-DC). A soil column infiltration test under wetting-drying conditions was conducted to
641 investigate dynamic changes of desiccation cracks and the accompanying water infiltration process. The variation of crack
642 geometry, including crack ratio, width and depth were measured. The soil volumetric water content, matric suction and water
643 drainage were also monitored. A new dynamic dual-permeability model (DPMDy) was developed to account for the PF-DC,
644 which includes physically-consistent functions in describing the variation of both porosity and hydraulic conductivity in crack
645 and matrix domains. The performance of the single-domain model (SDM), rigid dual-permeability model (DPM) and DPMDy
646 was evaluated by comparing their simulation results to the monitoring data.

647 Overall, the DPMDy performed not only better prediction on the crack evolution and hydrological response with respect to
648 the SDM and DPM, but also provided much better descriptions on the underlying physics involving the PF-DC. During the
649 drying periods, the matrix evaporation modeled by the DPMDy is lower than that of the SDM and DPM due to considering
650 the permeability decay induced by soil shrinkage. But the crack evaporation modelled in the DPMDy approach is the highest
651 because it managed to capture the raised crack permeability induced by drying-enlarging desiccation cracks. Compared to the
652 DPM with fixed crack volume, the DPMDy revealed that the crack closure process during wetting will lead to a faster pressure
653 head building-up process in the crack domain and higher water exchange rates from the crack to the matrix domain.
654 Additionally, using a fixed crack ratio in the DPM, whether it is the maximum or the average value from the experiment data,
655 will overestimate the infiltration fluxes of PF-DC but underestimate its contribution to the matrix domain.

656 The DPMDy developed here has a physically-consistent definition. It remedies the shortcomings of the RDPM and other
657 dynamic preferential flow models in defining the dynamic changes of desiccation cracks and hydraulic properties of the crack
658 domain and interface. Future works should focus on considering the hysteresis effect of the SWRC curve during wetting-
659 drying cycles in the model and its application to complex field situations.

661 Appendix A

662 **Fig. A1** and **Fig. A2** show the temporal evolution of the measured and simulated crack ratio on the soil surface, matric suction
663 (negative pore water pressure) and volumetric water contents at the five monitoring depths (5, 15, 25, 35 and 45 cm).

