**Abstract.** In light of the ongoing global climate crisis and related increases in extreme hydrological events, it is crucial to assess ecosystem resilience and - in agricultural systems - to ensure sustainable management and food security. For that purpose, comprehensive understanding of ecosystem water cycle budgets and spatio-temporal dynamics are indispensable. Evapotranspiration (ET) plays a pivotal role returning up to 90 % of incoming precipitation back to the atmosphere. Here, we studied impacts of soil types and management on an agroecosystem's seasonal cumulative ET ( $ET_{sum}$ ) and agronomic water-use efficiencies ( $WUE_{agro}$ , dry matter per unit of water used by the crop). To do so, a plot experiment with winter rye (September 17, 2020 to June 30, 2021) was conducted at an eroded cropland which is located in the hilly and dry ground moraine landscape of the Uckermark region in NE Germany. Along the experimental plot (110 m x 16 m), two closed chambers were mounted on a robotic gantry crane system (FluxCrane as part of the AgroFlux platform) and used to ~~continuously~~ determine ET. Three soil types representing the full soil erosion gradient related to the hummocky ground moraine landscape (extremely eroded: Calcaric Regosol, strongly eroded: Nudiargic Luvisol, non-eroded: Calcic Luvisol) and additional top-soil dilution (topsoil removal and subsoil admixture) were investigated (randomized block design, ~~3~~-three replicates per treatment). Five different ~~gap-filling modeling~~ approaches were used and compared in light of their potential for reliable  $ET_{sum}$  over the entire crop cultivation period as well as to reproduce short-term (~~day to day, e.g.,~~ - diurnal) water-flux dynamics. While machine learning approaches such as support vector machines (SVM) and artificial neural networks (with Bayesian regularization; ANN\_BR) generally performed well during calibration, SVM also provided a satisfactory prediction of measured ET during validation (k-fold cross validation,  $k = 5$ ).

We found significant, ~~major~~ differences in dry biomass (DM) and small trends in  $ET_{sum}$  between soil types, resulting in different  $WUE_{agro}$ . The extremely eroded Calcaric Regosol showed an up to 46 % lower  $ET_{sum}$  and up to 54 % lower  $WUE_{agro}$  compared to the non-eroded Calcic Luvisol. The key period contributing to 70 % of  $ET_{sum}$  ~~was spanned~~ from the beginning of stem elongation in April to harvest in June. However, differences in the  $ET_{sum}$  between soil types and topsoil dilution resulted

35 predominantly from small differences between the treatments throughout the cultivation, rather than only during this short period of time.

## 1 Introduction

Only 12 % of the world's land area is suitable for food and fiber production due to its highly productive soils (Blum 2013). Much of this land is already in use to ensure food security, mandated by a still growing human population paired with the ongoing climate crisis (Searchinger et al. 2018). Worldwide, land area is largely affected by soil degradation (Jie et al. 2002) and agriculture is closely related, since at least six degradation processes (e.g., erosion or compaction) are associated with it (Louwagie et al. 2011). In hummocky landscapes, erosion and associated topsoil dilution caused by, e.g., wind, water or tillage, affects the crop yields (Bakker et al. 2007; Biggelaar et al. 2003). In addition, weaker rootability on eroded soils suggests a higher susceptibility towards droughts (Schneider and Don 2019). However, methodologically studying the influence of small-scale soil heterogeneity (e.g., soil erosion) and land use (e.g., soil management) on the dynamics of the water balance (especially evapotranspiration (ET)) separately has been challenging. The effect of both factors can be significantly different with complex interactions, e.g., soil erosion can lead to differences in soil water storage capacity and management affects soil organic matter and water retention (Bakker et al. 2007; Biggelaar et al. 2003). Thus, a separate response analysis is an indispensable prerequisite for the development of site-specific land use procedures adapted to the changing climate conditions. Moreover, the climate crisis is affecting the amount and spatio-temporal distribution of precipitation worldwide, leading to more frequent and stronger precipitation events in high-precipitation regions (e.g., increase of 10 – 40 % in northern Europe; (DWD 2019) and fewer and weaker events in low-precipitation regions (e.g., up to 20 % decrease in the Mediterranean region and southeastern Europe; (Trenberth 2011). In Germany, annual precipitation is more than 800 mm in most regions of west and south Germany but only 400 - 500 mm y<sup>-1</sup> in the northeast (e.g., areas in Brandenburg and Mecklenburg-Western Pomerania; (Schappert 2018)). Here, dry hydrological conditions and erosion shaped landscapes meet. As crop yields and related crop productivity depend on various factors such as soil properties or water availability, such agriculturally used precipitation limited regions could face increasing problems.

ET describes the total amount of water that evaporates from a given area and is thus defined as the sum of soil evaporation (E), transpiration (T) and interception evaporation (Fohrer et al. 2016; Rothfuss et al. 2021). Generally, ET is one of the most important components of the hydrological cycle in terrestrial ecosystems, accounting for up to 100 % of ingoing precipitation (Hanson 1991). ~~With a share of up to 90 %, it is largely dominated by T in most terrestrial ecosystems, indicating that terrestrial vegetation is a dominant force in the global water cycle (Jasechko et al. 2013).~~ Due to the expected increasing dependency of a system's productivity on sufficient water supply with an accelerating climate crisis, quantifying the ET plays an important role to achieve a process-based understanding of the mitigation potential of different crops to drought in the future and to, e.g., establish a more efficient supplemental irrigation. Moreover, there is a tight link of carbon and water cycling in precipitation

65 limited systems because water loss by ET and the water use efficiency of a system can largely define its productivity (Tallec et al. 2013).

A particular challenge in current ET research is combining high-frequency with multi-treatment approaches. At the field scale for example, eddy covariance systems provide high-high-frequency estimates of ET of a homogeneous system (e.g., Ding et al. 2021), while ~~currently dominant~~ manual chamber approaches are able to precisely capture multi-multi-treatment effects (<1m<sup>2</sup>) on ET at the plot scale (e.g., Hamel et al. 2015). ~~However, the data frequency obtained by manual chamber observations is often too small to achieve reliable flux budget calculations in combination with data-driven gap-filling modeling, but lack the high frequency.~~ In this regard, modern automated chamber systems allow a combination of multi-treatment observation with a higher frequency of measurements ~~and thus high temporal resolution compared to manual chambers with multi treatment observation.~~ They provide ~~the a~~ unique opportunity to test ~~advanced data-driven gap-filling modeling~~ strategies, ~~using empirical, statistical, or machine learning approaches, with the aim of able to reproduce reproducing the diurnal variability in ET and the not only~~ seasonal cumulative ET (ET<sub>sum</sub>) ~~but day to day and diurnal variability in ET. In particular, Modern gap filling modeling methods approaches based on machine learning~~ (e.g., artificial intelligence and neural network approaches) have previously been limited to eddy covariance measurements. Coupling such advanced ~~gap-filling modeling~~ strategies with modern automatic chamber systems might be an ideal fusion of measurement frequency and the ability to capture treatment effects like ~~small-small~~ scale soil differences (Falge et al. 2001a; KIŞI and ÇIMEN 2009). AgroFlux – a ~~newly newly~~ developed sensor platform centered around closed chambers mounted on an robotic gantry crane (FluxCrane) – was initially built to capture the effect of soil type and management on GHG emissions and in particular CO<sub>2</sub> fluxes with high spatial and temporal resolution (Vaidya et al. 2021). The adaption of the system to measure ET provided us with the opportunity to analyze stand scale ET fluxes including the development of a data analysis tool for measured ET  ~~fluxes, and to~~ test different ~~gap filling modeling~~ strategies. We tested five different ~~gap filling modeling~~ strategies including basic statistic and advanced approaches including machine learning approaches. During the cultivation period of winter rye from mid-September 2020 to the end of June 2021, ET and relevant environmental and plant growth parameters were measured to identify the corresponding drivers of crop ET and productivity. The FluxCrane system covers a field where three different soil types are present, which reflect the erosion gradient typical for the hillside of the hummocky ground moraine landscape of northeast Germany. This made it possible to evaluate the impact of soil type as well as soil management on ET<sub>sum</sub>, seasonal development and agronomic water use efficiency (WUE<sub>agro</sub>; dry matter per unit of water used by the crop).

In the following, we will examine i) soil type and top-soil dilution effects on crop yield, ET<sub>sum</sub> and WUE<sub>agro</sub>, ii) the spatio-temporal variability of ET fluxes over the growing season, and iii) the suitability of various ~~gap filling modeling~~ strategies. The paper's aim is to establish an approach that would provide reliable predictions of ET fluxes both in terms of ET<sub>sum</sub> as well as diurnal trends of ET fluxes. We hypothesize that: i) eroded soils and top-soil dilution lead to decreased ET controlled by weaker plant growth, ii) WUE<sub>agro</sub> declines from least to most eroded soil type and with top-soil dilution; iii) the automated, continuous FluxCrane measurements result in unique insights into small-scale dynamics such as night time ET fluxes and ET fluxes during the non-growing season. Here, we hypothesize, that iv) the uncommonly ~~(compared to manual chamber systems)~~

large data set (compared to manual chamber systems) –allows for a robust use of gap-filling modeling strategies based on machine learning. We envisage that this will greatly improve  $ET_{sum}$  and subsequently  $WUE_{agro}$  based on automated closed chamber systems.

## 2 Material and Methods

### 2.1 Study Site-site and experimental design

The AgroFlux experimental platform is located in Brandenburg, a federal state in northeast Germany, near Dedelow within the Uckermark region (53° 23′ N, 13° 47′ E; ~50-60 m a.s.l). Brandenburg, which includes some of the driest regions in Germany, uses 48.6% or about 1.44 million hectares of its area for agriculture (Amt für Statistik Berlin-Brandenburg 2020). It is located in the continental climate zone and has a water deficit of about 150 mm during the growing season (Wessolek and Asseng 2006). The long-term (1991 to 2020; ZALF) mean annual air temperature in this region is 8.8°C with a mean annual precipitation and potential evapotranspiration of 467 mm and 637 mm, respectively (ZALF research station, Dedelow).- The focus of agriculture in Brandenburg is on grain production, which faces a variety of challenges due to increasingly dry conditions during the main growing season (Amt für Statistik Berlin-Brandenburg 2020). The Uckermark region is the most productive region for agriculture within Brandenburg. It is shaped by glaciation with a hilly to flat-wavy ground moraine landscape whose soils are strongly influenced by soil erosion (Nudiargic Luvisol, Calcaric Regosols, Colluvic Regosols) as well as redoximorphic soils (Stagno-, -Gleysols) (MLUK 2020). The strong soil heterogeneity and ongoing soil erosion, mainly by tillage, has a great influence on the productivity of the cultivated areas (Sommer et al. 2016). Today, only 20% of the land is not affected by past and present soil erosion due to tillage and water (Sommer et al. 2008; Wilken et al. 2020).-resulting in a very high spatial variability of soils (Wehrhan and Sommer 2021) and associated growing conditions for crops (Wehrhan et al. 2016). In combination with the ongoing climate crisis, it is proving difficult to develop land-use methods that allow reliable and sustainable arable farming under these challenging conditions.

