Abstract. Today, the most popular approaches in agricultural forecasting leverage process-based crop models, crop monitoring data, and/or remote sensing imagery. Individually, each of these tools has its own unique advantages but is, nonetheless, limited in prediction accuracy, precision, or both. In this study we integrate in situ and remote sensing (RS) soil moisture observations with APSIM model through sequential data assimilation to evaluate the improvement in model predictions of downstream state variables across 5 experimental sites in the U.S Midwest. Four RS data products and in-situ observations spanning 19 site-years were used through two data assimilation approaches namely Ensemble Kalman Filter (EnKF) and Generalized Ensemble Filter (GEF) to constrain model states at observed time steps and estimate joint background and observation error matrices. Then, the assimilation's impact on estimates of soil moisture, yield, NDVI, tile drainage, and nitrate leaching was assessed across all site-years. When assimilating in situ observations, the accuracy of soil moisture forecasts in the assimilation layers was improved by reducing RMSE by an average of 17% for 10cm and ~28% for 20 cm depth soil layer across all site-years. These changes also led to improved simulation of soil moisture in deeper soil layers by an average of 12%. Although crop yield was improved by an average of 23%, the greatest improvement in yield accuracy was demonstrated in site-years with higher water stress, where assimilation served to increase available soil water for crop uptake. Alternatively, estimates of annual tile drainage and nitrate leaching were not well constrained across the study sites. Trends in drainage constraint suggest the importance of including additional data constraint such as evapotranspiration. The assimilation of RS soil moisture showed weaker constraint of downstream model state variables when compared to the assimilation of in situ soil moisture. The median reduction in soil moisture RMSE for observed soil layers was lower, on average, by a factor of 5. However, crop yield estimates were still improved overall with a median RMSE reduction of 17.2%. Crop yield prediction was improved when assimilating both in-situ and remote sensing soil moisture observations and there is strong evidence that yield improvement was higher when under water-stressed conditions. Comparisons of system performance across different combinations of remote sensing data products indicated the importance of high temporal resolution and accurate observation uncertainty estimates when assimilating surface soil moisture observations.

Keywords: Model-data integration, Sequential Data Assimilation, APSIM, soil moisture

32 1. Introduction

33 To effectively address pressing global food security challenges, agricultural forecasting tools must exhibit high
34 accuracy and precision across spatial and temporal scales. As process-based crop models offer a system-level
35 representation of many soil and crop processes, they are increasingly recognized as practical forecasting tools in
36 agricultural research (Silva and Giller, 2021; Fer et al., 2021). However, their weakness comes from many
37 unaccounted uncertainties, such as those related to model parameters, initial conditions, and weather (Dokoohaki et
38 al., 2021). Prior studies have shown state data assimilation (SDA) to be a powerful tool to overcome this weakness in
39 process-based crop models (e.g. Dokoohaki et al., 2022a). SDA enables a temporally-continuous, high-dimensional
40 scaffold in which a variety of observations can be smoothly integrated using one of many robust, systematic
41 algorithms, such as the Ensemble Kalman Filter (EnKF; Dietze et al., 2017; Huang et al., 2019; Liu et al., 2021;
42 Dokoohaki et al., 2022a; Kivi et al., 2022). Through SDA, uncertainty around spatially-heterogeneous and dynamic
43 properties in agricultural systems can be constrained, thereby increasing precision and accuracy in estimates while
44 decreasing dependence on extensive site-level model calibration (Mishra et al., 2021).

45 Numerous past studies have used SDA to constrain crop model estimates, using observations on leaf area index (e.g.,
46 Nearing et al., 2012; Ines et al., 2013; Ma et al., 2013; Chen et al., 2018; Lu et al., 2021), soil moisture (Kivi et al.,
47 2022), biomass (e.g., Linker and Ioslovich, 2017) and evapotranspiration (e.g., Huang et al., 2015). For example, a
48 synthetic study by Zhu et al. (2017) found that the assimilation of coarse resolution surface soil moisture data into a
49 coupled soil water-groundwater numerical model constrained soil moisture estimates in the first 50 cm of the soil
50 profile despite explicitly unaccounted spatial heterogeneity in soil properties. These studies showed how SDA can
51 partially account for the spatial variability in soil hydraulic conductivity across broad regions without explicit model
52 calibration. In addition to incorporating spatial heterogeneity in soil properties, Kivi et al. (2022) demonstrated that
53 the assimilation of high quality and frequent in-situ soil moisture observations can substantially improve downstream
54 model predictions of tile drainage, nitrate (NO₃) leaching, and root-zone soil moisture (RZSM) for maize and
55 soybeans in the APSIM model. However, collecting field measurements of soil moisture for different cropping
56 systems, soils, and environments is expensive, extremely laborious, and time-consuming.

57 Alternatively, the assimilation of high-resolution Remote Sensing (RS) data products dramatically increases SDA
58 applications' range beyond in situ data availability by effectively capturing the spatiotemporal variability of many
59 agricultural state variables, such as vegetation cover and soil moisture, with consistency and high temporal frequency
60 (Peng et al., 2017). As a result, RS observations could be invaluable to constraining model predictions at the regional
61 scale and have been increasingly applied for agricultural forecasting in the data assimilation literature, as demonstrated
62 in literature reviews by Dorigo et al. (2007), Huang et al. (2019), and Weiss et al. (2020). The application of RS soil
63 moisture data products has been especially popular and successful in data assimilation-focused agricultural forecasting
64 studies. These data products, which characterize soil moisture content in the first 5 cm of the soil profile, pull
65 information from active and/or passive sensors of microwave reflectance. Due its high sensitivity to surface soil
66 moisture, many data products have been developed around available L-band microwave sensor information collected
67 by NASA's SMAP Mission (Kumar et al., 2018). The SMAP-HydroBlocks data products merges SMAP data with
68 the HydroBlocks land surface model to increase spatial resolution in the final estimates and improve scalability

69 (Vergopolan et al., 2021b), while the SMAP-Sentinel1 data product pairs SMAP data with Sentinel-1 radar
70 information to achieve similar goals (Das et al., 2019). Others, like the ESA-CCI data product (Dorigo et al., 2017),
71 compile information from multiple sensors, including the SMAP passive sensor, to allow for greater temporal
72 coverage. However, this approach comes at the cost of coarser spatial resolution.

73 Nonetheless, as demonstrated in past studies, the assimilation of RS soil moisture data has its limitations. First,
74 uncertainty and biases in RS data products are typically poorly defined (Huang et al., 2019). RS-based data products
75 are based on empirical relationships, and, as they are predicted as a function of surface reflectance, uncertainties in
76 the raw radiance will propagate unsupervised into final estimates (Weiss et al., 2020). Additionally, RS estimates
77 characterize soil moisture in only the top 5 cm of the soil profile and, thus, rely on models or empirical
78 parameterizations to describe the root zone soil profile. Among others, De Lannoy et al. (2007) and Monsivais-
79 Huertero et al. (2010) both found the assimilation of in-situ near-surface soil moisture observations to be far less
80 effective than that of in-situ root-zone soil moisture observations in constraining estimates of the greater soil water
81 profile. Yet, since the surface layer is typically the layer where fertilizers are added, the accurate estimation of surface
82 layer state variables is essential for today's agroecosystems (Verburg and CSIRO, 1996). To overcome relatively
83 coarse spatial resolution in RS data products, past studies have explored downscaling approaches (e.g.,
84 ChakrabartiChakrabarti et al., 2014) or leveraged additional in-situ datasets (e.g., Liu et al., 2021) to overcome
85 "mismatch" challenges and downscale RS soil moisture estimates to more accurately reflect field scale measurements
86 (Vergopolan et al., 2021a). However, the reliance on in situ observations of these approaches can limit system
87 transferability across broad regions (Peng et al., 2017). Moreover, as described by Crow et al. (2012), it can be difficult
88 to properly evaluate coarse soil moisture estimates with point-scale ground measurements due to unknown and often
89 significant sampling uncertainty. Data assimilation with process-based models has been previously applied as a robust
90 and scalable way to leverage information in coarse resolution soil moisture estimates (e.g. Vergopolan et al., 2021b).

91 Despite the immense theoretical potential of SDA with both in situ and RS observations, past studies have reported
92 inconsistent SDA performance in modeling crop yields. For example, de Wit and van Diepen (2007) observed
93 inconsistencies in yield constraint when assimilating soil wetness index (SWI) derived from 0.25° ERS1/2 microwave
94 radiance information into the WOFOST model across agricultural regions of Spain, Germany, France, and Italy. They
95 partially attributed poor predictions in certain regions to irrigation processes that were not captured by the model nor
96 coarse resolution SWI observations. Lu et al. (2021) also saw year-to-year variability in assimilation performance
97 when assimilating in situ observations of canopy cover and soil moisture for 6 site-years in Nebraska. When
98 assimilating soil moisture independently, canopy cover estimates were better constrained in drier years. They
99 suspected this to result from the canopy cover's lower sensitivity to soil moisture in the model when water is in surplus
100 (i.e., due to energy-limited conditions). We further suspect that SDA's inconsistent performance is related to the
101 misrepresentation of model processes linking soil moisture to crop- and soil-related variables (e.g., soil nitrogen, leaf
102 expansion, crop water uptake). As a result, direct upstream improvement of model state variables with SDA does not
103 always translate into improvement in downstream results. To understand the role of soil moisture data assimilation in
104 improving crop yields and better pinpoint areas for future improvement, a comprehensive assessment that investigates
105 performance across time and different genetic (G), environmental (E), and management (M) spaces is required.

106 Although a growing body of studies has attempted to quantify the impact of soil moisture assimilation in crop models,
107 such a comprehensive evaluation of in situ and RS soil moisture SDA in crop models across GxExM spaces is still
108 lacking (Folberth et al. 2016b).

109 To bridge this knowledge gap, we present a comprehensive assessment of soil moisture data assimilation as a method
110 for constraining crop model predictions across the U.S. Midwest. Building on the assimilation framework in Kivi et
111 al. (2022), we independently assimilated both in situ and RS soil moisture observations in the APSIM crop model at
112 five experimental sites in the U.S Midwest. With field data covering 19 site-years of corn and soybean cropping
113 systems across the region, this study tests the data assimilation system across a broader GxExM inference space and
114 quantifies the benefit of assimilating different RS soil moisture products in comparison to the in-situ soil moisture
115 observations. The main objectives of this study were:

- 116 1. To quantify how in situ soil moisture observations can constrain crop model forecasts of downstream estimates,
117 including root-zone soil moisture, crop yield, crop phenology via NDVI, tile drainage flow, and NO₃ leaching
118 through SDA.
- 119 2. To quantify the added benefit of RS soil moisture observations in improving crop model predictions of root-
120 zone soil moisture, crop yield, and crop phenology via NDVI through SDA.