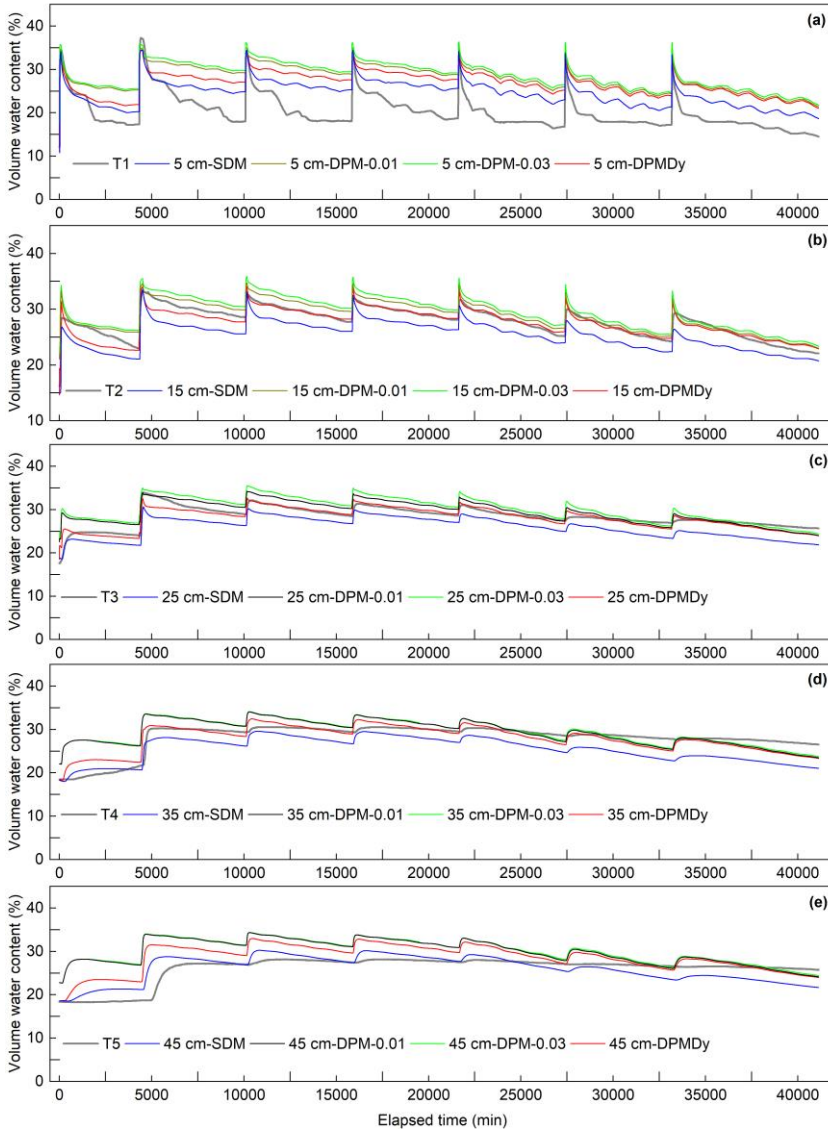

664 In **Fig A1a**, the simulated $w_{c,sim}$ was not only generally close to the $w_{c,exp}$ in value and trend, but also it captured the
665 transient slow decrease of $w_{c,exp}$ during low evaporation periods.

666 In **Fig A1b-f**, the matric suction (S_{sim}) simulated by SDM and DPMDy is close to each other and has average divergence of
667 2.75 kPa, 2.26 kPa and 5.02kPa to the measured data at the 5 cm, 25 cm and 45 cm depths, respectively. The S_{sim} simulated
668 by DPM has a greater average divergence of 2.78 kPa, 3.4 kPa and 7.43 kPa to the measured data at the three corresponding
669 depths.

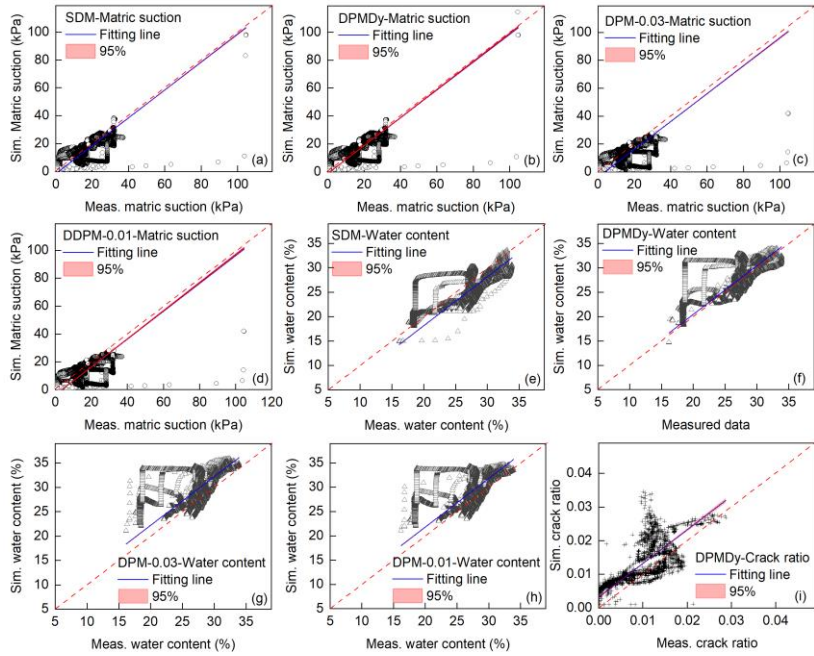

670 In **Fig A2a-e**, the volumetric water content θ_{sim} simulated by SDM was much lower than that simulated by DPMDy and
671 DPM. In most depths (except the 5 cm and 45 cm depth), SDM systematically underpredicted the volumetric water content
672 during both wetting and drying periods. By contrast, the θ_{sim} simulated by DPM-0.01 and DPM-0.03 overpredicted the
673 volumetric water content. The DPMDy gave overall better prediction results in most depths, but has significant divergences
674 to the measured data at the depth of 5 cm and so are the other two models.