The study was carried out on the 100 x 16 m FluxCrane experimental field, an integral part of the AgroFlux sensor platform located at the interdisciplinary research area CarboZALF-D (Fig. 1a). There is -an elevation difference of one meter and all relevant local erosion stages are covered (WRB 2014): non-eroded Calcic Luvisol (LV-cc), strongly eroded Nudiargic Luvisol

(LV-ng) and extremely eroded Calcaric Regosol (~~RG-ea~~; see Fig. 1b,e; (~~RG-ca~~; see Fig. 1b/c; Sommer et al. 2008; Wehrhan et al. 2016; Vaidya et al. 2021). Here we used 18 plots in total, ~~6-six~~ per soil type (Fig. ~~4e1d~~). For the ~~6-six~~ plots per soil type, a randomized, full-factorial design, each repeated three-fold, was adopted for topsoil dilution vs. non-topsoil dilution (first 8 to 9 cm). During the study period from September 2020 to June 2021 (286 days), winter rye of the hybrid variety SU Piano was grown with a density of 200 plants per m<sup>2</sup> on an area of 0.176 ha. The novel gantry crane automatic chamber system (Fig. ~~4d1e~~) was installed on this study site in 2019 (Vaidya et al. 2021). The attached gas exchange chambers were lowered on each plot on round structural steel frames with a diameter of 1.59 m and a basal area of 1.99 m<sup>2</sup>.

## 2.2 Cultivation and top-soil dilution

The AgroFLUX sensor platform site is located on a conventionally farmed agricultural area that is intended to represent a variety of soils in the region. Hence, top-soil dilution, tillage, cultivation and fertilizer application measures were implemented before and during the experiment. The manipulative field experiment was originally established to study the feedbacks of a dynamic disequilibrium in the carbon cycle of arable lands. Deep tillage or soil erosion lead to an admixture of subsoil material into the plough layer (Doetterl et al. 2016) which alters topsoil properties (SOC, clay content etc.). The resulting changes in the main rooting zone might reduce crop growth (Öttl et al. 2021). We mimic these common landscape processes in our top-soil dilution experiment under controlled conditions (Vaidya et al. 2021). After topsoil removal (1.2 t per plot; first 8-9 cm; 3 of the 6 plots per soil; July 14-15, 2020) we added the equivalent mass (1.2 t) of the respective subsoil horizons (E, Bt, Ck) taken from a large soil pit nearby. Thus, E horizon was applied to the prepared plots of the non-eroded Calcic Luvisol (LV-cc), Bt horizon on the strongly eroded Nudiargic Luvisol (LV-ng) and Ck horizon to the extremely eroded Calcaric Regosol (RG-ca). Subsequently, we mixed the added subsoil material with the remaining local Ap horizon. Finally, the chamber frames were reinstalled. In the following, the resulting treatments of the same soil types are labelled as non-diluted (n-d) and diluted (d). The actual tillage prior to sowing took place just before seeding on September 17, 2020. For this, the frames were removed, and the soil was loosened to a depth of 25 cm in west-east-direction. Sowing was done with a power harrow-drill combination. Fertilization was applied to all plots per soil type before and during the growing season using digestate from Pflanzenbauhof GbR (Uckermark, Germany), Triple Super Phosphate (TSP) and grain potash (Table B1). Due to initial changes in the topsoil structure (after the addition of subsoil material), germination differed between manipulated and non-manipulated plots. In order to achieve similar plant densities in all plots, replanting had to be done in all ~~non-diluted~~ plots within the frames (LV-cc: 13 plants per plot; LV-ng: 40 plants per plot; RG-ca: 82 plants per plot).- For general plant protection and soil treatment, herbicides were applied to the field prior to the growing season (e.g., glyphosate; September 3, 2020).

## 2.3 Gantry crane system description and gas exchange measurements

The ET flux measurements were carried out by a novel automated chamber system (FluxCrane) using a 5-meter-high gantry crane traveling on two 110 m tracks which has been described in detail (Vaidya et al. 2021). Briefly, the system designed by Pfannenstiel ProProject GmbH (Bad Tölz, Germany); is capable of moving in three dimensions: the x-axis for movement along

the track, the y-axis for movement perpendicular to the track, and the z-axis for vertical chamber movement. The FluxCrane carries two transparent chambers made of polymethyl methacrylate (PMMA; A: 1.986 m<sup>2</sup>; V: 3.756 m<sup>3</sup>). Since the two chambers do not move independently from each other along the track, frames were arranged in rows, from which each half was measured by one chamber. To ensure airtight sealing during chamber deployment, steel frames with a diameter of 1.59 m and a depth of 5 cm were installed into the soil and equipped with an approximately 10 cm wide foam ring were used to further increase the chambers bearing surface, while deployed. ET fluxes were determined by measuring the development of chamber headspace H<sub>2</sub>O concentrations (4 sec frequency) over 7 minutes in a flow-through non-steady-state (FT-NSS) mode (Livingston and Hutchinson 1995), using two infrared gas analyzers (one per chamber; LI-COR 850, Licor Biosciences, UK). The chambers have an average light transmittance of about 76 % (74% for chamber 1 and 78% for chamber 2), but the experiment was designed to minimize a reduction in ET due to reduced light availability, is not expected, in our case mostly (Fastest possible ET calculation after chamber closure; short closing times due to the short chamber closure time and ventilation). In addition, For more details see also (Pape et al. (2009)) concluded, that the PAR reduction had only a minor effect (< 5%) on photosynthesis for this type of chamber, which should be comparable or smaller for transpiration. Temperature differences during chamber closure were minimized by the short measurement time and ventilation (<1.5°C) with two small axial flow fans (5.61 m<sup>3</sup> min<sup>-1</sup>) used to homogenize the chamber headspace air. To compensate for the difference in tubing length between the chambers and the analyzer (chamber 1: 15 m vs. chamber 2: 22 m), a flow rate of 2.3 l min<sup>-1</sup> and 3.6 l min<sup>-1</sup> was set to obtain a similar sensor death time of 13 seconds. A CR6 data logger and a CDM-A116 analog multiplexer (Campbell Scientific Inc., USA) were used for data recording and storage. The plots were measured hourly up to 24 times a day in order to be able to detect daily variations. Due to the randomized measurement design, each plot was measured approximately twice per week, which would theoretically result in approximately 2200 measurements per plot throughout the entire season. However, the system was designed to shut down under high winds and cold temperatures, resulting in a true average of only 724 measurements per plot per season. Diurnal ET day- and nighttime fluxes considered in this study were calculated for the cultivation period from September 17, 2020 (sowing of winter rye), until harvest of winter rye on June 30, 2021.

## 2.4 Input parameters for gap-filling modeling

### 2.4.1 Environmental Parameters parameters

Relative humidity (RH) [%] (WXT520, Vaisala, FI) was measured during the ET flux measurements outside the chambers while temperature (T) [°C] (109, Campbell Scientific Ltd., USA) and incoming photosynthetically active radiation (PAR) [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ] (SKP 215, Skye Instruments Ltd., UK) were measured both outside as well as inside the chambers. Precipitation (Pr) [mm] (Tipping Bucket Rain Gauge 52203, R. M. Young Company, USA) and relative soil moisture (SM; 13 to 18 cm depth) [%] (ML2x, Delta-T Devices Ltd., UK) were measured at an adjacent field (< 25m; Fig. 1b).

## 195 2.4.2 Plant-specific parameters

Spectral plant indices, such as the ratio vegetation index (RVI; also simple ratio SR) were manually recorded weekly for all 18 plots using a near-infrared (NIR)/visible light (VIS) double, 2 channel sensor device (SKR 1850, Skye Instruments Ltd., UK) mounted on a 1.8 m handheld pole (Görres et al. 2014; Kandel et al. 2013), connected to a CR1000 data logger (Campbell Scientific Ltd., USA). The double, 2 channel sensor device consisted of an upward- and downward-facing sensor, measuring the incoming (VISi) and reflected (VISr) VIS at a wavelength of  $656 \pm 10$  nm and incoming (NIRi) and reflected (NIRr) NIR at  $780 \pm 10$  nm. The upward sensor was fitted with a cosine-correction diffusor for measurements of the incident radiation, while the downward sensor, installed 1.8m above the ground, had a  $25^\circ$  cone field of view, thus covering an area of  $0.5 \text{ m}^2$  during measurements (Görres et al. 2014). Each plot was measured once a week for 30 seconds, resulting in one mean value including 30 measurement points. The RVI was used as an indicator for standing crop biomass and is close to zero for a fallow surface and increases as plant cover increases. The RVI was calculated following Equ. 1:

$$RVI = \frac{\frac{NIRr}{NIRi}}{\frac{VISr}{VISi}} \quad (1)$$

Since only weekly plot-wise RVI data were available, daily RVI data were obtained by fitting a sigmoidal function for initial plant growth in the fall up to stagnation due to plant inactivity in the winter and a polynomial function for shoot elongation and later senescence during spring growth and summer maturation, respectively (Fig. A1). During the period from November 24, 2020 to March 22, 2021, which we refer to as the non-growing season, no plant growth was assumed due to average daily temperatures below  $5^\circ\text{C}$  ( $<3$  consecutive days).