121 **2. Methods**

122 Sections 2.1 and 2.2 describe the five experimental sites and the in-situ observations employed in this study for model
123 set-up, SDA, and evaluation. Section 2.3 outlines the four different RS soil moisture data products that were
124 assimilated, and Section 2.4 presents the data-assimilation system used in this study. Lastly, Section 2.4.5 defines the
125 different simulation experiments performed.

126 **2.1 Study sites**

127 This study focused on five experimental sites across the U.S. Midwest with in-situ observations of soil moisture, crop
128 yield, nitrate load, and tile drainage flow for 19 years between 2011 and 2019. Site IL was the Energy Farm, a well-
129 monitored experimental site in central Illinois that was the focus of the development and initial evaluation of the
130 employed data-assimilation system (Kivi et al., 2022). Site IN, MN, OH, and SD were available through the
131 Transforming Drainage (TD) project (Chighladze et al., 2021). The TD project database is publicly-available and
132 contains high-quality data from 39 tile-drained research sites with data spanning over 200+ site-years. The available
133 observations include data on tile drainage, yield, water table, water quality, and soil characteristics, among many
134 others. Though numerous sites were available as part of the project, the experimental design and data available for
135 each site-year varies widely in the database. For consistency, this work required that each site-year include a plot with:
136 (1) a free tile drainage system, (2) available NO₃ load and tile flow data at the plot level, (3) available in situ soil
137 moisture observations, (4) maize or soybean crops, and (5) a rain-fed system. We identified only 17 site-years across
138 five sites in the database which satisfied all these criteria.

139 To properly set up the APSIM model for each of the five sites, we included all available site information on each year,
140 cropping system, residue type, planting and harvesting details, tillage practices, and fertilizer applications as constants

141 in the simulations. Following updated information available through Moore et al. (2021), the IL site includes tillage
142 practices in the model set-up and increased nitrogen (N) fertilizer from 64.6 kg N/ha, to 202 kg N/ha. Detailed
143 information on the plot and management information for all five sites are included in the Supplementary Materials
144 (Table A1). Study sites will be referred to by their given study IDs in Figure 1.

145 **2.2 Observation data**

146 *In situ soil moisture*

147 Across the study site-years, sub-daily soil moisture (SM) observations were collected at various soil depths between
148 10 and 105 cm using soil sensors; the measured depths and sensor type varied by site. All observations are available
149 in units of volumetric water fraction (VFW; mm/mm). For the 4 TD sites, SM observations were only available as
150 daily averages. For consistency, SM observations at IL (available at 15-minute intervals) were aggregated to daily
151 averages when at least 40 15-minute observations were available. Observations from the winter months (December-
152 March) were excluded due to the influence of freezing soils. Across all site-years, in situ SM assimilation was
153 performed with available observations for the 10- and 20-cm soil depths, which hereinafter will be referred to as SM3
154 and SM4, respectively. All other available SM observations for deeper soil layers were used to evaluate model root-
155 zone SM estimates. SM observations were paired with an APSIM soil layer based on the recorded sensor depth and
156 the site soil profile. In the case that more than one observation was available for a given APSIM soil layer, the average
157 SM was computed for each day and layer with the assumption of uniform SM in the layer.

158

159 *Harvested maize and soybean yields*

160 Data on harvested yield for the TD sites were available for each site-year with 1-3 replicated measurements. These
161 replicated observations were averaged and converted from grain at standard moisture content (i.e., 15.5% for maize
162 and 13% for soybean) to dry-grain weight for best comparison with the APSIM model output. Observations for IL
163 were already recorded as dry-grain weights and given in units of kg/ha. Across 12 maize site-years, observed yields
164 ranged from 6.51 to 13 Mg/ha with an average yield of 9.93 Mg/ha. The 7 soybean site-years had observed yields
165 ranging from 2.78 to 4.15 Mg/ha with an average yield of 3.50 Mg/ha.

166

167 *Remotely sensed Normalized Difference Vegetation Index (NDVI)*

168 The normalized difference vegetation index (NDVI) can be used to quantify vegetation greenness and reasonably track
169 the phenological development of crops (Gao and Zhang, 2021). In this study, NDVI observations from Landsat
170 between 2011 and 2019 were used to evaluate APSIM's performance in predicting crop phenology for each site-year.
171 NDVI time series were extracted at each site location from Landsat 7 and 8 remote sensing imagery courtesy of the
172 U.S. Geological Survey via Google Earth Engine and derived from the red (RED) and near-infrared (NIR) spectral
173 bands using the following equation:

174

$$NDVI = \frac{NIR - RED}{NIR + RED} \quad (1)$$

175

176 *In situ measurements of tile drainage and nitrate load*

177 Daily observations of tile drainage flow (mm) and NO₃ load (kg NO₃-N ha⁻¹) were available for all 19 site-years.
178 Any missing daily drainage values for the TD sites had been imputed previously and used to approximate missing
179 values of daily NO₃ load, as described by Helmers et al. (2022). Methods and instrumentation used to collect and
180 process the TD sites and IL data are presented by Helmers et al. (2022) and Kivi et al. (2022), respectively. In this
181 study, daily values for tile drainage flow and NO₃ load were summed to annual values for comparison with model
182 output. For the purposes of this analysis, we assumed any day with NA tile drainage flow values in the data had no
183 drainage and no NO₃ loss.

184 **2.3 Remote sensing soil moisture**

185 To assess the performance of SM data assimilation with satellite-based observations, we included 4 RS data products
186 that span different temporal and spatial resolutions (Table 1). These observations were extracted at the point level for
187 the study sites and serve to represent the first 5 cm of the soil profile or surface SM. Observations from the winter
188 months (i.e., December-March) were removed to avoid issues with snow cover and freezing soils. The product IDs
189 provided in Table 1 will be used to identify each data product.

190

191 *ESA-CCI*

192 The RS dataset with the coarsest spatial resolution in this study was the ESA-CCI SM product. Each year, the European
193 Space Agency Climate Change Initiative (ESA CCI) algorithmically merges information from 3 active (e.g., ASCAT
194 A/B) and 10 passive (e.g., SSM/I, AMSR-E, SMOS, SMAP) microwave sensors to estimate daily surface SM globally
195 for over 40 years. Dorigo et al. (2017) provide complete documentation on how these data products are produced.
196 Here we used the combined product (version v06.1), which includes daily uncertainty estimates. Several past studies
197 have assimilated this data product into process-based models with varying levels of success (e.g., Zhou et al., 2016;
198 Liu et al., 2017; Liu et al., 2018; Naz et al. 2019).

199

200 *SMAP-HydroBlocks*

201 The SMAP-HydroBlocks surface SM dataset has the highest spatial resolution in this study. It was introduced by
202 Vergopolan et al. (2021b) by combining the HydroBlocks land surface model, a Tau-Omega radiative transfer model,
203 machine learning, in situ SM observations, and SMAP remotely sensed satellite observations to estimate surface SM
204 with 30-meter resolution across the contiguous United States. In specific, the Hydroblocks model was coupled with a
205 Tau-Omega radiative transfer model (HydroBlocks-RTM) and used to simulate SM, soil temperature, and brightness
206 temperature at a 3-hour, 30-meter resolution. Brightness temperature estimates from NASA's Soil Moisture Active
207 Passive (SMAP) mission were then merged with the HydroBlocks-RTM estimates using a spatial cluster-based
208 Bayesian merging scheme (Vergopolan et al., 2020). Using the inverse HydroBlocks-RTM, SM was estimated at
209 SMAP overpass time at 30-m spatial resolution. Vergopolan et al. (2021b) reported an RMSE of 0.07 mm³/mm³ after
210 comparing SMAP-Hydroblocks estimates to in situ observations from 233 independent experimental sites. This study

211 is the first to assimilate SMAP-HydroBlocks SM estimates into a crop model. SM morning and afternoon retrievals
212 were aggregated to a daily resolution, and site-level estimates were computed as the mean value of any data point
213 within 0.0005° of the given site location. The uncertainty estimate for each observation was calculated based on the
214 spatial variability of selected data points for that time step and the reported standard error (SE = 0.07 mm³/mm³) as :
215

$$Var(Y_{s,t}) = Var(y_t) + SE^2 \quad (2)$$

216
217 where, for site s at the tth available time step, Y represents the site-level SM estimate, and y presents SM estimates
218 within 0.0005° of the site location.

219
220 SMAP-Sentinel1
221 The SMAP-Sentinel1 SM product was produced by merging information collected by the SMAP L-band radiometer
222 and the Copernicus Project Sentinel-1 C-band radar. After the malfunction of the SMAP radar in 2015, Sentinel-1
223 active microwave data were used with passive microwave sensor information from the still-operating SMAP
224 radiometer to estimate surface SM content globally using the active-passive algorithm. Although the merged product
225 increased the revisit interval from 3 to 12 days, it enabled retrievals at two different spatial resolutions (i.e., 1 km and
226 3 km; Lievens et al., 2017). Upon comparing the estimates with in situ SM measurements, Das et al. (2019) reported
227 RMSE for SMAP-Sentinel1 SM estimates as roughly 0.05 m³/m³. In this study, this value was applied as the standard
228 error for SM estimates at both spatial resolutions and at all available time steps. Retrievals were available for all TD
229 site-years but were unavailable for IL for unknown reasons.

230 **2.4 Data-assimilation system**

231 This study uses the data-assimilation system developed and evaluated in Kivi et al. (2022). The original system
232 leveraged the pSIMS platform, APSIM crop model, Ensemble Kalman Filter (EnKF), and an algorithm presented by
233 Miyoshi et al. (2013) to estimate and propagate uncertainties, perform sequential data assimilation, and generate daily
234 agricultural forecasts at the field scale. The workflow is illustrated in Figure 2. APSIM management variables that
235 were known include planting and harvest dates, fertilizer amount, type, and timing, tillage type, depth, and timing,
236 crop type, row spacing, sowing density, and, if available, planting depth.

237 **2.4.1 Model parameter priors**

238 Initial soil water, cultivar, and residue weight were randomized across model ensembles for each site to incorporate
239 uncertainty around initial conditions. If unavailable in the management data, planting depth was also randomized and
240 drawn from different prior distributions for each crop. These distributions represented reasonable planting depth
241 ranges for the two crops in the Midwest, as described in extension websites produced by the University of Missouri
242 (Luce, 2016) and Michigan State University (Staton, 2012). Using a uniform prior distribution, planting depths ranged
243 from 1.5 to 2.5 inches for maize and 1 to 2 inches for soybean.