675
 676 **Fig. A1** Temporal evolution of the measured and simulated crack ratio and matric suction at different depths. (a) Measured
 677 and simulated crack ratio (Dynamic DPM) on soil surface; (b-f) Measured and simulated matric suction (Single domain model,
 678 DPM and Dynamic DPM) at depths of 5 cm, 15 cm, 25 cm, 35 cm and 45 cm.

679
 680 **Fig. A2** Temporal evolution of the measured and simulated volumetric water content at depths of 5 cm, 15 cm, 25 cm, 35 cm
 681 and 45 cm. Note that the simulated volumetric water content demonstrated here is the total volumetric water content that
 682 combined with the combined matrix and crack domains using Eq. (8)

Notation

PF-DC	Preferential flow induced by desiccation cracks
SDM	Single-domain model
EMs	Explicit crack models
DPoM	Dual-porosity model
DPM	Rigid dual-permeability model with fixed crack ratio and hydraulic conductivity
DPM-0.01	Rigid dual-permeability model with crack ratio of 0.01
DPM-0.03	Rigid dual-permeability model with crack ratio of 0.03
DPMDy	Dynamic DPM with changing crack ratio and hydraulic conductivity
WD cycles	Wetting-drying cycles

θ	Total water content (combined matrix and crack domains), m^3m^{-3}
θ_{exp}	Volumetric water content measured in the experiment, m^3m^{-3}
θ_m	Volumetric water content of the matrix domain, m^3m^{-3}
θ_c	Volumetric water content of the crack domain, m^3m^{-3}
$\theta_{m,s}$	Saturated volumetric water content of the matrix domain, m^3m^{-3}
$\theta_{m,r}$	Residual volumetric water content of the matrix domain, m^3m^{-3}
$\theta_{c,s}$	Saturated volumetric water content of the crack domain, m^3m^{-3}
$\theta_{c,r}$	Residual volumetric water content of the crack domain, m^3m^{-3}