## 2.5 ET flux calculation and gap-filling modeling

### 2.5.1 ET Flux calculation

The workflow included various steps to pre-process data obtained by the FluxCrane, calculate ET fluxes and finally applying and validating the different gap-filling modeling procedures (Fig. A2). ET flux calculation was performed based on the ideal gas equation (Eq. 2) modified by (Hamel et al. 2015) using an adapted R-script, based on those presented by (Hoffmann et al. 2015).

$$ET_{flux} = \frac{c_{H_2O} \times P \times M_{H_2O}}{R \times T} \times \left( t \times \frac{V}{A} \right) \left[ \frac{mm}{d} \right] \quad (2)$$

$$ET_{flux} [mmol \text{ m}^{-2} \text{ s}^{-1}] = \frac{ET_{flux} \left[ \frac{mm}{d} \right]}{(t \times 1000)} * \left( \frac{1}{M_{H_2O}} \right) \quad (3)$$

With  $ET_{flux}$  [ $\text{mm d}^{-1}$ ] being the evapotranspiration rate,  $c_{H_2O}$  the moles of water per total moles present, P the gas pressure [Pa],  $M_{H_2O}$  the molar mass of water [ $18 \text{ g mol}^{-1}$ ], R the gas constant [ $8.314 \text{ m}^3 \text{ Pa K}^{-1} \text{ mol}^{-1}$ ], T the temperature [K] inside the chamber, t the time factor [86.4], V the chamber volume [ $\text{m}^3$ ] and A the basal area [ $\text{m}^2$ ]. The ET flux in  $\text{mmol m}^{-2} \text{ s}^{-1}$  (Equ. 3)

225 was also calculated to ensure comparability with other studies. The first 15% of each measurement ~~were-was~~ discarded prior  
to flux calculation; to prevent a disturbance due to initial homogenization of the chamber headspace air. The temporal change  
was determined by linear regressions on several subsets of the data generated based on a variable moving window with a  
starting window size of 1:20 minutes (20 consecutive data points) and a maximum length of 2 minutes (30 consecutive data  
points). This procedure resulted in several ET fluxes for each measurement, from which the best flux was subsequently selected  
230 using a set of soft and hard criteria. Soft criteria included: (i) checking whether the conditions for the application of a linear  
regression were fulfilled (normality, variance homogeneity, linearity); (ii) no outliers were present ( $\pm 6x$  interquartile range);  
(iii) temperature variation during the measurement was  $< 1.5$  °C. Calculated fluxes per measurement that did not meet the  
quality criteria were discarded. Afterwards applied hard -criteria reduced potentially remaining multiple fluxes per  
measurement further to the ideal ET flux. Since the air in the chamber headspace reached higher water saturation with  
235 increasing time, hard criteria were based on the selection of the flux which showed the shortest temporal distance to the start  
of measurement and had the maximum length.

During the measurements, various events could lead to erroneous ET fluxes such as e.g., fog (saturation of the chamber  
interior), sensor failures, or chamber leakage due to failure in chamber deployment. Erroneous fluxes were hence discarded.  
In addition, potential differences of the measurements between the sensors of both chambers were evaluated by the  
240 measurements of ambient air during periods of no chamber deployment.

A complete data set of hourly data points for the 286 days of the cultivation period would consist of 6,888 measurements per  
treatment. After the flux calculation and filtering using the soft and hard criteria, a total of 13,011 ET flux measurements were  
performed, resulting in approximately 2,169 measurements per treatment. ~~For-On~~ individual plots, an average of 723  
~~measurements were available (Table B2; ranging from 624 to 1,210; accounting for 10.5 % on average)-measurements were-~~  
245 ~~measured and the remaining were predicted by the gap approaches (Table B2; 89.5% on average).~~

### 2.5.2 Gap-filling Modeling ET fluxes

To ~~gap fill~~ model ET fluxes, five different ~~gap filling~~ approaches were used and compared with each other. Gap-filling Modeling  
procedures included: 1.) a simple statistical approach: Mean diurnal variation (MDV); two empirical approaches: namely 2.)  
non-linear regression (NLR) and 3.) Look-Up-Tables (LUT) as well as two machine learning approaches: with 4.) Support  
250 Vector machine (SVM) and 5.) artificial neural network with Bayesian regularization (ANN\_BR).

MDV (Falge et al. 2001b; Moffat et al. 2007) is used to calculate missing hourly values through interpolation of values  
measured at the same hour during adjacent days. Thus, for the season with 286 days, the missing values were calculated for  
every hour, generating 24 values per day.

NLR is based on parameterized non-linear equations using the mean least square method to express the relation between the  
255 total seasonal data of ET and T, RH, SM, PAR and RVI. Half-hourly values were predicted using the predictor variables and  
obtained function parameters.

~~Gap-filling~~ Modeling missing ET fluxes using the LUT approach is based on the assumption of similar ET fluxes during similar environmental conditions, whereby similarity is defined through a number of thresholds for the different environmental variables. Thus, missing ET-fluxes can be predicted based on the environmental conditions as well as the RVI associated with the missing data. To do so, measured ET-fluxes per subplot were split into different classes ( $C_{sturges}$ ) based on T, RH, SM, PAR and RVI, with their class limits determined by Sturges rule (Equ. 4, (Harkins 2022)). Within this study, on average, 12 classes of equal size were formed covering the range of all parameters.

$$C_{sturges} = \frac{1+3.32 * \log(n)}{\log(10)} \quad (4)$$

265

~~Gaps in~~ ET-fluxes were subsequently ~~filled~~ ~~assigned~~ with the average ET flux of the class corresponding to obtained environmental parameters ~~within the gap~~. In case, no class could ~~be~~ attributed to measured environmental conditions ~~within a gap~~, the average ET flux was used.

SVM is a black-box model, where a computer algorithm learns by teaching data to assign values to objects or classes (Noble 2006). As mentioned by (Kim et al. 2020)), the SVM uses a slack variable to circumvent unseparated parameters due to noise or extreme values in the data, as well as the radial basis kernel function based on previous SVM studies for upscaling fluxes (Ichii et al. 2017; Xu et al. 2018).

In comparison, ANN\_BR is a combination of a purely empirical nonlinear regression model with a stochastic Bayesian algorithm for regularizing the network training (Schmidt et al. 2018). An artificial neural network (ANN) consists of nodes connected by weights representing the regression parameters (Bishop and others 1995; Hagan et al. 1996; Moffat et al. 2007; Kubat 1999; Rojas 1996). The network is trained by providing it with sets of input data such as the environmental and plant-specific parameters mentioned earlier and the associated output data in the form of e.g., ET flux values. Similar to (Moffat et al. 2007), all techniques evaluated use the classical back-propagation algorithm, where the training of the ANN is performed by propagating the input data through the nodes via the weighted connections and then back-propagating the error and adjusting the weights so that the network output optimally approximates the ET-fluxes. Subsequent to this training, the underlying dependencies of the ET fluxes on the environmental and plant-specific input variables are mapped to the weights and the ANN is used to predict half-hourly ET fluxes, where the performance of the ANN depends on several criteria.

## 2.6 Seasonal cumulative ET, ~~Water-water Use-use Efficiency-efficiency~~ and crop ET

ET<sub>sum</sub> were determined using half-hourly or hourly ET values predicted by all five ~~gap-filling~~ modeling approaches (~~Figure 6, Figure A3—A6~~). Daily averages [mm d<sup>-1</sup>] and ET<sub>sum</sub> (mm cultivation period<sup>-1</sup>) were formed in order to view the development over the entire cultivation period. The amount of plant biomass in dry mass (DM) [kg] was recorded during harvest for each treatment, which, in combination with ET<sub>sum</sub> yields the agricultural water use efficiency WUE<sub>agro</sub> ((Hatfield and Dold 2019), Equ. 5). ~~This is the WUE<sub>ABG</sub> variant of WUE<sub>agro</sub>, as the dry mass is total aboveground biomass (Katerji et al. 2008).~~

$$290 \quad WUE_{agro} = \frac{DM}{ET_{sum}} \quad (5)$$

To obtain a comparable value for the  $ET_{sum}$  calculated by the FluxCrane, crop evapotranspiration ( $ET_c$ ) was calculated (Allen 1998).  $ET_c$  (Equ.6) was calculated from the crop factor  $K_c$  ( $K_{c\_ini} = 0.3$ ;  $K_{c\_mid} = 1.15$ ;  $K_{c\_end} = 0.4$ ) and the potential evapotranspiration  $ET_0$  using monthly averages (DWD 2022).

$$295 \quad - \quad ET_c = K_c \times ET_0 \quad (6)$$

## 2.7 Statistical analysis

All calculations were performed using the statistical software R (R Core Team, 2021) version 4.0.4. Therefore, several packages (Table B3) were used to calculate the ET fluxes and to perform subsequent gap-filling modeling as well as for the visualization of results.

~~To check the general precision and accuracy of all gap-filling modeling approaches, all measured values were compared.~~ comparison was conducted between all measured values with and their associated corresponding predicted values for each treatment. Additionally ~~For validation, the~~ k-fold cross validation method ( $k = 5$ ) was ~~performed~~ implemented on using the resulting ET data to ~~test-evaluate~~ the predictive outcome performance of the approaches and ensure robust statistics analysis. To accomplish this, each data set was divided into five subsets, each comprising 20% of the total data. The modeling process was then repeated five times, utilizing 80% of the data to calculate the missing 20% and generate a complete dataset without relying on the original data. Subsequently, this dataset was compared against the measured data to evaluate the modeling approaches. Then ~~Finally, all performance metrics including~~ the coefficient of determination (R<sup>2</sup>), mean absolute error (MAE), normalized root mean square error (NRMSE) and Nash-Sutcliffe efficiency (NSE) were calculated for both calibration and validation. These metrics ~~and were~~ used to define performance classes (Table 1) to-for evaluating the accuracy of the approaches for-in the given setup (Moriassi et al. 2015). To determine parameter impact on ET, linear and non-linear models were used. Lastly, differences of  $ET_{sum}$ , DM and  $WUE_{agro}$  between treatments were tested with the Kruskal-Wallis-test and Dunn-Bonferroni post-hoc test.

## 3. Results

### 315 3.1 Environmental parameters

The study year was significantly warmer (mean temperature 9.6 °C) and wetter (508 mm annual precipitation) between July 1, 2020 and June 30, 2021, compared to mean annual air temperature (8.8 °C) and precipitation (467 mm). In particular, temperatures (Fig. 2a) were above average in the fall and winter period in 2020 as well as June, 2021. On the other hand, April

and May, which are crucial for crop growth, were colder and also drier. Daily mean RH (Fig. 2b) ranged between 50 % and 92.4 % with increasing diurnal variation in warm periods. PAR (Fig. 2c) largely reflected the seasonal variation of the day length with a maximum of  $1860 \mu\text{mol m}^{-2} \text{s}^{-1}$  (half-hourly measurements), and reduced values during longer storm events and high cloud cover (e.g., through changes in photosynthesis). The SM at 13 to 18 cm depth largely reflects the intensity of precipitation events (Fig. 2d), ranging from 12 % to 29 %. One exception is a prominent increase in mid-February that can be attributed to low temperatures and subsequent snowmelt. The largest precipitation events ( $> 10 \text{ mm d}^{-1}$ ) occurred on September 26, 2020 with 12 mm, on December 24, 2020 with 15 mm and on February 3, 2021 with 16 mm. A sharp declining trend in SM and no response to precipitation events is evident from April (about 25 %) to harvest in June (about 12 %). However, this can be explained by a high water consumption of the fully developed crop stand and canopy interception. Shallower SM sensors at 3 to 8 cm (not shown) indeed responded to these precipitation events albeit weakly, indicating the infiltration to deeper soil layers was impaired.