244 Prior distributions were also set to incorporate uncertainty around cultivar. For maize, nine cultivar parameters were
245 ensembled, including the six cultivar parameters (i.e., `tt_flower_to_maturity`, `tt_flower_to_start_grain`,
246 `tt_maturity_to_ripe`, `tt_emerg_to_endjuv`, `head_grain_no_max`, `grain_gth_rate`). The other three parameters (i.e.,
247 `largestLeafParams1`, `leaf_init_rate`, `leaf_app_rate1`) were drawn from Dokoohaki et al. (2022b), who identified maize
248 cultivar parameters that were influential for estimates of leaf area index (LAI) in the APSIM Maize module and
249 optimized their value distributions using a hierarchical Bayesian optimization approach across the U.S. Midwest.
250 Table A.2 gives more detailed information on all randomized parameters and their prior distributions. We completed
251 a preliminary assessment of the Maize module at each of the study sites and found that, under the given parameter
252 value ranges, APSIM was capable of appropriately simulating the phenological development and grain yield for maize
253 at each site.

254 The selection of soybean cultivars for each site was determined using a semi-systematic approach. First, a range of
255 maturity groups was determined for each site based on a study by Mourtzinis and Conley (2017), which delineated
256 soybean maturity groups across the U.S. We defined the upper and lower maturity group bounds for each site using
257 the bounding zone contour lines for each site location in Figure 4 of Mourtzinis and Conley (2017). Then, initial
258 APSIM simulations were performed for each site using all APSIM-defined soybean cultivars falling within the
259 prescribed maturity group range. The model results were compared to the observed soybean yields at each site, and
260 the best-performing maturity group (MG) for each site was determined. The final range for each site was
261 approximately $MG \pm 0.5$. In each ensemble, the cultivar for each crop at each site was assumed to be constant across
262 all site-years.

263 **2.4.2 Weather and soil model drivers**

264 To incorporate uncertainty around soil and weather into our simulations, a Monte Carlo sampling approach was used
265 to randomly assign ensembles of weather and soil drivers to model ensembles. For each study site, ten weather
266 ensembles from the ERA5 reanalysis data product were employed to characterize solar radiation, maximum air
267 temperature, minimum air temperature, precipitation, and wind speed at the daily resolution and at each site location.
268 ERA5 is a global gridded reanalysis data product from the European Centre for Medium-Range Weather Forecasts
269 (ECMWF), which characterizes the weather state variables at hourly time steps with associated uncertainties
270 (Hersbach et al., 2020). In addition, 25 soil ensembles were generated from the SoilGrids global gridded soil database
271 (Hengl et al., 2014) for each site location. These ensembles cover 30 soil properties (including available water lower
272 limit, bulk density, drained upper limit, organic carbon, soil class, and pH) and were created by sampling from each
273 soil parameter mean and uncertainty values available in the SoilGrids dataset.

274 **2.4.3 PROSAIL model**

275 Since APSIM does not currently estimate NDVI, APSIM was coupled with the PROSAIL model described in
276 Dokoohaki et al. (2022b) to estimate daily NDVI values and enable the appropriate evaluation of the model's
277 simulation of crop phenology at the study sites. The PROSAIL model is a radiative transfer tool that combines
278 PROSPECT, a leaf optical properties model, and SAIL, a canopy bidirectional reflectance model, to estimate spectral
279 reflectance for a given vegetative area based on soil and plant/canopy properties (Jacquemoud et al., 2009). In this

280 study, APSIM's daily forecasts of soil and plant variables were transformed and used as inputs into the PROSAIL
 281 model to compute the spectral reflectance for each ensemble. Then, for each day and ensemble, the estimated spectral
 282 information was used to estimate NDVI using the vegetation index function within the hsdar R library (Lehnert et al.,
 283 2019). Further details on the coupling protocols can be found in Dokoohaki et al., (2022b).

284

285 **2.4.4 Ensemble Kalman filter with the Miyoshi algorithm**

286 The data-assimilation system(which we will call EnKF-Miyoshi hereinafter) employs the ensemble Kalman filter
 287 (EnKF) to assimilate SM observations into the APSIM model. The EnKF merges information from the model
 288 ensemble forecast distribution and observations (with associated uncertainty) at each time step to optimally estimate
 289 the state of the system (Evensen, 2003). The system also leverages the Miyoshi algorithm in series with the EnKF to
 290 improve estimates of the two system uncertainty matrices (i.e., Pf and R) and improve filter performance. Based on
 291 diagnostic innovation statistics, the Miyoshi algorithm estimates a forecast inflation scalar (Δ) and observation
 292 uncertainty (R) at each analysis time step. At time step t with available data, the system follows the following steps:

- 293 1. The mean (X_f,t) and the variance-covariance matrix (P_f,t) of the model forecast ensemble are computed to
 294 define the forecast distribution, which is assumed to follow a Normal distribution.
- 295 2. The observed distribution (Y_t) is also assumed to be Normal with mean y_t and variance-covariance matrix
 296 R_t , where $R_t = R^*$ from the previous analysis time step or $R_1 = \Sigma$. Σ is a diagonal matrix that assumes 10%
 297 standard error for each observed state variable.
- 298 3. The Kalman Gain (K) is computed as follows, where $\Delta_t = \Delta^*$ or $\Delta_1 = I$ (I is the identity matrix) and H is the
 299 observation operator:

$$K_t = \Delta_t P_{f,t} H^T (R_t + H \Delta_t P_{f,t} H^T)^{-1} \quad (3)$$

300

- 301 4. The analysis distribution, which assumes a Normal distribution, is determined with mean ($X_{a,t}$) and
 302 variance-covariance matrix ($P_{a,t}$).

$$\begin{aligned} X_{a,t} &= X_{f,t} + K_t (Y_t - H X_{f,t}) \\ P_{a,t} &= (I - K_t H) P_{f,t} \end{aligned} \quad (4)$$

303

- 304 5. The model ensemble is updated at each time step according to the analysis distribution based on each
 305 ensemble's likelihood within the forecast distribution.
- 306 6. Δ^* and R^* are recomputed using the following series of equations, where d_{o-a} and d_{o-f} represent the
 307 observation-analysis and observation-forecast innovations for the current time step, respectively, E denotes
 308 the expectation operator, and ρ is a user-defined weight given to the new estimate. A lower bound of 1 is
 309 imposed on each entry in Δ_{est} and only the diagonal entries of R_{est} are maintained.

$$\begin{aligned} E(d_{o-a} d_{o-f}^T) &= R_{est} \\ \Delta_{est} &= \frac{d_{o-f}^T d_{o-f} - R_{est}}{H \Delta_t P_{f,t} H^T} \end{aligned} \quad (5)$$

$$R^* = (\rho)R_{est} + (1 - \rho)R_t$$

$$\Delta^* = (\rho)\Delta_{est} + (1 - \rho)\Delta_t$$

310

311 **2.4.5 Generalized ensemble filter**

312 However, the EnKF-Miyoshi workflow as established cannot robustly handle observation operators (H) that change
 313 dimensions over time. However, to reduce information loss within the system, H must be able to adapt according to
 314 the number of observations available. To increase flexibility in system configuration, an alternative sequential data
 315 assimilation approach was tested in this work to replace the EnKF-Miyoshi method. The new method, hereinafter
 316 called the Generalized Ensemble Filter (GEF), comprises a fully numerical Bayesian approach to estimating the
 317 analysis distribution and an inflation scalar. The model resembles the approach presented by Raiho et al. (2020) and
 318 Dokoohaki et al., (2022a) and has the following form at analysis time step t:

$$Q \sim U(0.001, 5)$$

$$X_A \sim N(X_{f,t}, P_{f,t} + (Q - 1) * \text{diag}(P_{f,t})) \quad (6)$$

$$Y_t \sim N(X_A, R_t)$$

319

320 where Q is the estimated forecast inflation scalar and XA is a drawn sample from the analysis distribution. The
 321 estimation of XA and Q was completed using a Markov Chain Monte Carlo (MCMC) approach by leveraging the
 322 nimble R library (de Valpine et al., 2017). Though not explored in this study, this approach also allows for the
 323 definition and estimation of more complex relationships between observations and model forecasts (e.g., nonlinear
 324 observation operators).

325 In this study, the GEF was applied over the EnKF-Miyoshi workflow when (1) more than one observation was
 326 assimilated for a single state variable at a given time step or (2) the number of available observations varied throughout
 327 a simulation (i.e., changing H). Conversely, the GEF approach was ineffective for cases where only one observation
 328 was available at a given time step, as the MCMC algorithm did not converge due to limited data. The EnKF-Miyoshi
 329 was applied in these settings.

330

331 **2.4.6 Simulation schemes**

332 All simulations in this study were performed with 100 ensembles and with a 4-month initialization period starting on
 333 1 Jan of the first year at each site. There were nine different simulations performed for each site in this study which
 334 varied in terms of observations assimilated and assimilation method applied. First, two “baseline” runs were completed
 335 across all 19 site-years to establish system performance benchmarks. As a lower bound on performance, a free model
 336 simulation was performed with no data assimilation. SM sensor observations were also assimilated into the model to
 337 represent a reasonable benchmark data assimilation setting. Next, two groups of runs were performed to test the
 338 assimilation of RS SM data products: “individual” and “additive” runs. In the “individual” runs, all 4 RS data products
 339 were assimilated independently within the system. These runs were performed to compare the value of different RS
 340 data products directly. Then, in the “additive” runs, observations from multiple RS data products were jointly
 341 assimilated into the system following an additive approach. The first iteration included only ESA observations, and

342 each subsequent iteration added another data product until all 4 data products were included (i.e., ALL). Data products
 343 were added in succession based on availability, such that the first data product tested had the highest average number
 344 of observations per year. By sequentially adding new data products, the additional impact of each RS data product
 345 could be evaluated. To allow for the application of the GEF in runs with more than one data product, a minimum of 2
 346 observations per day were required for the “additive runs” to ensure the convergence of the MCMC algorithm. For all
 347 runs where RS data were assimilated, only site-years after 2014 were investigated due to the limited temporal extent
 348 of RS data products.

349 2.5 System evaluation

350 This study applied the year-average ensemble weighting strategy, as presented in Kivi et al. (2022), to leverage all
 351 available information from the simulations and evaluate the results more accurately. In each site-year simulation, daily
 352 weights were assigned to each ensemble as the likelihood of producing the daily estimate given the analysis
 353 distribution, and ensemble weights were normalized across the model ensemble for each day. Finally, the average
 354 annual weight for each ensemble was computed for each site-year. The application of annual weights in the analysis
 355 was the most robust for evaluating yearly estimates (e.g., yield, cumulative NO₃ load, cumulative tile drainage).