$S_{e,m}$	Saturation degree of the matrix domain, m^3m^{-3}
$S_{e,c}$	Saturation degree of the crack domain, m^3m^{-3}
α_m	Parameter for the van Genuchten water retention curve of the matrix domain, 1/m
n_m	Parameter for the van Genuchten water retention curve of the matrix domain, 1/m
m_m	Parameter for the van Genuchten water retention curve of the matrix domain, 1/m
α_c	Parameter for the van Genuchten water retention curve of the crack domain, 1/m
n_c	Parameter for the van Genuchten water retention curve of the crack domain, 1/m
m_c	Parameter for the van Genuchten water retention curve of the crack domain, 1/m
h_m	Pressure head of the matrix domain, m
h_c	Pressure head of the crack domain, m
C_c	Specific water capacity of the crack domain which is defined as $d\theta_c / dh_c$, 1/m
C_m	Specific water capacity of the matrix domain which is defined as $d\theta_m / dh_m$, 1/m
K_s	Total transient saturated hydraulic conductivity of the soil (combined matrix and crack domains), m/s
K_c	Transient hydraulic conductivity of the crack domain, m/s
$K_{c,s}$	Saturated hydraulic conductivity of the crack domain, m/s
$K_{c,max}$	The maximum crack hydraulic conductivity when the crack reaches its maximum crack aperture, m/s
$K_{c,min}$	The minimum crack hydraulic conductivity when the crack reaches its minimum crack aperture, m/s
$K_{c,r}$	Relative hydraulic conductivity of the crack domain, m^3m^{-3}
K_m	Transient hydraulic conductivity of the matrix domain, m/s
$K_{m,s}$	Saturated hydraulic conductivity of the matrix domain, m/s
$K_{m,max}$	The maximum matrix hydraulic conductivity prior to soil shrinkage, m/s
$K_{m,r}$	Relative hydraulic conductivity of the matrix domain, m^3m^{-3}
K_a	Hydraulic conductivity between the matrix and crack domains, m/s
$K_{\theta_{min}}$	An improved hydraulic conductivity between the matrix and crack domains reformulated by Gerke et al. (2013), m/s
Γ_w	Water exchange term between the crack and matrix domains, 1/s
w_c	Crack ratio, which is defined as volumetric ratio between the crack domain and the overall soil volume, m^3m^{-3}
$w_{c,exp}$	Surface crack ratio measured in experiment, m^2m^{-2}
$w_{j,exp}$	Average crack aperture (or crack width) measured in the experiment, m
$w_{j,max}$	The maximum average crack aperture measured in the experiment, m
d_{max}	The maximum crack depth measured in the experiment, m
w_m	Volumetric ratio between the matrix domain and the overall soil volume, m^3m^{-3}
α_w	Effective water transfer coefficient, $1/m^2$
V	Total soil volume (combined matrix and crack domains), m^3
V_m	Volume of the soil matrix domain, m^3
V_c	Volume of the crack domain, m^3
V_p	Total pore volume, m^3
$V_{p,m}$	Pore volume in the matrix domain, m^3
$V_{p,c}$	Pore volume in the crack domain, m^3
\mathcal{E}	Total soil porosity (combined matrix and crack domains), which is defined as V_p/V , m^3m^{-3}
\mathcal{E}_m	Effective porosity of the matrix domain, which is defined as $V_{p,m}/V_m$
\mathcal{E}_c	Effective porosity of the crack domain, which is defined as $V_{p,c}/V_c$
i	Total effective infiltration rate (combined matrix and crack domains), m/s
i_m	Effective infiltration rate of the matrix domain, m/s

i_c	Effective infiltration rate of the crack domain, m/s
e_m	Effective evaporation rate of the matrix domain, m/s
e_c	Effective evaporation rate of the crack domain, m/s
r	Rainfall intensity, m/s
AE	Actual evaporation rate, m/s
PE	Potential evaporation rate, m/s
S	Total matric suction at the soil surface, kPa
S_{exp}	Soil matric suction measured in the experiment, kPa
g	Gravitational acceleration constant, m/s ²
ω_w	Molecular mass of water, kg/mol
ξ	Dimensional empirical parameter with a suggested value of 0.7
h_a	Relative humidity of soil overlying air
γ_w	Unit mass of water, kN/m ³
R	Universal gas constant, J/mol·K
T_s	Soil surface temperature, °C
ϕ_{max}	Total porosity (or the maximum porosity) of a soil core prior to soil shrinkage, which is defined as V_p/V and thus equals to the ε , m ³ m ⁻³
ϕ_{min}	The minimum porosity of the matrix domain, m ³ m ⁻³
ϕ_{matrix}	Porosity of the matrix domain, which is defined as $V_{p,m}/V$, m ³ m ⁻³
ϕ_{crack}	Porosity of the crack domain, which is defined as $V_{p,c}/(V_m+V_c)$, m ³ m ⁻³
ϕ_{sub}	Porosity of the subsidence zone, which is defined as voids induced by soil subsidence divided by the total soil volume, m ³ m ⁻³
U	A unified water content, which is defined as the gravimetric water content u divided by its saturated value u_{max}
P	Functional shape parameters of the soil shrinkage curve
q	Functional shape parameters of the soil shrinkage curve
ν	Water kinematic viscosity, m ² /s
t_p	Beginning of ponding time after each rainfall, min
Δh	Pressure difference between the crack and matrix domains, which is defined as $h_c - h_m$