### 3.2 Plant development

RVI estimates are based on weekly measurements. Two temporal periods in particular were relevant for plant growth: i) the period from germination to the non-growing season in winter; and ii) the growing period after winter until harvest (Fig. A1). The maximum RVI values were all reached at a similar time (May 15, 2021 to May 18, 2021). In this regard, the non-diluted non-eroded soil LV-cc n-d had the highest RVI (16.46 on average), while the diluted non-eroded soil LV-cc d showed lower values (13.88 on average). The strongly eroded soil of LV-ng revealed the same pattern with a higher RVI for non-diluted (12 on average) and lower RVI on diluted (10.35 on average) treatments. The extremely eroded soil of RG-ca, on the other hand, showed huge differences between the non-diluted and diluted treatments (10.95 vs. 5.87 on average). Apart from that, the maximum standard deviation differed between non-diluted and diluted treatments for the three soil types (LV-cc:  $1.65 < 3.29$ ; LV-ng:  $1.09 < 1.94$ ; RG-ca:  $1.17 < 0.82$ ). Higher RVI values were already reached in non-eroded and strongly eroded soils compared to extremely eroded soil during the initial growing season in fall of 2020 until the non-growing season. Thus, mean RVI values of 4.47 to 6.63 were obtained for non-eroded and strongly eroded soils, while the extremely eroded soils had mean RVI values of only 3.61 (n-d) and 2.31 (d).

### 3.3 ET Fluxes

The seasonal development (Fig. 3) of the quality-screened measured ET fluxes is similar for all treatments: a short growth phase after germination ( $1 - 2 \text{ mmol m}^{-2} \text{s}^{-1}$ ) is followed by a decrease of fluxes until and during the non-growing season in winter ( $< 0.1 \text{ mmol m}^{-2} \text{s}^{-1}$ ), when hardly any plant activity is found due to low temperatures. After the non-growing season, fluxes quickly return to their maximum fall level ( $1 - 2 \text{ mmol m}^{-2} \text{s}^{-1}$ ) and then increase rapidly ( $> 5 \text{ mmol m}^{-2} \text{s}^{-1}$ ). On the non-eroded soil (LV-cc), this rapid increase continued into June, while ET fluxes on the eroded soils (LV-ng and RZ-ca) already peaked in May. In addition, there is a clear difference in the maximum fluxes measured between soil types with  $6.7 \text{ mmol}$

350  $\text{m}^2 \text{s}^{-1}$  for both treatments of non-eroded LV-cc, 5.6 / 6.5  $\text{mmol m}^{-2} \text{s}^{-1}$  (n-d / d) for LV-ng, and 5.8 / 5.1  $\text{mmol m}^{-2} \text{s}^{-1}$  (n-d / d) for RG-ca. Notably, there is a data gap from late April to late May due to sensor failure.

### 3.4 ~~Gap-filling~~ Modeling and validation

Pronounced differences of tested ~~gap-filling~~ modeling approaches in terms of respective calibration statistics could be found. Calibration-~~model~~-performances differ in their scatter around the 1:1-agreement plots (Fig. 4) and associated coefficients of determination ( $R^2$ ). NLR shows a clear overestimation at low and underestimation of higher ET fluxes (Table B4). Compared to that, MDV more accurately predicts low/high ET fluxes, but is characterized by a much lower precision due to a higher variance (Table B4). Among all ~~gap-filling~~ modeling approaches, displayed calibration statistics (Table 2) indicate a very good or good (Table 1) prediction for SVM, ANN\_BR, MDV and LUT over the entire range of observed ET fluxes. Considering the k-fold cross-validation (Fig. 5, Table 3), ANN\_BR and SVM perform good, while MDV shows partially satisfactory statistics, and LUT shows unsatisfactory statistics due to allocation problems that arise when no class is found for the given climate conditions and the mean is used. Statistically, ANN\_BR and SVM were similarly good in predicting observed ET fluxes (Table 2 and 3), even if they show a small tendency to overestimate low ET fluxes (Table B4). However, ~~gap-filled~~ modelled ET fluxes using ANN\_BR showed a large number of predicted negative ET fluxes (1547 on average per plot; Fig. A6) throughout the cultivation period. These fluxes occurred to an unrealistic degree during times when RH was significantly below saturation and plants were active (e.g., during the daytime period), resulting in a reduction in ~~seasonal cumulative~~  $\text{ET}_{\text{sum}}$  between 1 and 51 mm, depending on the treatment. This is most likely a ~~method-method~~-specific extrapolation problem (see discussion) and the reason we use SVM for final budget estimations.

### 3.5 ~~Diurnal Treatment differences~~ ET fluxes, $\text{ET}_{\text{sum}}$ -and crop ET

The model was able to predict the diurnal trends of ET fluxes during the cultivation period (Fig. 6). One representative day per month was selected in terms of the highest number of measurements. The two days of September and May have a reduced accuracy (ME: -0.22 and -0.3) due to a slight overestimation by the SVM modeling, while most of the other days are modeled accurately (ME  $\leq \pm 0.06$ ). Additionally, the seasonal development of the SVM-predicted ET is depicted in Fig. 7 (see Fig. A3 - A5 for the other modeling approaches) and demonstrates a similar pattern to the measured fluxes described in Section 3.3.

375 In general, eroded soils tend to have a negative effect on  $\text{ET}_{\text{sum}}$ . However, this trend was not statistically significant (Kruskal-Wallis-Test,  $\text{ET}_{\text{sum}}$ :  $\chi^2 = 3.04$ ,  $\text{df} = 5$ ,  $p = 0.69$ ). For DM and WUE, on the other hand, the Kruskal-Wallis test indicated a ~~differed~~-significantly ~~difference~~ between treatments (Kruskal-Wallis-Test, DM:  $\chi^2 = 14.58$ ,  $\text{df} = 5$ ,  $p = 0.01$ ; WUE:  $\chi^2 = 11.12$ ,  $\text{df} = 5$ ,  $p = 0.05$ ). The subsequent Dunn-Bonferroni post-hoc test revealed only a significant difference in DM between non-eroded LV-cc n-d and eroded RG-ca d ( $p = 0.013$ ). However, no statistically significant pairwise differences were found for WUE. The amount of plant biomass in dry mass (DM) [kg] is decreasing from non-diluted to diluted and from less eroded soil types to more eroded soil types. DM ranges from  $1.5 \pm 0.13 \text{ kg m}^{-2}$  for LV-cc n-d to  $0.85 \pm 0.2 \text{ kg m}^{-2}$  for RG-ca d.  $\text{WUE}_{\text{agro}}$

is decreasing from less eroded to more eroded soil types ranging from  $7.25 \pm 1.23 \text{ g DM kg}^{-1} \text{ H}_2\text{O}$  to  $4.69 \pm 0.71 \text{ DM kg}^{-1} \text{ H}_2\text{O}$  (Fig. 89).

In order to compare the individual treatments, daily ET and  $\text{ET}_{\text{sum}}$  were calculated (Fig. 67). ET was affected by T, RH, PAR, and RVI, whereas only a small correlation was found with SM (Fig. 78). Higher ET fluxes were induced by increases in T, PAR and RVI, whereas increasing RH resulted in lower ET fluxes.  $\text{ET}_{\text{sum}}$  (Fig. 8a9a) ranges between  $212 \pm 45 \text{ mm}$  (LV-cc n-d) and  $180 \pm 29 \text{ mm}$  (RG-ca d).

$\text{ET}_0$  for the observed study period (September 2020 – June 2021) and region (Uckermark) was 370 mm (DWD 2022). We used the monthly values to calculate the  $\text{ET}_c$  using  $\text{ET}_0$  and the crop coefficient (Allen 1998), resulting in an  $\text{ET}_c$  of 263 mm for the cultivation period.

## 4 Discussion

In the following, we will discuss i) the effects of soil-type and top-soil dilution on  $\text{ET}_{\text{sum}}$ , yield (DM) and  $\text{WUE}_{\text{agro}}$ , along with ii) the spatio-temporal variability of ET fluxes over the cultivation period, and iii) the suitability of the gap-filling modeling strategies used in this study as well as potential ways forward to improve our approaches.

### 4.1 Effects of soil-type and top-soil dilution on ET

In the studied region, soil types vary in their suitability for agricultural cultivation (MLUK 2020). Luvisols support large water fluxes due to their clay-depleted, deep top-soils in combination with the clay-enriched and mostly decalcified sub-soils. They are among the most productive soils in Brandenburg (MLUK 2020; Stahr 2022). Regosols are generally only moderately suitable for arable farming. They are usually found on hilltops and are characterized by parent material near to the surface, lack of depth development, and limited rootability due to the dense, carbonate-rich parent material. They typically have low water availability and plant growth (Herbrich et al. 2018). They are formed by erosion of agricultural Luvisols as relatively organic matter rich top-soil is removed and deeper, nutrient-depleted lower soil layers are mixed into the cultivated layer (Arriaga and Lowery 2003; Pimentel and Kounang 1998).

~~In addition,~~ the carried out top-soil dilution aimed at testing one of the processes of an approach to enhance soil C storage through top-soil deepening. Topsoil deepening through deeper ploughing might store originally top-soil-bound SOC in the deeper subsoil and generate SOC recharge in the diluted C poor top-soil (Sommer et al. 2016). The latter being tested during this study by the carried out top-soil dilution. However, side effects include, similar to erosion, nutrient deficiency and weaker rootability leading to decreased crop growth and yield (Al-Kaisi and Grote 2007; Schneider et al. 2017; Feng et al. 2020). The boundary soil conditions established by erosion and top-soil dilution may not only impact crop growth and yield but also disrupt the crop water balance, especially with the expected increase in drought and heat events in Central Europe (Spinoni et al. 2018). Consequently, farmers might become limited in their choice of crops due to water availability.