356 To evaluate the accuracy and precision of model forecasts for each site-year simulation, we utilized the root mean
 357 squared error (RMSE), spectral norm, and weighted variance. RMSE was calculated for each run to quantify changes
 358 in accuracy between runs, while the spectral norm and weighted variance were employed to quantify changes in
 359 precision. Additionally, to help standardize accuracy measures across site-years, a normalized RMSE (nRMSE) was
 360 calculated as :

$$nRMSE (\%) = 100 * \frac{RMSE}{\bar{Y}} \quad (7)$$

361 where \bar{Y} is the average observed value. Changes in accuracy and precision between the free model and SDA were
 362 quantified by computing the relative change in each metric for the two runs. For example, for calculating the change
 363 in RMSE, we computed :

$$\Delta RMSE = \frac{RMSE_{SDA} - RMSE_{FREE}}{RMSE_{FREE}} \quad (8)$$

364 The coefficient of determination (R²) was used to compare model performance for each state variable more effectively
 365 across all observed time points. It was calculated as :

$$R^2 = 1 - \frac{\sum_{t=1}^T (Y_t - \bar{X}_t)^2}{\sum_{t=1}^T (Y_t - \bar{X}_t)^2 + \sum_{t=1}^T (\bar{X}_t - \bar{Y})^2} \quad (9)$$

366 where Y_t is the observed value at the t th observed time step and \bar{X}_t is the simulated weighted mean at the t th observed
 367 time step. All observations ($n = T$) from all site-years were included in this calculation. Separate R² values were
 368 computed for the Free and SDA results. Weighted mean estimates were computed using annual ensemble weights. In
 369 addition spectral norm, and weighted variance were estimated as follows:

$$\|Pf\|_2 = \sqrt{\text{Maximum Eigenvalue of } P_f^H P_f} \quad (10)$$

370 Where P_f^H represents the conjugate transpose of P_f .

371

$$Variance = \frac{\sum_{i=1}^N (w_i - (\bar{x}w))^2}{\frac{(N-1)}{N}} \quad (11)$$

372 Where N is the number of ensembles, w_i is the average weight of the i th ensemble, $\bar{x}w$ is the weighted mean across
373 ensembles, and x_i is the forecasted value of the i th ensemble.

374 To identify and quantify relationships between variables, one of two correlation statistics was employed depending
375 on the sample size of the data. When comparing data with a sufficiently large sample size ($n > 30$), the Pearson
376 correlation coefficient (r) was calculated to determine the direction and strength of the linear relationship between two
377 variables.

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} * \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}} \quad (12)$$

378 When comparing data at the site-level ($n \leq 19$), the Spearman rank-order correlation coefficient (r_s) was applied,
379 which is a nonparametric measure of the strength and direction of the monotonic relationship between two variables.
380 Though the sample size in this case is still too small for proper application, the Spearman coefficient was applied as
381 its assumptions are less strict than the Pearson coefficient. It is calculated as :

$$r_s = 1 - \frac{6 \sum_{i=1}^n d_i^2}{n(n^2 - 1)} \quad (13)$$

382 where the d_i is the distance between the two ranks of the i th complete pair (i.e., x_i and y_i). For both coefficients, a test
383 for association between paired samples was used to determine significance.

384 3. Results

385 The results in section 3.1 evaluate the forecast accuracy and precision of in situ SM SDA in comparison to
386 the free model. Section 3.2 investigates changes in forecast accuracy and precision when assimilating SM RS
387 observations. The individual runs are assessed with regard to their data characteristics (i.e., retrieval interval and single
388 vs. multi-sensor development), and the additive runs are evaluated in succession to determine the relative impact of
389 added observations. Lastly, the impact of RS-based SDA on the forecast accuracy and precision of state variables is
390 investigated and compared.

391

392 3.1 Assimilation of in situ soil moisture

393 3.1.1 Impact on soil moisture

394 Across all assimilation time steps, the free model tended to overpredict SM within the two assimilation layers
395 (Fig. 3). Therefore, the adjustment in the SDA analysis step typically reduced the total amount of water in the soil
396 profile. In SM forecasts for the two assimilation layers (i.e., SM3 and SM4), SDA performed as well or better than
397 the free model in accuracy across all site-years. The median change in RMSE due to SDA was -17% and -28% for

398 SM3 and SM4, respectively (Fig. 4). Average forecast precision for SM3 and SM4 was also increased with SDA in
399 84% of cases and by 23% on average.

400 The three site-years where precision was not increased in SDA include OH in 2013 and 2014 and MN in
401 2013. Interestingly, these site-years were among those with the most remarkable improvement in accuracy. This
402 relationship is intuitive considering the nature of the Miyoshi algorithm, which systematically inflates model forecast
403 uncertainty at time steps when observed and forecasted SM distributions differ substantially. At the cost of reduced
404 forecast precision, such inflation allows for the filter to pull the model forecast toward the observed distribution and
405 improve accuracy in future predictions.

406 SDA's constraint of SM3 and SM4 also led to the indirect constraint of SM in deeper soil profile layers. Across all
407 site-years with available data, the median change in RMSE for SDA estimates of SM5, SM6, and SM7 was -14%, -
408 8%, and -14%, respectively. In terms of precision, SDA had an overall positive impact on lower layer SM estimates.
409 The average change in weighted variance was -16%, -6%, and -20% for estimates of SM5, SM6, and SM7,
410 respectively.

411 **3.1.2. Impact on NDVI and crop yield**

412 Overall, in comparison to the free model, SDA improved yield estimates by explaining 17.7% more variation
413 in observed yield values and improving yield accuracy in 63% of site-years (Table 3). SDA accuracy was most
414 effective in site-years facing greater water stress. In those cases where yield estimates were improved, SDA often
415 increased available soil water at critical points in crop development, reducing crop soil water deficit factors and
416 increasing yield compared to the free model (Fig. A1). The most evident example of SDA yield improvement is IN in
417 2012, where the free model estimated complete maize crop failure (i.e., no grain yield) due to leaf senescence in mid-
418 July, but SDA estimated a harvestable crop due to increased soil water in the early season (Fig. 5). However, SDA's
419 impact on yield precision was inconsistent; roughly 53% of site-years saw reduced precision in yield estimates.

420 Overall, the free model accurately captured the phenological development of the cropping systems simulated
421 in this study, as demonstrated by the good agreement between observed and simulated NDVI (Fig. A2). SDA's impact
422 on NDVI accuracy was similar to its impact on yield accuracy, such that it typically either increased accuracy due to
423 lessened water stress or did not substantially affect the model performance. A comparison of R2 values demonstrates
424 that SDA helped to explain 4.8% more variation in observed NDVI values compared to the free model. Intuitively,
425 the site-years with the greatest jumps in NDVI accuracy also usually showed great improvement in yield accuracy,
426 highlighting a well-defined physiological relationship between vegetation and grain yield in APSIM's Maize and Plant
427 modules. SDA's impact on NDVI precision was inconsistent, such that 63% of site-years reduced precision in
428 estimates.

429 **3.1.3 Impact on tile drainage and nitrate load**

430 Across the 19 site-years, the free model and SDA showed overall poor performance in estimating annual
431 drainage with nRMSE values ranging from 18-215% with a median value of 54.3% for SDA and from 20-250% in
432 the free model with a median value of 52.4% . In the site-years with the lowest accuracy, APSIM often overpredicted
433 drainage in both the free model and SDA. However, these cases of considerable overestimation in drainage were also
434 among those site-years that were most improved by SDA. 8 of the 11 site-years where SDA improved estimates of

435 annual drainage were cases where the free model overestimated tile flow. In these scenarios, SDA functioned to
436 remove available water from the soil profile and correctly lower the amount of water lost from the system. In the
437 remaining site-years where SDA did not improve drainage accuracy, SDA increased RMSE values by 32% on average.
438 SDA's impact on precision for annual drainage estimates was highly variable. 63% of site-years saw improvement in
439 precision, but four site-years saw an immense reduction in precision (i.e., between 107-146% reduction).
440 APSIM also struggled to accurately estimate the annual NO₃ load for the tested site-years in this study (Fig. A3). For
441 the free model, nRMSE values ranged from 23-681% with a median value of 83.7% and, for SDA, nRMSE values
442 ranged from 17-833% with a median value of 86.9%. Considering the SDA constraint, estimates of annual NO₃ load
443 were the most poorly constrained in terms of accuracy and precision. SDA's impact on precision was split, increasing
444 precision in 53% of site-years. Accuracy was improved for just 32% of site-years. Among those six site-years where
445 SDA increased NO₃ load accuracy, SDA typically reduced estimates compared to the free model. Improved sites were
446 often maize years characterized by high input winter precipitation (Jan-Apr). No clear environmental nor agronomic
447 trend was identified among those 11 site-years where SDA reduced accuracy.

448 **3.2 Assimilation of remote sensing soil moisture products**

449 **3.2.1 Individual assimilation runs**

450 As expected, the individual influence of each RS data product was heavily dependent on its multi- or single-
451 sensor design and temporal availability. ESA, the most widely available data product, had the greatest impact on both
452 assimilation and downstream state variables. In contrast, assimilation with 1KM and 3KM imposed only slight
453 changes in estimates when compared to the free model. However, ESA did not always lead to improvements in model
454 performance. As demonstrated in Figure 6, ESA results were more variable across site-years in terms of the accuracy
455 of state variable estimates, in some cases leading to great improvement and, in other cases, leading to reduced
456 performance. ESA reduced accuracy in predicting SM3 and SM4 in most site-years (i.e., 80-90%) but was the most
457 effective in improving accuracy in estimates of annual yield, SM6, and SM7. ESA also outperformed the other 3 RS
458 data products in constraining forecast precision for all state variables, improving precision in 70-100% of site-years.
459 Importantly, it showed the greatest reduction in the spectral norm of the SM covariance matrix when compared to the
460 free model, indicating the best constraint of SM precision across the entire profile .

461 Alternatively, the assimilation of SMAP-HB, another temporally frequent RS data product, demonstrated
462 more conservative performance than ESA across state variables. For almost all state variables,
463 it also performed similarly or better than the free model. However, any improvements (or reductions) in forecast
464 accuracy were more moderate than observed with ESA. For example, accuracy in yield estimates was improved more
465 consistently with SMAP-HB (90%) compared to ESA (70%), but the maximum improvement in a tested site-year was
466 a 53% accuracy increase compared to a 95% increase with ESA. This trend in the results highlights an important trade-
467 off when assimilating more certain observations (i.e., ESA-CCI) at a coarse spatial resolution over less certain
468 observations at high spatial resolution (i.e., SMAP-HB) when both data products have unknown biases. In terms of
469 forecast precision, SMAP-HB was overall quite effective in constraining state variable predictions, especially when
470 compared to 1KM and 3KM. However, SMAP-HB underperformed compared to ESA in this regard. 1KM and 3KM

471 both underperformed in accuracy constraint when compared to ESA and SMAP-HB, showing little to no change in
472 RMSE compared to the free model.