As predicted, we observed a significant decline in yield with erosion and top-soil dilution during the study period. However, the impact of soil-type-specific erosion intensity and top-soil dilution on  $ET_{sum}$  was not as pronounced and the trend of declining  $ET_{sum}$  with soil-type and top-soil dilution was not statistically significant among all treatments ( $212 \pm 45$  mm on non-eroded Calcic Luvisol to  $180 \pm 29$  mm on extremely eroded top-soil diluted Calcaric Regosol). Notably, the studied year 2020/21 was comparatively wet (231.1 mm precipitation during the observed period), and potential effects of lower rootability and enhanced drought stress were not observed during the main growth period. This is of great importance because the Uckermark region generally has an overall water balance of about 1 (precipitation input equals  $ET_{pot}$  output) and is therefore water or energy limited depending on the annual precipitation and  $ET_{pot}$  of each year. For example, the extremely dry year of 2018 was very likely water limited with an annual precipitation of  $< 450$  mm and a predicted  $ET_{pot}$  of  $> 650$  mm and thus by far exceeding annual precipitation. However, the year 2021 had an annual precipitation of about 600 mm and a predicted  $ET_{pot}$  of  $< 575$  mm (DWD 2022). Hence, in rather wet years, like the observed 2021, plant growth in the region is rather energy limited (of course dependent on precipitation during the growth period). This fits with our results, as during the studied period, most plots had a lower  $ET_{sum}$  than cumulative precipitation. However, it is very likely that the  $ET_{pot}/Pr$  ratio, and in fact also the observed actual  $ET_{sum}/Pr$  ratio will vary considerably between wetter and drier years and between different crops (particularly winter vs. summer crops).

Additionally, the observed imbalance of response in yield vs.  $ET_{sum}$  led to significantly reduced  $WUE_{agro}$ . In a period of consecutive dry years, a lower  $WUE_{agro}$  could additionally have a negative effect on the water and carbon balance of the whole system, since the water consumption becomes less efficient, especially for the Calcaric Regosol- (up to 36% less yield per used amount of water; (Meena et al. 2020). This could further exacerbate the drought and potentially lead to legacy effects. Finally, winter crops and especially winter rye, are more resilient to drought (Ehlers 1997) due to their head start in growth. Hence, a long-term investigation ~~spanning with~~including other crops (e.g., summer cereal crops) and management strategies would be particularly interesting, as a greater decrease in ET may be observed with soil-specific erosion intensity.

#### 4.2 Seasonal variability of ET fluxes and WUE

Over the entire cultivation period, ET fluxes responded particularly to crop growth, first during the establishment period in fall (mid of October to mid of November) and then again during the main growth period in spring (end of March to mid of May). The close relation of measured ET flux dynamics to RVI- (Fig. 78; e.g., Hanks et al. 1969) can be associated with increasing T rates that strongly compensate for the suppression of E, as canopy biomass increases (Dubbert et al. 2014; Groh et al. 2020). Over the diurnal cycle, ET reacted to changes in environmental conditions, particularly temperature and RH, which together define the vapor-pressure deficit (VPD), as well as PAR. In particular, crops that have been bred to prioritize carbon gain over water conservation will tend to respond to rising VPD strongly (Dubbert et al. 2014; Massmann et al. 2019). Air temperature, humidity and PAR together with increasing biomass (expressed as higher RVI) controlled ET variability during the peak growth period in spring until harvest. SM, on the other hand, did not have a limiting effect on ET, which we attribute to the

wet conditions during the observation period (see above), confirming that the observed crop cycle was not limited by water  
445 availability.

One of our expectations was that ~~expected~~ differences in  $ET_{sum}$  would result mainly from differences during the main  
vegetation period from April to harvest due to variations in biomass and thus T. However, while the growing season between  
April and June is responsible for a large portion of  $ET_{sum}$ , ranging from 66 % to 73 %, it is only responsible for a small portion  
of differences between treatments, with a maximum of 14.3 mm from the non-eroded soil\_-types. The combined fall and winter  
450 period, on the other hand, is responsible for a difference of up to 17.5 mm in  $ET_{sum}$  between non-eroded and extremely eroded  
soil\_-types, although it accounts for 27 % to 34 % of  $ET_{sum}$  only. This is interesting, because it suggests that the reason behind  
the soil type differences in ET for winter rye are caused by static differences (e.g., lower biomass) and suppressed E (e.g., a  
shift in the T/ET ratio) rather than dynamic differences (e.g., the vegetation responses to environmental drivers or drought).  
This should be further evaluated by partitioning ET into T and E. The described FluxCrane is particularly suited for such an  
455 approach by combining flux and in-situ stable isotope approaches (Dubbert et al. 2014; Rothfuss et al. 2021). Beside the overall  
slight reduction of  $ET_{sum}$  on eroded soil\_-types and top-soil diluted treatments, measured ET fluxes were larger on extremely  
eroded plots at the beginning of the growing season before canopy closure which could be explained by a lower soil cover.  
This may be related to the fact that a lower vegetation cover, which is visible in the RVI, can lead to higher E prior to canopy  
closure (Dubbert et al. 2014; Hu et al. 2009; Raz-Yaseef et al. 2012; Wang et al. 2012).

#### 460 **4.3 ~~Gap-filling~~ Modeling approaches**

Methodologically, the study faced two main challenges: accurately quantifying  $ET_{sum}$  and realistically predicting diurnal  
variations during both, the low ET winter and high ET summer periods. Among the ~~gap-filling~~ modeling approaches compared  
in this study, only NLR showed calibration statistics less than good (Table 2). While the LUT showed very good calibration  
results, the allocation problems that occur when no class is found (Fig. 5) and the mean is used, resulted in the lowest predictive  
465 ability during validation over the full range of measured ET fluxes. Some studies also obtained quite plausible results for LUT  
and MDV (Boudhina et al. 2018; Falge et al. 2001a; Moffat et al. 2007), and adjusting the classes of the LUT could further  
improve the results of this approach. However, with the available dataset, the only way to avoid allocation problems was to  
use fewer classes. This resulted in a loss of variability, making diurnal differences invisible and ET estimates less accurate.  
MDV, on the other hand, partially showed only satisfactory values during validation (Table 3), while SVM and ANN  
470 performed good or very good according to the defined classes (Table 1). Additionally, previous studies found that MDV (as  
well as LUT) performs particularly weakly with increasingly large gaps (Moffat et al. 2007; Kim et al. 2020). Especially for  
conditions where no measurements could take place due inter-alia environmental conditions (large gaps in winter), the fact  
that MDV takes averaged values of adjacent measurements could explain the rather bad predictions. This is similar for LUT,  
since no classes could be created for conditions where no measurements took place. The machine learning approaches SVM  
475 and ANN\_BR, on the other hand, are not as sensitive to larger observational gaps because their training includes all  
measurements. For seasonal variability and budgets, we achieved the best performance with the SVM approach, while ANN

showed reduced daily and seasonal cumulative ET due to an unrealistic amount of predicted negative fluxes (up to 51 mm; Fig. A6A5). However, the best approach for gap-filling modeling or gap-filling can vary depending on the application and investigated parameters. For example, in gap-filling gap-filling methane fluxes using eddy covariance (Kim et al. 2020), ANN\_BR was superior to SVM.

Another important aspect of gap-filling modeling is potential over- or underestimation of fluxes. (Shrestha and Shukla 2015), for example, attempted to predict actual lysimeter ET using different approaches (e.g., ANN\_BR and SVM) and crops (pepper, watermelon) in a subtropical environment. Best predictions were obtained with SVM (pepper: 204.7 mm lysimeter vs. 181.8 mm SVM; watermelon: 231.71 mm lysimeter vs. 189.83 mm SVM). However, they reported overestimation of low fluxes and underestimation of high fluxes by ANN\_BR and SVM. In our study, we observed a tendency to slightly overestimate small fluxes using SVM based gap-filling modeling (Fig. B4). In this regard, using plot specific multi-depth SM data could also improve the predicted  $ET_{sum}$  based on SVM in the future. Similarly, we expected considering wind speed to improve ET prediction, but could not find an effect on observed ET for the study period.

Furthermore, it must be noted that the quality of SVM (and ANN\_BR) predictions is highly dependent on the amount of data available (Chia et al. 2020; Abudu et al. 2010). Consequently, we tested the minimum amount of data necessary to provide predicted ET fluxes of good quality (see criteria in M&M). For the particular-specific dataset, already even as little as 50 % of the total data available (minimum 300 measurements) provided good results. Thus, we emphasize that capturing a large variability of fluxes under different environmental conditions seems to be more important than a merely large data set.

#### 4.4 Accuracy Evaluation of the new system and comparison with other measurement techniques

$ET_c$  was 263 mm ~~from during~~ the cultivation period. ~~This, which~~ is comparable to our observed results ( $ET_{sum}$ ) of 212 mm for non-eroded Calcic Luvisol. ~~However, it is important to consider given~~ that  $ET_0$  calculations using the Penman-Monteith equation (FAO56-PM) are reported to overestimate  $ET_0$  and ~~thus consequently~~  $ET_c$  (Allen 1998). Thus, our FluxCrane  $ET_{sum}$  seem sensible overall. ~~Nevertheless however, it is advisable a to directly comparison compare them with between the FluxCrane,~~ lysimeter~~s~~ and potentially ~~drone drone~~-based observations of  $ET$  ~~would be advisable~~. This is particularly true relevant in light of ongoing discussions surrounding method constraints of estimating ET across scales (Ding et al. 2021; Ghiat et al. 2021; Hamel et al. 2015).

For ~~example instance, there is a nearby lysimeter experiment with a~~ multi treatment ~~lysimeter experiment is located nearby the FluxCrane and conducted by~~ (Groh et al. 2020). They report a wide range of  $ET_{sum}$  for the period between 2014 and 2018 (300 to 600 mm), with the lower range boundary being comparable to our results (considering that we only calculated budgets for the ~~9-9-months~~ growths-cultivation period and excluded the fallow period during the summer months with high ET). It has to be noted, however, that not only environmental conditions but also crops studied in (Groh et al. 2020) varied from year to year and, more importantly, from our study, hampering comparability between studies. However, the direct vicinity of two large large-scale set-ups able to estimate  $ET_{sum}$  should be utilized in the future. Another lysimeter based study conducted in

Brunswick (Lower Saxony, Germany) for a cultivation season of winter rye report a range of observed ET fluxes very comparable to our study, with less than 1 mm day<sup>-1</sup> in winter to a maximum of 6 - 7 mm day<sup>-1</sup> in summer (bfg 2023).

Finally, filling data gaps modeling using statistical and empirical approaches is used in many fields e.g., to calculate of reference ET (ET<sub>0</sub>) with limited meteorological parameters (Chia et al. 2020) or ET from eddy-covariance measurements as well as canopy chamber measurements (Hui et al. 2004; Moffat et al. 2007; Falge et al. 2001a; Falge et al. 2001b; Hamel et al. 2015; Kübert et al. 2019). The connection between gap-filling modeling approaches, in combination with the described continuous high-resolution long-term ET measurements of numerous small-scale treatments, gives additional opportunities to observe the progression of ET over an entire cultivation season and, for example, to identify key periods that drive overall treatment differences.

Here, our combined approach of automated chamber measurements of ET with data driven modeling fills a unique application niche among the different methods to quantify ET fluxes. In comparison, eddy-covariance (e.g., Boudhina et al. 2018; Simpson et al. 2019), and lysimeter-based observations (Groh et al. 2020) are unparalleled in measurement frequency and therefore only require filling gaps, which are typically much smaller compared to our approach. However, eddy-covariance systems operating at the ecosystem scale are not able to detect small-scale spatial heterogeneities in ET fluxes, e.g., to test the effects of soil type, management, etc., or different crops grown simultaneously (Anapalli et al. 2018). Lysimeter approaches, on the other hand, are useful for combining small-scale spatial heterogeneity with high-frequency measurements, but are limited to water cycle applications and a direct link to carbon/GHG dynamics is not straightforward.

Classic manual gas exchange chamber applications are capable of analyzing small-scale spatial effects (e.g Macagga et al. 2023; Antonijević et al. 2023). However, despite the ability to observe diurnal cycles, the total amount of measured data is usually very limited. Typically, campaign-based measurements are performed approximately every 3 weeks (Huth et al. 2017). This results in a total maximum amount of about 300 fluxes per treatment (3 replicates, 6 measurements per plot per campaign). Even when measurement campaigns are performed more frequently, the available fluxes remaining after quality checks are quite limited (see e.g., Dubbert et al. 2014 with 22 measurement campaigns in 8 months resulting in ~297 fluxes per treatment). Under these conditions, combining chamber measurements with data-driven ET flux modeling approaches is usually limited to very simple approaches (e.g., Falge et al. 2001a). In the present study, the automated FluxCrane generated approximately 7-10 times the amount of ET fluxes compared to manually operated chambers. In addition, the system is not as disruptive to plant growth. For example, permanently installed automated canopy chambers or manually conducted approaches, tend to physically harm the canopy and have condensation issues due to permanently installed tubing and inappropriate air mixing within the chamber (e.g., Hamel et al. 2015). Moreover, the ability to observe nighttime fluxes has great potential to study previously overlooked short-term dynamics in ET and to improve the representation of underlying processes in process-based hydrological modeling, compared to manually operated chambers. This offers several benefits: 1) dynamic developments in ET fluxes and differences between treatments are easier to analyze (even if only the measured fluxes are considered), 2) the much larger number of fluxes available bears the potential to apply data-driven ET flux modeling using advanced statistical, empirical, and machine-learning based algorithms.

545 Compared to other methods for estimating ET, such as eddy covariance measurements (e. g., Boudhina et al. 2018; Simpson et al. 2019), our approach is able to highlight small scale treatment differences, such as soil type differences and associated erosion stages, in a heterogeneous field with a relatively high number of different treatments simultaneously. In addition, the system is not as disruptive to plant growth. For example, permanently installed canopy chambers or manually conducted approaches, tend to physically harm the canopy and have condensation issues due to permanently installed tubing and inappropriate air mixing within the chamber (e. g. Hamel et al. 2015). The FluxCrane eliminates these problems by providing continuous measurement and a constant flow of air through the attached canopy chambers. Moreover, the ability to observe 550 nighttime fluxes has great potential to study previously overlooked short term dynamics in ET and to improve the representation of underlying processes in process based hydrological gap filling, compared to other measurement systems and especially to manually operated chambers.

#### 4.4 Conclusion and outlook

555 ~~Where~~, we present a possibility to obtain ~~not only~~ plausible  $ET_{sum}$  ~~but also~~ and diurnal cycles of ET by using the novel FluxCrane system in combination with data-driven SVM based gap filling modeling. We expected strong negative effects of eroded soils and top-soil dilution on  $ET_{sum}$  as well as yield. However, crop yield responded much more strongly to eroded soils and top-soil dilution than  $ET_{sum}$  in the observed rather wet year, leading to strong negative shifts in  $WUE_{agro}$ . The novel FluxCrane, combined with data driven modeling, fills the unique application with its potential to observe temporal flux dynamics and seasonal budgets for distinct landscape elements simultaneously, ~~combines the contrasting benefits of eddy covariance and manual chamber techniques~~. Thus, the new system has a large potential to bring new insights into water-flux dynamics and budgets, ~~and, in combination with measurements of NEE-CO<sub>2</sub> measurements, the novel FluxCrane could give new insights in ecosystem WUE in a high spatio-temporal resolution using NEE (net ecosystem exchange). In addition, coupled with the GEP (gross ecosystem production) and innovative measurements such as in-situ stable water isotopes (Dubbert et al. 2014; Kübert et al. 2020). (Dubbert et al. 2014; Kübert et al. 2020), a separation of ET into T and E would be possible to assess crop performance by assessing due to the plant specific WUE (Tallec et al. 2013) or to study root water uptake dynamics (Deseano Diaz et al. 2023; Kühnhammer et al. 2020). into growth season dynamics of WUE in the future.~~ This is particularly relevant for regions with strong spatial heterogeneity in soils and generally low precipitation the studied region in like the Uckermark ~~with its strong spatial heterogeneity in soils and its generally low precipitation and~~. Finally, the novel FluxCrane is unique in its potential to combine it with ~~innovative measurements such as in situ stable water isotopes (Dubbert et al. 2014; Kübert et al. 2020). Stable water isotopes could be used to separate the ET into T and E. This separation is of crucial importance for the terrestrial water balance and as well as for the prediction of future ecosystem feedbacks (Groh et al. 2020). Klicken Sie hier, um Text einzugeben.~~ Water isotopes might also be used to study root water uptake dynamics (Deseano Diaz et al. 2023; Kühnhammer et al. 2020).

## 575 **5 Code availability**

The codes produced for this study are available from the corresponding author upon request.

## **6 Data availability**

The data sets produced for this study are available from the corresponding author upon request.

## **7 Author contributions**

580 AD, MD conceived and planned the study. MS, GV, MH supervised automated measurements and conducted complimentary field measurements. AD analyzed the data and wrote a first version of the manuscript. All authors contributed to manuscript writing.

## **8 Competing interests**

The authors declare that they have no conflict of interest.

## 585 **9 Acknowledgements**

The authors acknowledge funding by the German Federal Ministry of Food and Agriculture (FNR Grant: 22404117) and the German Science Foundation (DFG Grant DU1688/6-1). The authors are very grateful to the Pfannenstiel ProProject GmbH for the excellent collaboration in designing as well as constructing the gantry crane system and ATTEC Automation GmbH for programming the system control. The study was a part of the CarboZALF project of the Leibniz Centre for Agricultural Landscape Research (ZALF). The CarboZALF project was financially supported by the German Federal Ministry of Food, 590 and Agriculture ~~and Consumer Protection~~ (BMELV) and the Ministry of Environment, Health and ~~Consumer Climate Protection~~ (MLUVMLUK) of the State of Brandenburg. The authors thank the Experimental Infrastructure Platform (EIP) of ZALF for assistance with field measurements and John Marshal and Sebastian Fitting for proofreading the manuscript.

**Figures:**

910

**Figure 1:** (a) AgroFLUX research site in the CarboZALF-D experimental area with (b) the 110 x 16 m field where ~~(d)~~ three different soil types (LV-cc: non-eroded calcic Luvisol, LV-ng: highly eroded nudiargic Luvisol, and RG-ca: extremely eroded calcare Regosol) (c) 18 measurement plots of (e) the FluxCrane operates on ~~(c)~~ 18 measurement plots of (e) three different soil types (LV-cc: non eroded calcic Luvisol, LV-ng: highly eroded nudiargic Luvisol, and RG-ca: extremely eroded calcare Regosol). Soil moisture and precipitation measurements were taken in the marked area (black circle, b). The separation of non-diluted (unframed green) and diluted (framed light green) plots can be seen in (c).