473 Considering the four individual runs, more frequent assimilation time steps also led to a more robust
474 performance of the EnKF-Miyoshi workflow. Filter divergence (i.e., when the observed mean falls outside of the 95%
475 credibility interval of the analysis distribution) occurred at 52% and 59% of analysis time steps for 1KM and 3KM,
476 respectively, but occurred at only 44% and 30% of analysis time steps for SMAP-HB and ESA, respectively. For
477 estimates of observation uncertainty, the Miyoshi algorithm predicted greater uncertainty for most RS observations
478 than what is reported in the literature. The average standard error in ESA observations was reported to be 0.02 ± 0.004
479 mm^3/mm^3 but estimated in this study as $0.05 \pm 0.01 \text{ mm}^3/\text{mm}^3$. Standard errors in 1KM and 3KM estimates were
480 reported as $0.05 \text{ m}^3/\text{m}^3$ but estimated by the system to be $0.07 \pm 0.02 \text{ mm}^3/\text{mm}^3$ and $0.06 \pm 0.01 \text{ mm}^3/\text{mm}^3$,
481 respectively. Miyoshi estimated similar uncertainty values for SMAP-HB observations as reported in the literature
482 (i.e., $0.07 \pm 0.02 \text{ mm}^3/\text{mm}^3$).

483 **3.2.2 Additive runs**

484 The baseline run for the additive RS-SDA runs was ESA, which demonstrated inconsistent constraint of
485 forecast accuracy and strong constraint of forecast precision. The second most available data product, SMAP-HB, was
486 the next RS data product added to the system. New SMAP-HB observations, on average, imposed a -0.012 mm/mm
487 change in μ_a and a -0.0003 change in Pa for SM1 estimates. For downstream forecast accuracy, the addition of SMAP-
488 HB led to improved and/or more consistent constraints for all state variables except SM7 (Fig. 6). At times, the added
489 information from SMAP-HB dampened the benefit of SDA, reducing accuracy improvement. For forecast precision,
490 +SMAP-HB precision was overall better than the free model but with reduced performance compared to ESA.

491 The subsequent additions of the sparser 1KM and 3KM RS data products were less impactful than the
492 addition of SMAP-HB. New 1KM observations imposed an average -0.0004 mm/mm change in μ_a , and, later, new
493 3KM observations imposed an average -0.0003 mm/mm change in μ_a . These changes were less than 4% of the change
494 imposed by the initial addition of SMAP-HB. Neither additional data product produced a notable average change in
495 Pa. Following these minimal changes in SM1, there was also little change in forecast accuracy and precision for
496 downstream state variables in +1KM and ALL when compared to +SMAP-HB (Fig. 6). Adding 1KM observations to
497 +SMAP-HB did hold some benefit for accuracy and precision in SM3 and SM4, while the effect of the 3KM
498 observations was almost negligible or, even at times, harmful to system performance.

499 **3.2.3 Impact on APSIM model estimates**

500 When considering the impact of surface SM data assimilation on downstream model variables, we focus on
501 results where all available RS observations were assimilated for each site. Hereinafter, we refer to the compilation of
502 these runs across the five sites as RS-SDA.

503 Overall, RS-SDA had minor impacts on the soil water profile relative to the free model. Figure 7 demonstrates
504 differences between the free model and RS-SDA in SM1 estimates. For several site-years, RS-SDA estimated
505 significantly higher SM1 values in the early growing season (i.e., May-Jun). In the late season and fall, RS-SDA often
506 estimated lower SM1 values. The impact of these SM1 changes on lower layer SM values seemed to decrease with
507 depth, such that differences between the free model and RS-SDA mean estimates were more subtle in deeper layers.

508 This reduced impact on lower layers is also, in part, a reflection of the increasing total soil water volume represented
509 by soil layers down through the profile (see Table 3 for layer depths). Nonetheless, any differences in SM estimates
510 did not lead to notable changes in accuracy for any SM layer (Table 3). Notable changes were visible in the soil water
511 deficit factors for several growing seasons, such that RS-SDA led to reduced water stress for the growing crop. We
512 speculate that this results from increased available soil water in the root zone during initial periods of crop water
513 uptake (i.e., June). Forecast precision for soil water-related estimates also did not change substantially with
514 assimilation. For SM1 estimates, assimilation substantially reduced variability across site-years (Fig. 7). In many
515 cases, this constraint in the surface soil layer did not propagate into significant changes for precision in lower layer
516 estimates (Fig. 7). However, on average, precision was improved rather than reduced with assimilation, with the most
517 significant downstream constraint in the soil layers closest to the surface.

518 RS-SDA demonstrated partial constraint of aboveground estimates. Considering the R2 values reported in
519 Table 3, RS-SDA explained roughly 4% more variation in yield observations than the free model. All site-years except
520 OH 2015 demonstrated increased yield accuracy, and 60% of sites demonstrated increased yield precision with RS-
521 SDA. Based on these results, there is evidence that surface SM data assimilation can constrain, to some extent,
522 estimates of annual yield. Compared to its effect on yield estimates, RS-SDA was less impactful in its constraint of
523 NDVI. However, since the free model could reasonably predict NDVI ($R^2 = 0.69$), there was less potential for
524 improvement with SM assimilation. 60% of site-years had increased accuracy, and 70% had increased precision for
525 NDVI estimates following SDA.

526 **4. Discussion**

527 **4.1 Sensitivity of APSIM model estimates to in situ soil moisture**

528 In this study, the extent to which in situ SM data assimilation affected APSIM model predictions depended
529 on each state variable's sensitivity to the assimilated state variable (i.e., soil moisture). Deeper layer SM estimates—
530 the most sensitive state variables to SM3 and SM4—were the most strongly constrained. Figure A1 demonstrates the
531 significant linear relationship between daily changes in forecasted SM3 and SM4 due to SDA and daily changes in
532 SM estimates for all deeper soil layers. As expected with a cascading water balance model, the strength of the linear
533 relationship weakens as the vertical distance between soil layers increases. In the model, SM in each layer can
534 influence SM estimates of deeper soil layers, but only indirectly through its influence on the SM in the layer
535 immediately below it. Therefore, the influence of the assimilation layers is reduced by each subsequent SM process
536 down through the soil profile and is weakest in the final soil layer (SM7). Nevertheless, the constraint of SM7 was
537 still quite strong in SDA. By assimilating SM for two upper soil layers, the accuracy of SM estimates improved
538 immensely by simply leveraging the pre-existing model structure (compare to Liu et al., 2017).

539 Crop yield showed the next strongest constraint in SDA. However, as noted in previous studies, its sensitivity
540 to SM SDA was conditional (Lu et al., 2021; Kivi et al., 2022). While changes in SM affected lower layer SM at all
541 analysis time steps, crop yield was only affected when the changes impacted crop water stress. Daily crop water uptake
542 is determined in APSIM as the minimum of crop water demand and soil water supply. Therefore, SDA could only

543 influence crop yield when the soil water adjustment pushed the water supply above or below the demand threshold.
544 For this reason, greater SDA improvement was found in crop yield estimates during water-stressed site-years. Other
545 pathways through which SM can impact crop yield in APSIM, like soil N cycling, did not play a strong role in this
546 study.

547 The impact of SM SDA on APSIM drainage estimates can also be beneficial given certain conditions. As
548 shown in the results, drainage was affected by SM3 and SM4 through 2 pathways: (1) changes in total soil water with
549 assimilation adjustment and (2) changes in crop water uptake due to changes in crop water stress. The role of each of
550 these pathways varied over the year, such that the presence of a growing crop and root system weakened the sensitivity
551 of drainage estimates to changes in the assimilation layers. To quantify this change in sensitivity, we divided daily
552 model forecasts into two categories: with crop water uptake (June-Sept) and without crop water uptake. Then, the
553 relationship between changes in SM3 and SM4 and changes in drainage was analyzed separately for each group. There
554 was no significant linear relationship when looking at SM3 changes in either case. However, the linear relationship
555 between changes in SM4 and changes in daily drainage was stronger when no crop was present ($r = 0.23$, $p = 0.00$)
556 than when a crop was present ($r = 0.14$, $p = 0.00$). This is similar to Hu et al. (2008), who identified notable changes
557 in drainage dynamics during rapid crop growth compared to out-of-season dynamics in SPWS model simulations.

558 Among the state variables considered in SDA, NO₃ leaching showed the weakest and most complex
559 relationship with SM3 and SM4 in APSIM. Therefore, logically, the presented system performed most poorly in its
560 constraint of annual NO₃ leaching estimates. In APSIM, daily NO₃ leaching estimates are computed as the product
561 of two different daily values: estimated NO₃ concentration in the lowest soil layer and estimated tile drainage.
562 Therefore, in addition to its impact on drainage, SDA can affect NO₃ load estimates through (1) changes in N cycle
563 processes via SM rate factors (see Fig. 2 in Kivi et al., 2022) and (2) changes in the vertical movement of soil water
564 (and N solutes) through the soil profile. In a validation study of APSIM N processes, Sharp et al. (2011) also observed
565 inconsistent model behavior in annual leaching estimates for their experimental site in New Zealand when simulating
566 three years of a potato-rye rotation. Their final calibration of the model only improved one of the annual estimates but
567 did not constrain estimates in the other two years. In fact, many past studies have highlighted nitrate leaching estimates
568 as a broader forecasting challenge (Stewart et al., 2006; Sharp et al., 2011; van der Laan et al., 2014; Brilli et al.,
569 2017). As highlighted already in the literature, missing processes related to snowmelt (Ojeda et al., 2018), and tillage-
570 related infiltration (Malone et al., 2007; Brilli et al., 2017; Ojeda et al., 2018), or preferential flow could help to
571 improve APSIM performance. Though there is still potential for the presented system to improve nitrate leaching
572 estimates, further investigation and constraint of the APSIM N and soil water cycles will be necessary to ensure
573 consistent performance.

574 **4.2 Impact of remote sensing soil moisture data assimilation**

575 The assimilation of RS surface SM observations imposed a far weaker constraint on APSIM state variables
576 compared to the assimilation of the soil sensor observations. For example, the median reduction in SM RMSE ranged
577 from 7-27% across different layers of the soil profile with soil sensor observations, but, with RS observations in RS-
578 SDA, it ranged from roughly 1-5% (Table 3). The weakened constraint with RS-SDA was likely more than an issue

579 of observation inaccuracies. Instead, there is greater evidence to show that changes in SM1 simply had less influence
580 on downstream state variables than changes in SM3 and SM4. This is due, in part, to the increased vertical distance
581 between the surface SM layer (SM1) and other observed soil layers (i.e., SM3-7). The APSIM SoilWat module
582 operates as a cascading water balance model to estimate the movement of water and solutes between and across soil
583 layers (Dokoohaki et al., 2018). Thus, the assimilation adjustment of the SM1 estimate would not be as strongly tied
584 to lower layer estimates when using a top-down approach. Yet, surface SM data assimilation notably changed SM2
585 estimates, the SM estimates for the layer just below it. This result reflects the findings of Lu and Steele-Dunne (2019),
586 who assimilated RS surface SM observations into a surface energy balance model. They found that SDA improved
587 SM estimates in the second layer to a greater extent than in lower layers when comparing estimates to observations.
588 Since observations were not available for SM2 at the study sites, this hypothesis could not be tested within this work.