915

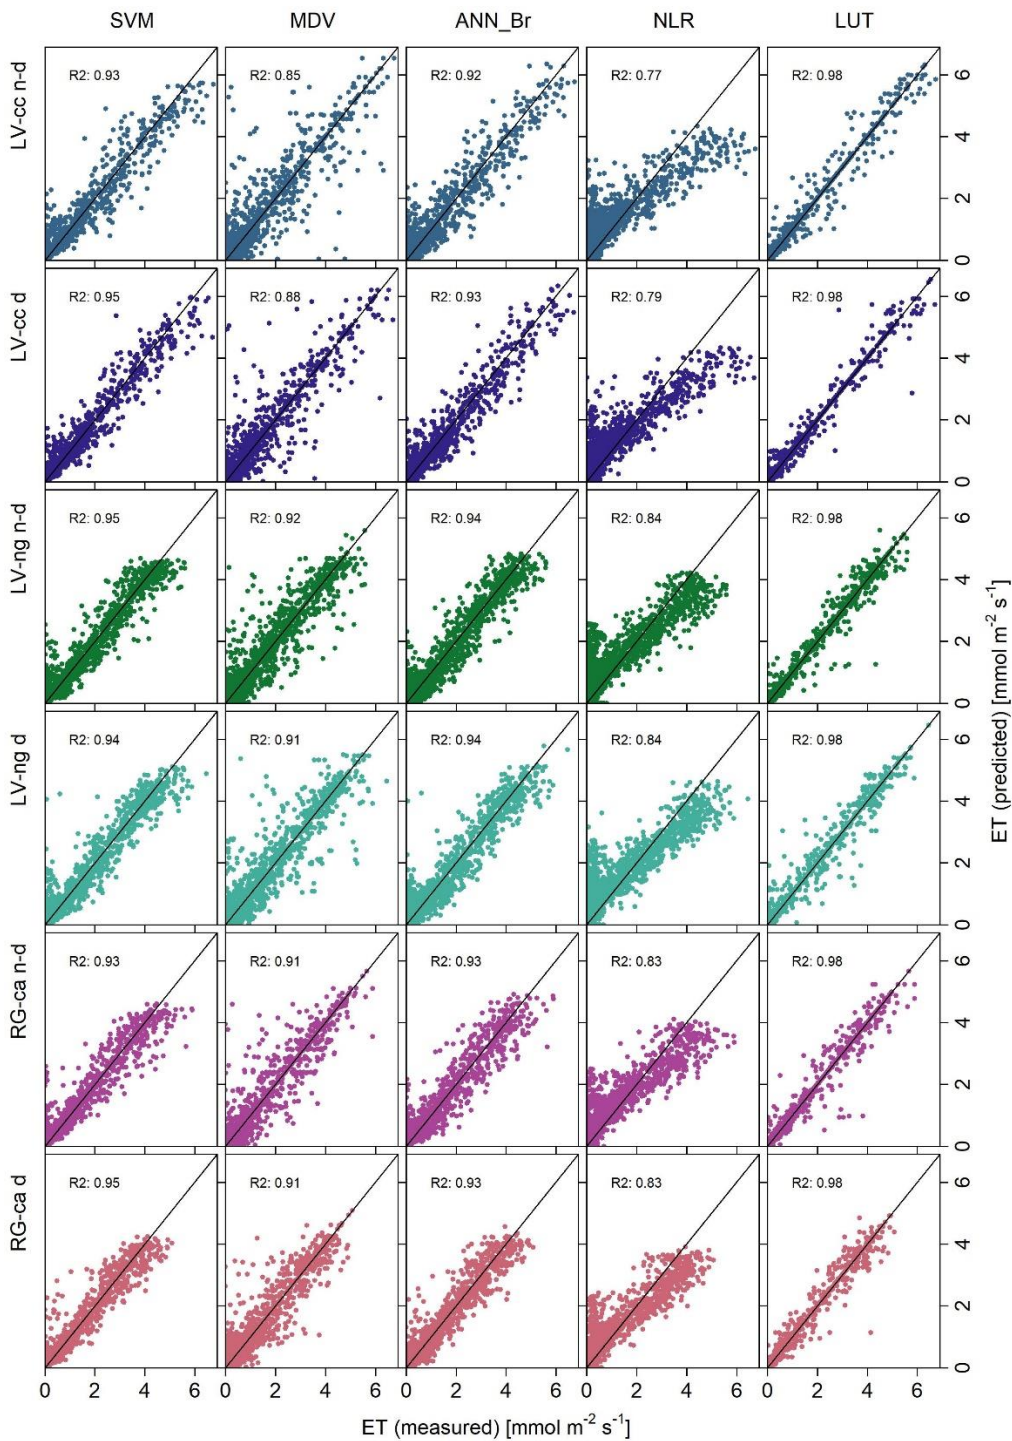

**Figure 2:** Environmental parameters during the measurement period with (a) daily mean temperatures (T; orange line; light gray = corresponding variation) and daily mean relative humidity (RH; black line; dotted lines = corresponding variation), (b) daily mean temperatures (T; orange

| line: light gray = corresponding variation), (c) incoming photosynthetically active radiation (PAR; purple) and (ed) soil moisture (SM; blue line) and precipitation (PR; blue bars).

930

**Figure 3:** Measured and quality-screened (by soft and hard criteria) ET fluxes of the three soil types over the entire observation period (non-diluted treatments on the left, diluted treatments on the right).

935

**Figure 4:** Comparison of the measured (bottom) with the predicted (left) ET fluxes and associated r-squared values (R2) of the calibration results of all modeling approaches. The black line represents

the 1/1 line. The different modeling treatments approaches are shown on top, the approaches treatments on the right/left.

**Figure 5:** Comparison of the measured (**bottom**) with the predicted (**left**) ET fluxes and the associated r-squared values (R2) of the validation results of all **modeling** approaches. The black line represents the 1/1 line. The different **treatments-modeling approaches** are shown on top, the **approaches-treatments** on the **right/left**.

**Figure 6:** Diurnal cycles in ET fluxes during the cultivation season for one sample day per month (day with the most measurements) and corresponding mean error (ME; two digits rounded). Measured ET is shown in blue, predicted ET is shown in red.

950

**Figure 67:** Daily mean ET sums (colored lines) of the different treatments and seasonal cumulative ET ( $ET_{sum}$ ; dashed lines) with standard deviation between replicates (light and dark gray).

955 **Figure 78:** Relationship between ET and temperature (T) [°C], relative humidity (RH) [%], photosynthetically active radiation (PAR) [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ], and ratio vegetation index (RVI) [ $\text{mmol m}^{-2} \text{s}^{-1}$ ], and associated regression lines. Statistical values ( $r^2$  and  $p$ ) for the relationship between ET and response variables (environmental parameters) are presented in the table.

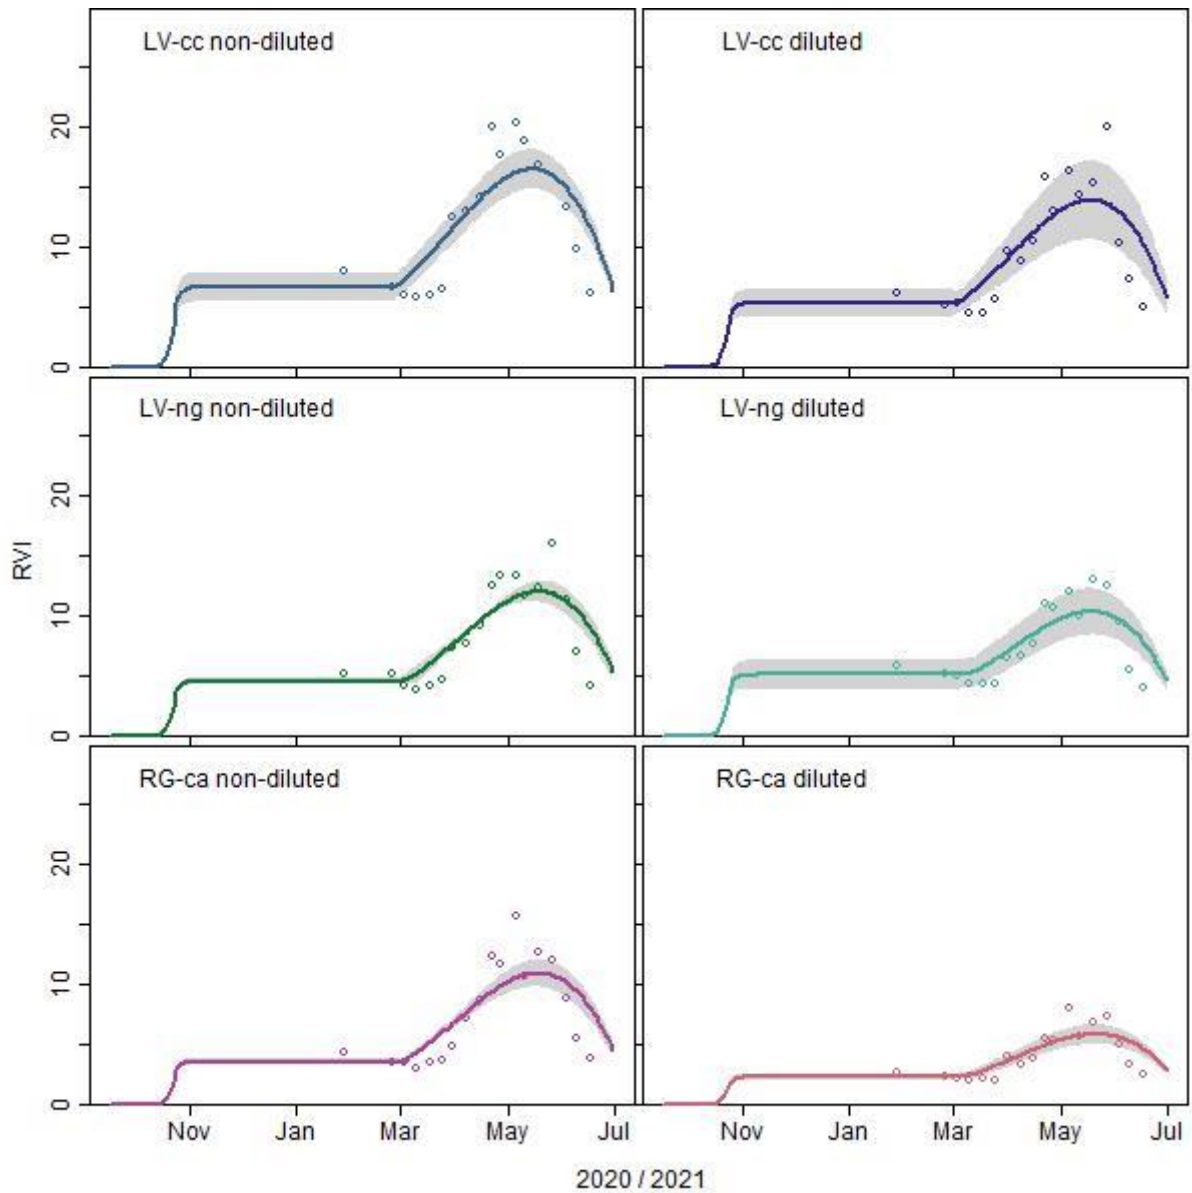

960

965

970

**Figure 89:** Averaged seasonal cumulative ET ( $ET_{sum}$ ) [mm] (a), harvest in form of dry mass (DM) [kg] (b), and  $WUE_{agro}$  of the different treatments and the associated standard deviation.

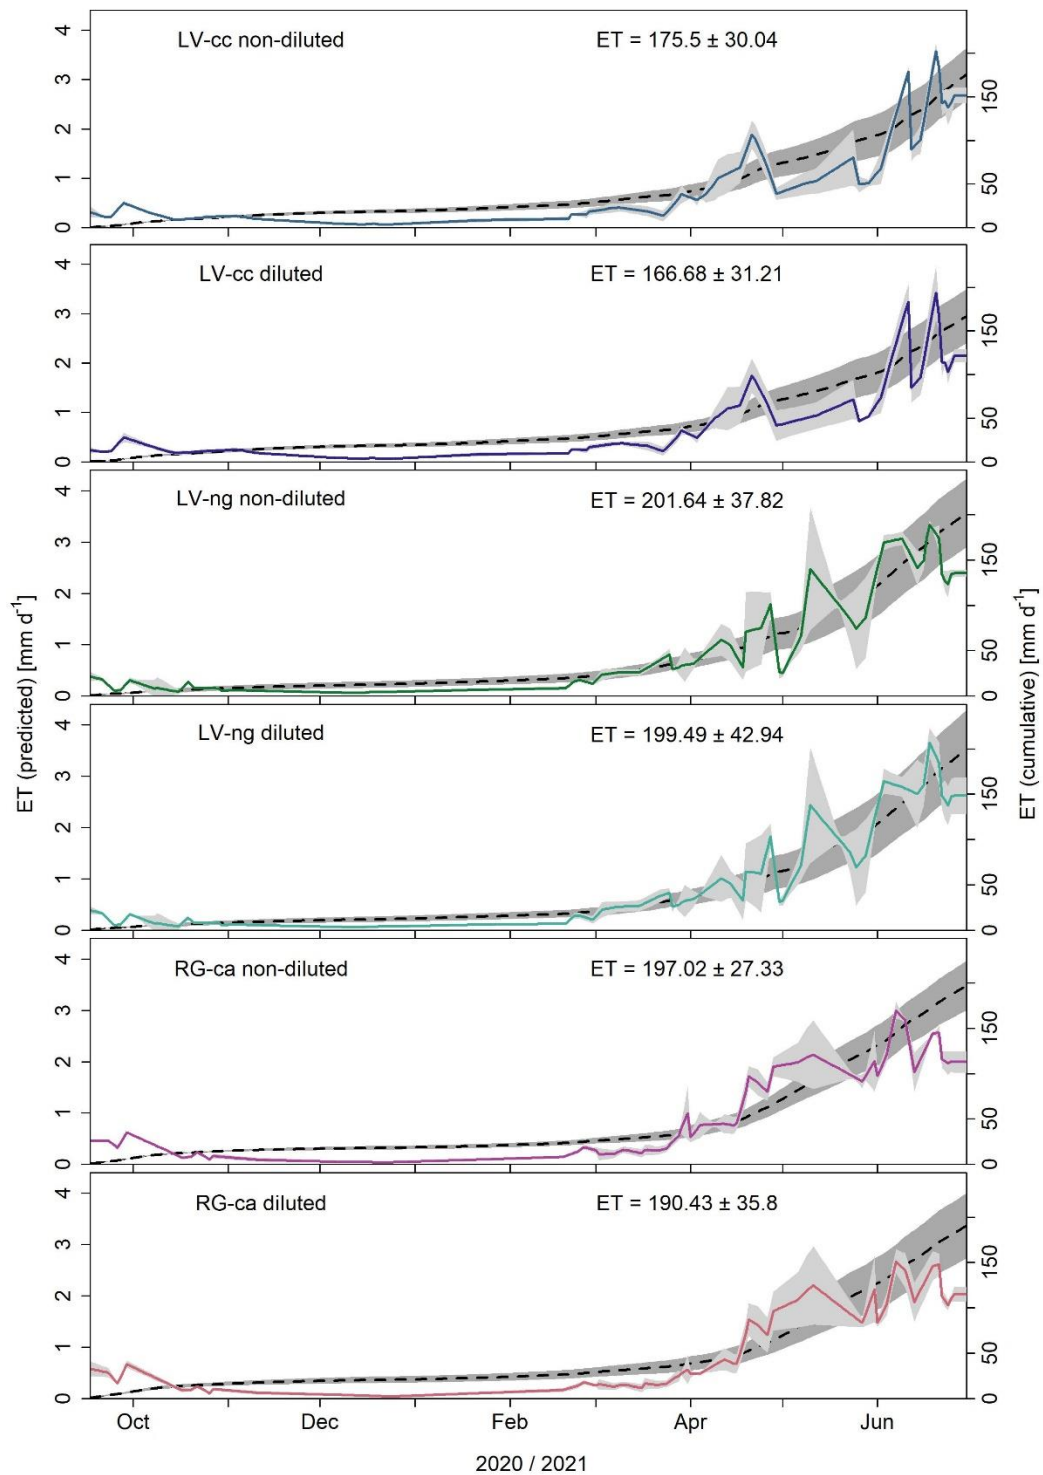

**Figure A1:** RVI fit (colored lines) of the different treatments with the standard deviation between replicates (light gray) and the corresponding averages of the daily measurements (points).

**Figure A2:** Schematic representation of the main steps of the presented data processing: raw data preparation was followed by a campaign-specific ET-flux calculation. Then, environmental parameters were used for [gap-filling modeling](#) using five different approaches. After calibration and validation, the most accurate approach was used for [gap-filling ET flux modeling](#).

**Figure A3:** -LUT predicted daily mean ET sums (colored lines) of the different treatments and seasonal cumulative ET ( $ET_{sum}$ ; dashed lines) with standard deviation between replicates (light and dark gray).

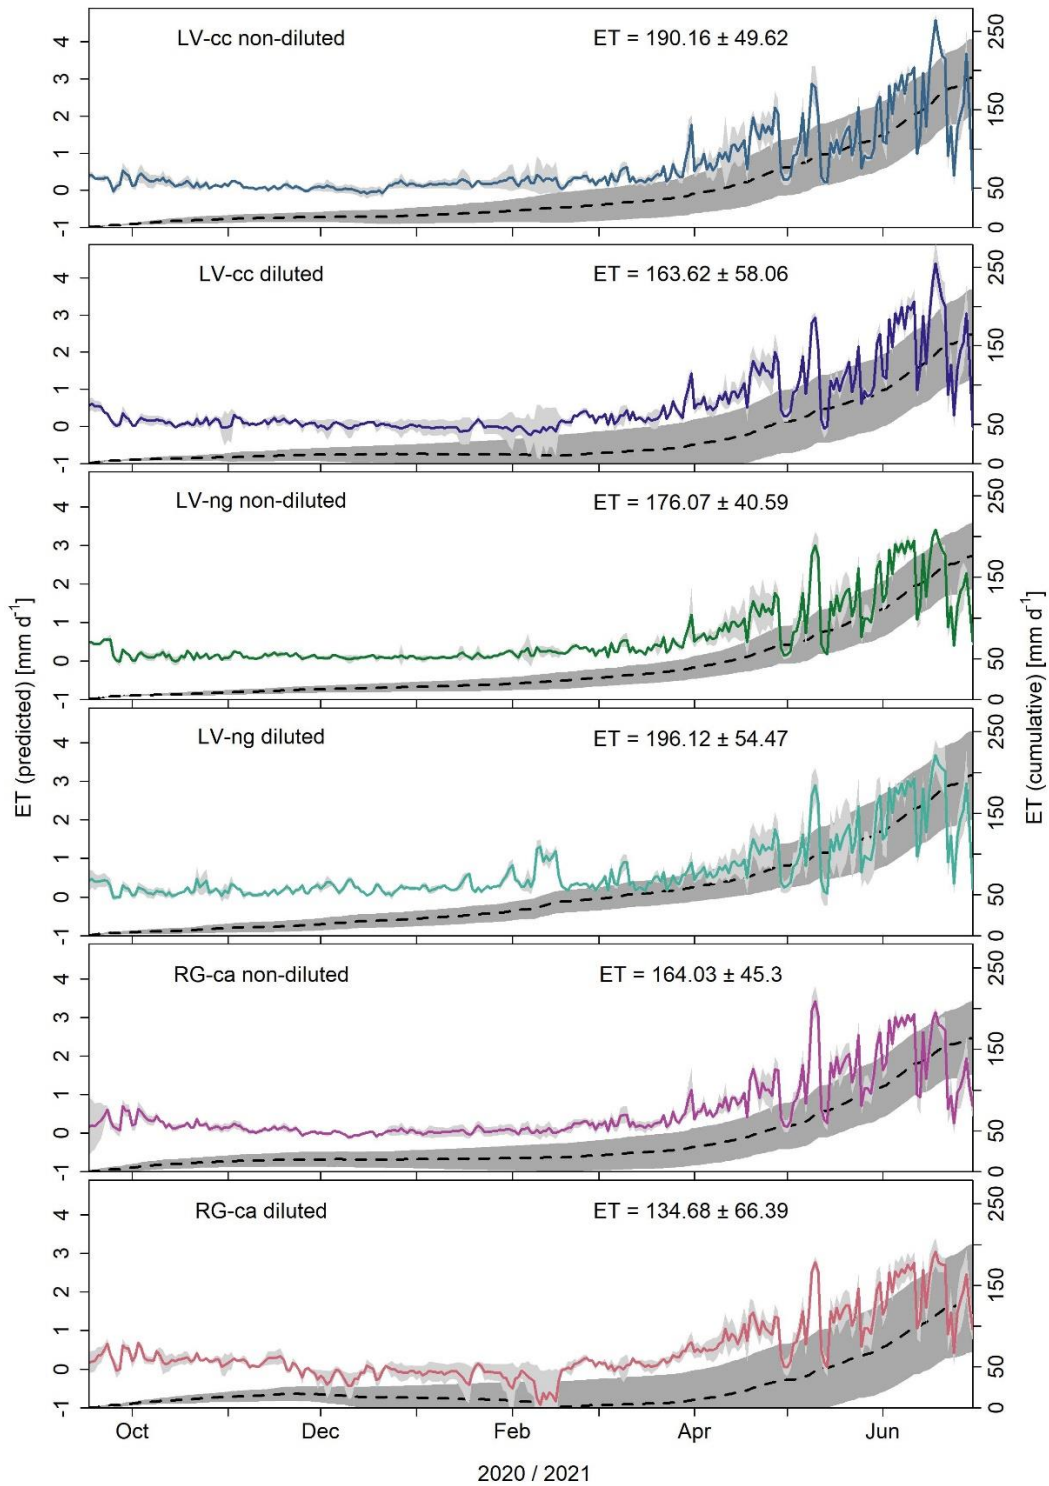

**Figure A4:** -MDV predicted daily mean ET sums (colored lines) of the different treatments and seasonal cumulative ET ( $ET_{sum}$ ; dashed lines) with standard deviation between replicates (light and dark gray).

**Figure A5:** -NLR predicted daily mean ET sums (colored lines) of the different treatments and seasonal cumulative ET ( $ET_{sum}$ ; dashed lines) with standard deviation between replicates (light and dark gray).

1000

**Figure A6:** -ANN\_BR predicted daily mean ET sums (colored lines) of the different treatments and seasonal cumulative ET ( $ET_{sum}$ ; dashed lines) with standard deviation between replicates (light and dark gray).

## Appendix B:

**Table B1:** Fertilization information for the field.

1005

Date	Amount	Details
15.10.2020	161 kg P <sub>2</sub> O <sub>5</sub> ha <sup>-1</sup>	applied on 6 plots of LL as TSP
22.03.2020	77 kg P <sub>2</sub> O <sub>5</sub> ha <sup>-1</sup>	as Triple Super Phosphate (TSP)
22.03.2020	259 kg K <sub>2</sub> O ha <sup>-1</sup>	as 40% grain potash
16.09.2020	30 kg N ha <sup>-1</sup>	10 m <sup>3</sup> ha <sup>-1</sup> digestate
10.03.2021	91 kg N ha <sup>-1</sup>	30 m <sup>3</sup> ha <sup>-1</sup> digestate
08.04.2021	45 kg N ha <sup>-1</sup>	12 m <sup>3</sup> ha <sup>-1</sup> digestate