589 The two assimilation protocols (i.e., assimilation of SM1 vs. assimilation of SM3 and SM4) were also
590 markedly different in the quantity of soil water associated with their assimilation adjustments. Where soil layers 3 and
591 4 corresponded to almost 14% of the soil profile (20 cm depth), the near-surface soil layer only corresponded to about
592 3.6% of the soil profile (5 cm depth). Thus, when considering the top-down effect of SM assimilation on lower layers,
593 each adjustment with RS assimilation had just 25% of the impact of the previous system given the same adjustment
594 in volumetric soil water content. This 5-fold reduction in potential impact closely mirrors the change in RMSE
595 reduction for SM layers highlighted above (i.e., 7-27% to 1-5%). One way to overcome this limitation of surface SM
596 is to leverage the strong covariance between SM1 and SM in nearby layers (i.e., SM2) to directly nudge their values
597 within the analysis time step using, for example, an augmented state vector (e.g., Kivi et al., 2022) or exponential filter
598 approaches (e.g., Albergel et al., 2008).

599
600 RS surface SM data assimilation still demonstrated strong potential for improving APSIM forecasts within
601 this study. First, the assimilation of surface SM improved estimates of crop yield overall when compared to the free
602 model, with a median RMSE reduction of 17.2%. Past RS SM data assimilation studies had similar success in
603 improving crop yield estimates, and several attributed the improvement to increased surface SM and reduced crop
604 water stress with SM assimilation (e.g., Ines et al., 2013; Chakrabarti et al., 2014). We speculate that the model
605 performance indicate that water stress likely played an important role. Although direct observations are not available
606 for crop water uptake to test this hypothesis, we suspect RS-SDA accurately increased available soil water at critical
607 growth stages and, thus, increased crop water uptake.

608 **4.3 Comparison of remote sensing soil moisture data products**

609 The four different RS SM data products varied quite broadly in spatial resolution, varying from 30 meters to
610 0.25°. However, their individual assimilation performance seemed to be most closely tied to the temporal availability
611 of observations. ESA with a multi-sensor nature had an average, 219 observations per growing season and showed
612 the best overall constraint of forecast precision and good constraint of forecast accuracy in downstream state variables.
613 Alternatively, the 1KM and 3KM data products, which each had an average of 7 observations per growing season,
614 had almost no impact on forecast accuracy and only a slight impact on forecast precision. Although this study was not

615 designed to independently test the impact of temporal and spatial resolution on performance, it echoes the findings of
616 Lu and Steele-Dunne . (2019), who found a high temporal resolution to be far more important to assimilation
617 performance than high spatial resolution. They suspected that increased time between assimilation adjustments
618 allowed errors in model structure, inputs, and/or parameters to go unchecked for more extended periods of time,
619 thereby allowing the magnitude of simulation errors to become large and unreasonable. More frequent assimilation
620 helps mitigate the impact of such model errors and improve overall crop model predictions by correcting errors more
621 often (De Lannoy et al., 2007; Pauwels et al., 2007; Lu et al., 2021). Alternatively, in the case of low temporal
622 resolution, a recalibration-based assimilation approach or the inclusion of a bias correction method might be more
623 appropriate (De Lannoy et al., 2007; Curnel et al., 2011).

624 When comparing RS data products in this study, it is important to recognize that all data products considered
625 in this work are based, in part, on SMAP radiometer data. SMAP-HB merged SMAP brightness temperature data with
626 the HydroBlocks-RTM model, ESA includes SMAP as one of its ten passive microwave sensors, and 1KM and 3KM
627 rely on SMAP for passive microwave information within their derivation. In the first iteration, ESA contributed most
628 of the information provided by the SMAP radiometer to the model and, therefore, imposed large changes in SMI
629 estimates. Then, with each additional data product, the overall impact on the analysis distribution weakened as much
630 of the new information had already been provided to the system. It is also important to note that given that all data
631 products directly or indirectly are based SMAP, the successive assimilation of these data products can introduce error
632 covariances between the model runs and the observations. This may potentially result in an over or under estimation
633 of the uncertainty, thereby affecting the performance of the filter. Therefore, further investigation into the impact of
634 including these error covariances between the data products is deemed necessary in order to enhance the accuracy of
635 the EnKF filter.

636 The Miyoshi algorithm often estimated higher observation uncertainty (R) than the values reported in the
637 literature. This is unsurprising as RS SM data products, like most RS data products, often have poorly characterized
638 uncertainties (Peng et al., 2021). For each data product, uncertainty is typically reported as a standard error value after
639 comparing the data product to a limited set of observations. This estimate does not capture all possible sources of
640 uncertainty and cannot be easily generalized to different places or time points (Huang et al., 2019). Yet, in the additive
641 runs, these uncertainty values were applied uniformly across time and space. Future applications of the GEF scheme
642 could benefit from additional terms in the model that could capture R or the use of the Miyoshi algorithm. These
643 approaches may better estimate observation uncertainties within the system's context.

644 **5. Conclusions**

645 In the study, we assessed the extent to which soil moisture data assimilation can improve APSIM model forecasts. We
646 used a generalizable and novel data-assimilation system to assimilate RS and in situ soil moisture measurements across
647 the U.S. Midwest 19 site-years, and evaluated how direct soil moisture constraint affected downstream model
648 estimates of root-zone soil moisture, crop yield, tile flow, and nitrate leaching. Our results highlighted the capacity of
649 soil moisture data assimilation to improve model estimates of crop yield in water-limited conditions, increasing crop
650 water uptake at critical points in the growing season. Soil moisture data assimilation also improved estimates of soil

651 moisture throughout the profile in most cases but did not well constrain nitrate leaching or tile drainage. This indicates
652 a need for better constraint of both the soil water and soil nitrogen cycles in the APSIM model.

653 This work also lays the groundwork for future regional applications of soil moisture data assimilation. Importantly,
654 our findings reaffirmed soil moisture data assimilation's ability to "localize" gridded weather estimates of precipitation
655 to reflect observed values more accurately. Since cropping systems are highly sensitive to precipitation inputs, this is
656 a strong advantage of soil moisture data assimilation for forecasting applications where coarse-resolution weather
657 drivers are employed. Though RS soil moisture data assimilation could be an effective way to overcome limited
658 availability of in situ data, our work shows that assimilation of in situ surface soil moisture is not as powerful as the
659 assimilation of in situ root-zone soil moisture values in terms of model constraint. If the former is applied, additional
660 constraints or an augmented state-vector approach would be necessary to achieve higher system performance. When
661 selecting a RS soil moisture data product for data assimilation applications, high temporal resolution due to multi-
662 sensor satellite availability and accurately estimated observation uncertainty are two critical components for optimal
663 system performance. To that same point, combining several data products at different spatial resolutions can help to
664 reduce assimilation intervals within the system. Further investigation is needed to independently test the impact of
665 observation sample size (i.e., number of data products), temporal resolution, spatial resolution, and uncertainty on
666 system performance. Moreover, the data products considered in this study do not represent the full range of RS soil
667 moisture data products that are available publicly. This work should be expanded to evaluate data products derived
668 from other satellites/derivations both individually and in combination with other sources to exhaust all available
669 options.

670 **6. Code and data availability**

671 Code and observational data used in this study will be provided upon request.

672 **7. Author contribution**

673 MK was responsible for code development, performing the simulations and writing the manuscript. NV contributed to
674 revising the manuscript and providing SMAP-HB dataset. HD was responsible for developing the initial idea, code
675 development, writing and supervising the study.

676 **8. Competing interests**

677 The contact author has declared that neither they nor their co-authors have any competing interests.

678 **9. Acknowledgements**

679 The authors would like to thank all those on the Energy Farm team who made the presented case study possible. In
680 particular, we would like to thank Carl Bernacchi, Bethany Blakely, Michael Masters, Grace Andrews and Heather

681 Goring-Harford, who made the Energy Farm dataset available and performed the analyses for the nitrate leaching data,
682 and Konrad Taube and Haley Ware, who helped with water collection and water filtering in 2018 and 2019. We also
683 want to thank Caitlin Moore and Evan Dracup, who helped to collect and process much of the other data from the
684 plot. Additionally, we wanted to acknowledge those funding sources that supported the work of the Energy Farm
685 team. First, the data used in this study was funded in part by (1) the Leverhulme Centre for Climate Change Mitigation,
686 funded by the Leverhulme Trust through a Research Centre award (RC-2015-029), (2) the Center for Advanced
687 Bioenergy and Bioproducts Innovation (CABBI) at the University of Illinois, and (3) the Global Change and
688 Photosynthesis Research Unit of the USDA Agricultural Research Service.

867

868

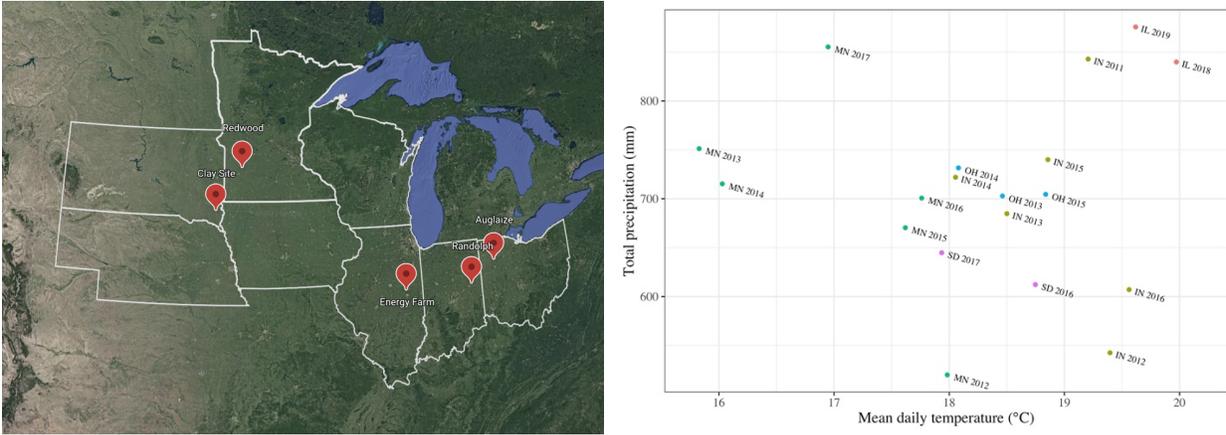

Figure 1. (A) Site map (ESRI) and (B) scatterplot demonstrating site-year total precipitation and average daily temperature (°C) for each site-year between April and October. Climate information was extracted and averaged across the 10 ERA5 weather ensembles for each site-year.

869

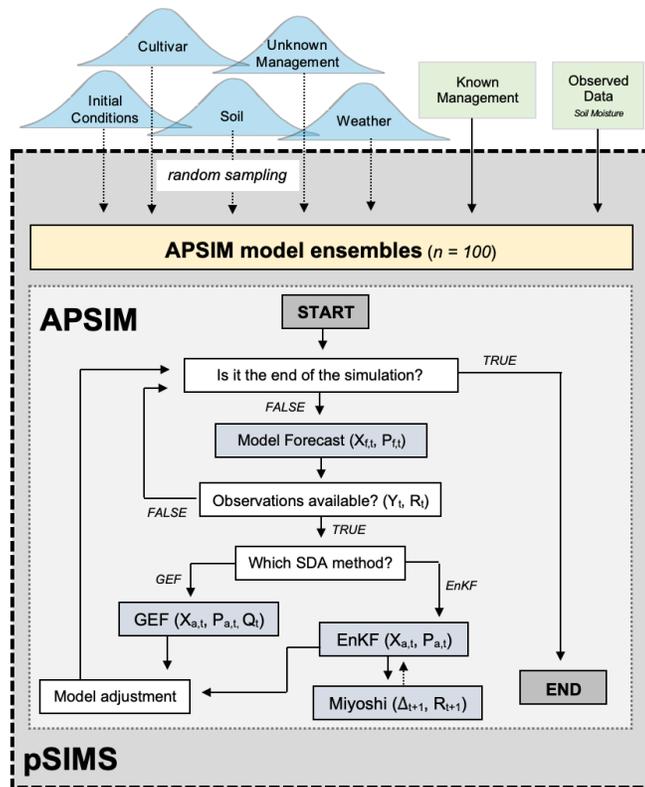

Figure 2. Schematic demonstrating the workflow of the data assimilation system. System inputs represented by blue Normal distributions have incorporated uncertainty in this study, while green rectangles represent known values that were included as constants.

870

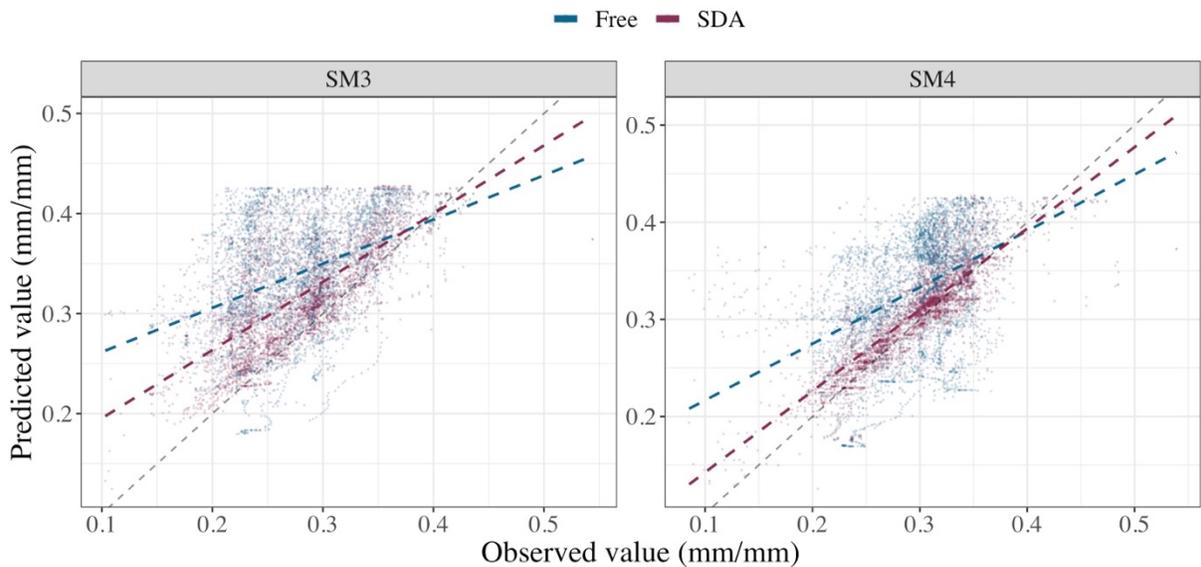

Figure 3. One-to-one plots for soil moisture estimates (mm/mm) in the two assimilation layers for the free model and in situ SDA across all analysis time-steps and site-years. The least-squares regression line is shown for both schemes next to the black dashed 1:1 line, demonstrating a perfect fit.

871

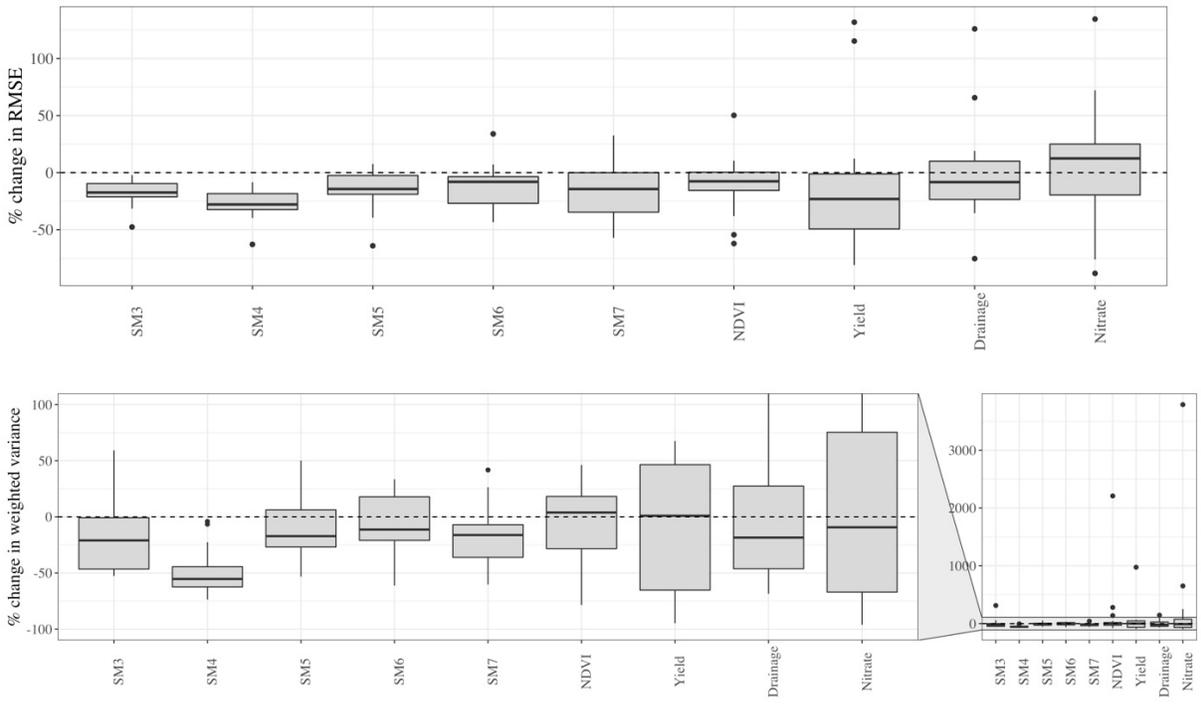

Figure 4. Boxplots demonstrating the distribution of relative change in (a) accuracy (RMSE) and (b) precision (weighted variance) due to in situ SDA for each state variable across all site-years. The relative change is computed with respect to the free model run, with negative values indicating SDA improvement.

872

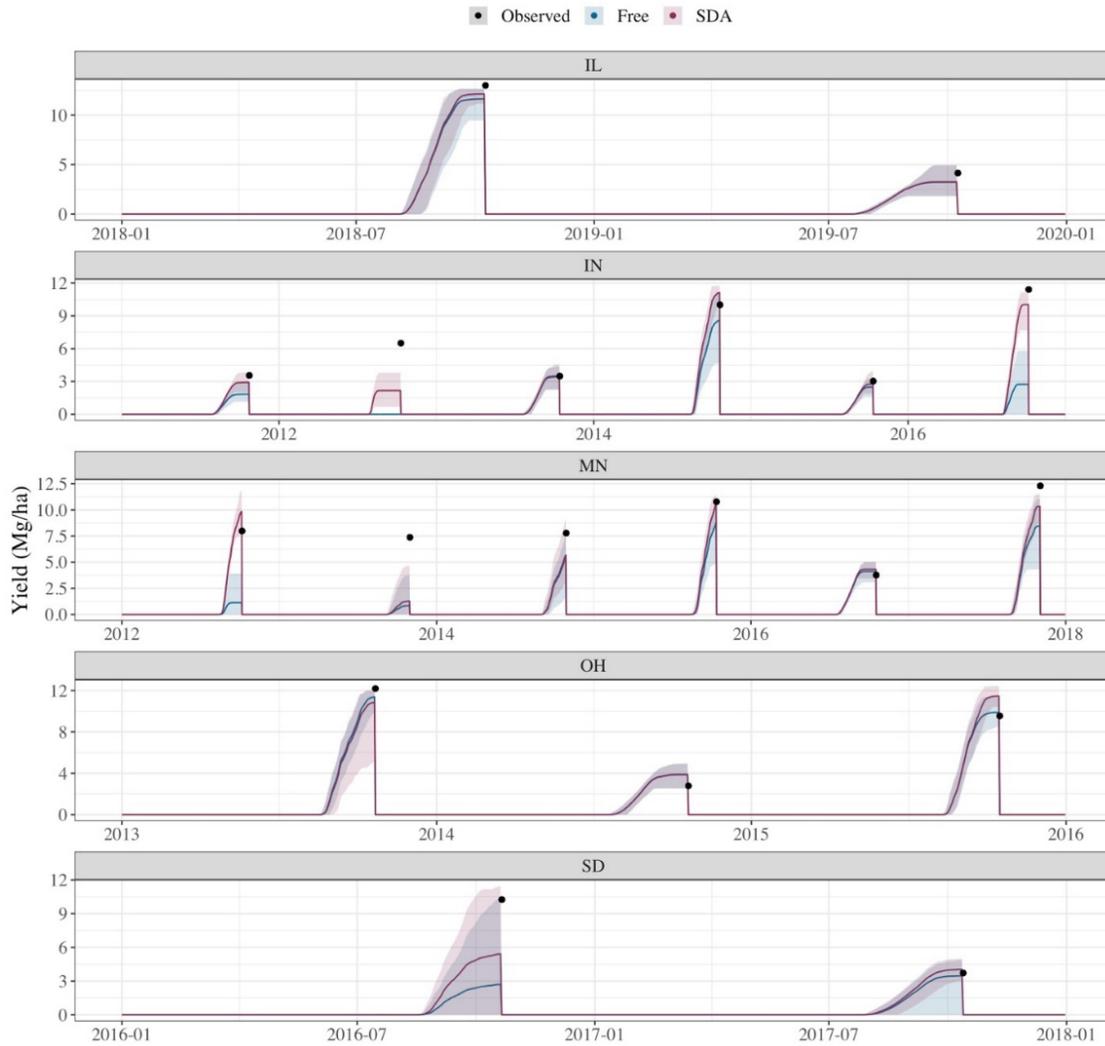

Figure 5. Time series of yield estimates for the free model and in situ SDA with mean daily estimates demonstrated with line graphs and the 95% credible intervals demonstrated by the shaded regions. Black points represent the observed harvest date and yield for each site-year.

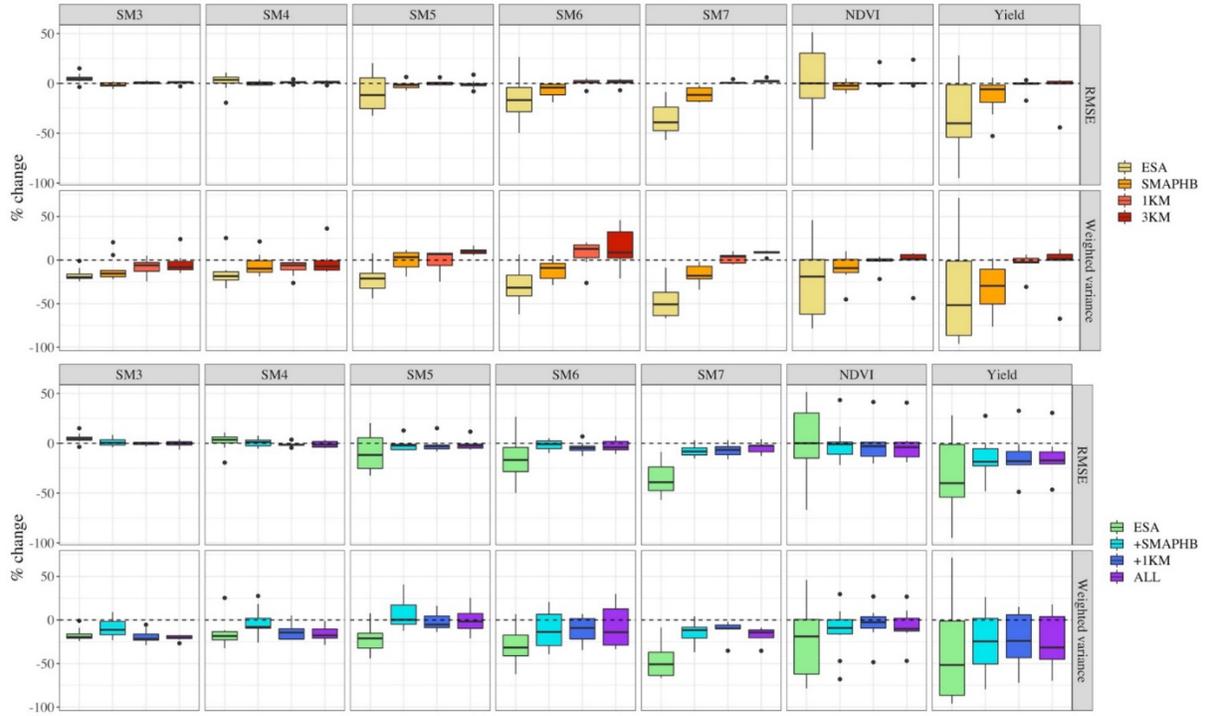

Figure 6. Boxplots demonstrating the distribution of relative change (%) in state variable accuracy (RMSE) and precision (weighted variance) for the (a) individual and (b) additive runs across all site-years. Change is computed relative to the free model results. Negative values indicate improvement (e.g., $(RMSE_{\text{ES}} - RMSE_{\text{EF}}) / RMSE_{\text{EF}}$).

874

875

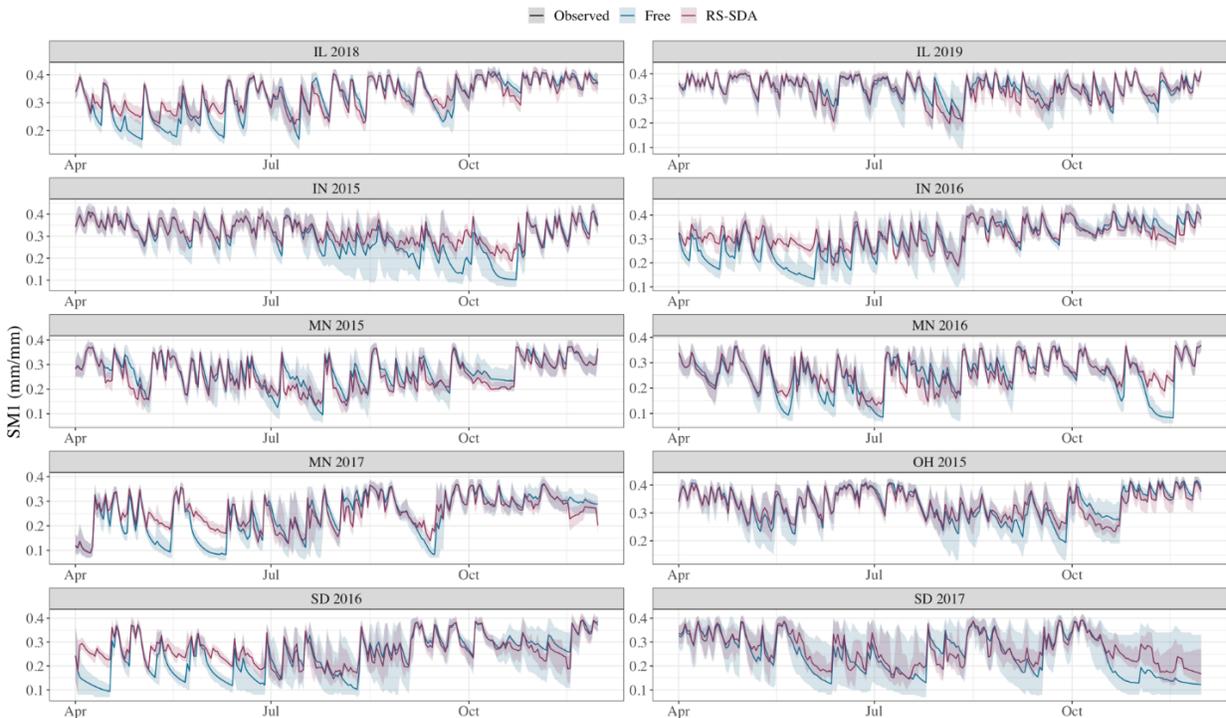

Figure 7. Time series of SM1 estimates from the free model and RS-SDA with the mean daily estimates demonstrated with line graphs. The shaded regions indicate 95% credibility intervals.

876

Table 1. Overview of remote sensing soil moisture data products.

Product	Product ID	Temporal coverage	Temporal frequency	Spatial resolution	Average data availability	Average observation variance	Reference
ESA-CCI	ESA	1978-2019	1-2 days	0.25°	219 days	0.0003	Dorigo et al. (2017)
SMAP-Hydroblocks	SMAP-HB	2015-2019	1-3 days	30 m	127 days	0.0050	Vergopolan et al. (2021b)
SMAP-Sentinel1	1KM/3KM	2015-now	12 days	1 km/3 km	7 days	0.0025	Das et al. (2019)

^aAvailability is calculated after removing observations in the winter months (i.e., Dec-Mar) and is given on a per-year basis.

877

878

Table 2. Overview of system configuration for the nine runs performed in this study. SDA methods include the Ensemble Kalman Filter (EnKF) coupled with the Miyoshi algorithm, and the Generalized Ensemble Filter (GEF). The former method of these two methods provided systematic estimates of R applied within the system, but the latter method used literature values. The state variables included in Xf are given.

Run group	Name	SDA method	R estimates	Temporal extent	State variable(s)	Observation(s)
Baseline	Free	N/A	N/A	2011-2019	N/A	N/A
	SDA	EnKF	Miyoshi	2011-2019	SM3, SM4	In situ soil sensor
Individual Runs	ESA	EnKF	Miyoshi	2015-2019	SM1	ESA
	SMAP-HB	EnKF	Miyoshi	2015-2019	SM1	SMAP-HB
	1KM ^a	EnKF	Miyoshi	2015-2019	SM1	1KM
	3KM ^a	EnKF	Miyoshi	2015-2019	SM1	3KM
Additive Runs	+SMAHB	GEF	Literature	2015-2019	SM1	ESA, SMAP-HB
	+1KM ^a	GEF	Literature	2015-2019	SM1	ESA, SMAP-HB, 1KM
	ALL ^a	GEF	Literature	2015-2019	SM1	ESA, SMAP-HB, 1KM, 3KM

^a Observations for 1KM and 3KM were not available for IL, and thus simulations were not performed for the site.

879

880

Table 3. Summary statistics to quantify the impact of in situ SDA (IS) and RS-SDA (RS) on forecast accuracy of APSIM state variables. The “Ns” column indicates the number of site-years with available data for each state variable and each run, and the “ns” column indicates the total number of observations across site-years for each run. A subscript (F) denotes a value computed for the free model estimates, a subscript (IS) denotes a value for the in-situ SDA estimates, and a subscript (RS) denotes a value for RS-SDA runs. The median change (D) in RMSE was computed for both runs. Two values for R2F are given for the different data subsets demonstrated in the “N” and “n” columns.

State variable	Depth (cm)	N _{IS} (N _{RS})	n _{IS} (n _{RS})	Δ RMSE _{IS}	Δ RMSE _{RS}	R ² _F	R ² _{IS}	R ² _{RS}
SM3 <i>mm/mm</i>	9.1 – 16.6	19 (10)	12252 (5592)	-17.4%	-0.9%	0.49 (0.48)	0.57	0.48
SM4 <i>mm/mm</i>	16.6 – 28.9	19 (10)	12735 (6141)	-27.9%	-2.8%	0.52 (0.43)	0.73	0.43
SM5 <i>mm/mm</i>	28.9 – 49.3	17 (8)	11325 (5101)	-14.3%	-2.6%	0.45 (0.45)	0.38	0.45
SM6 <i>mm/mm</i>	49.3 – 82.9	19 (10)	12846 (6169)	-8.0%	-1.0%	0.42 (0.43)	0.34	0.42
SM7 <i>mm/mm</i>	82.9 – 138	9 (6)	5715 (3265)	-14.3%	-5.4%	0.43 (0.44)	0.34	0.43
NDVI <i>unitless</i>	-	19 (10)	244 (134)	-7.6%	-1.8%	0.62 (0.69)	0.66	0.71
Yield <i>Mg/ha</i>	-	19 (10)	19 (10)	-23.1%	-17.2%	0.55 (0.53)	0.73	0.59
Annual drainage <i>mm</i>	-	19	19	-8.3%	-	0.47	0.46	-
Annual NO ₃ load <i>Kg NO₃-N/ha</i>	-	19	19	+12.5%	-	0.42	0.45	-
