## Abstract

10 Methodological advancements have been made in in situ observations of water stable isotopes that have provided valuable insights in ecohydrological processes. The continuous measurement capabilities of laser-based analyzers allow for high temporal resolutions and non-destructive, minimally invasive study designs of such in situ approaches. However, isotope analyzers are expensive, heavy, and require shelter and access to electrical power

15 which impedes many in situ assays. Therefore, we developed a new, inexpensive technique to collect discrete water vapor samples in the field via diffusion-tight inflatable bags that can later be analysed in the lab. In a series of structured experiments, we tested different procedural settings, bag materials, and closure types for diffusion-tightness during storage as well as for practical handling during filling and extraction. To facilitate re-usage of sampling

20 bags, we present a conditioning procedure using ambient air as primer. In order to validate our method, direct measurements through hydrophobic in situ probes were compared to repeated measurements of vapor sampled with our bags from the same source. All steps are summarized in a detailed SOP. This procedure represents the preparation and measurement of calibration and validation vapor standards necessary for processing of unknown, field-

25 collected vapor samples in the foreseen application. Performing pertinent calibration procedures, accuracy was better than 0.4‰ for  $\delta^{18}\text{O}$  and 1.9‰ for  $\delta^2\text{H}$  after one day of

storage. Our technique is particularly suitable in combination with minimal-invasive water vapor sampling in situ probes that have already been employed for soils and tree xylem. It is an important step towards [minimally invasive](#) monitoring [of](#) stable isotope distributions and also time-series in [virtually undisturbed](#) soils and trees without the need to have field-access to an analyzer. ~~It is~~ ~~and~~ therefore a promising tool for many applications in eco-hydrology and meteorology.

## 1 Introduction

Analyses of stable isotope composition of hydrogen and oxygen ( $\delta^2\text{H}$  and  $\delta^{18}\text{O}$ ) in soils and plant water have proven to be powerful tools and are therefore widely employed in ecology, hydrology, and related disciplines. Stable isotopes of pore water have been used to provide insights into soil evaporation (Zimmermann et al., 1967; Allison, 1982; Allison et al., 1983; Barnes and Allison, 1988; Walker et al., 1988) and groundwater recharge rates (Dincer et al., 1974; Saxena, 1984; Darling and Bath, 1988, [Koeniger et al., 2016](#)). They were used in soil hydrology to study unsaturated and saturated subsurface flow processes, mixing and residence times (Sklash and Farvolden, 1979; Buttle and Sami, 1990; McDonnell, 1990; Stewart and McDonnell, 1991; Gazis and Feng, 2004; Laudon et al., 2004; Garvelmann et al., 2012; [Beyer et al., 2016](#)), and to quantify evapotranspiration partitioning (Brunel et al., 1997; Hsieh et al., 1998a; Yopez et al., 2005; Rothfuss et al., 2010; [Wang et al., 2012](#); [Dubbert et al., 2013](#); [Quade et al., 2019](#)). Applications of water stable isotopes in ecology have allowed researchers to identify plant water sources (Dawson & Ehleringer, 1991), to describe water use patterns (Schwinning et al., 2002), and to determine competitive interactions (Ehleringer et al., 1991, [Meißner et al., 2012](#)). In plant physiology, insights into plant hydraulic architecture (Drake & Franks, 2003) were possible with isotope techniques, root water uptake was quantified (Rothfuss & Javaux, 2017; [Fan et al., 2017](#); [Seeger & Weiler, 2021](#)) as well as hydraulic lift (Caldwell & Richards, 1989; Meunier et al., 2018).

Conventionally, measurements of pore water and tree xylem water isotope composition are obtained through destructive sampling of soil cores or manual collection of sapwood and subsequent water extraction for isotope ratio mass spectrometry (IRMS) analysis (Ehleringer et al., 2000, West et al., 2006) or Isotope Ratio Infrared Spectrometry (IRIS) (Baer et al., 2002; Gupta et al., 2009). ~~IRMS~~ These instruments ~~allows~~ allow for high measurement precision (Horita & Kendall, 2004), but ~~is~~ are comparably expensive in the case of IRMS and generally requires highly time-consuming and laborious sample pre-treatment (Kerstel & Gianfrani, 2008). A less expensive and overall more convenient approach relying on laser-based water stable isotope analyzers is the direct vapor equilibration laser spectrometry (DVE-LS) where samples of soil matrix, rocks or plant tissue are in equilibrium with a corresponding vapor phase (Wassenaar et al., 2008; Hendry et al., 2015; Gralher et al., 2021).

Feldfunktion geändert

Although promising, the disadvantage is still that destructive soil sampling or harvesting of plant material generally prevents repeated samples from ~~one place~~ the exact same position. Additionally, repeated sampling of xylem imposes the risk of killing the tree or weakening it due to fungal infestation. Moreover, taking branch samples can be challenging or even impossible for tall trees. Generally, ~~D~~estructive sampling restricts the number of samples that can be obtained over time and space. This makes high-frequency or even continuous measurements difficult to sustain or simply infeasible. Number and spatiotemporal scope of lab-scale experimental setups as well as environmental isotope studies continued to expand, but were still limited by the available indirect observational techniques (West et al., 2010).

Feldfunktion geändert

The growing distribution of laser-based water stable isotope analyzers in recent years also enabled minimal-invasive, direct, continuous, and simultaneous measurements of  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  of water vapor. Only herewith, time series observations from the same point became possible. Available ~~isotope ratio infrared spectroscopy (IRIS)~~ instruments allow for measurements at a precision and accuracy comparable to that of IRMS (Berden et al., 2000;

[Baer et al., 2002](#); Crosson, 2008; Kerstel and Gianfrani, 2008; Gupta et al., 2009).

Importantly, laser-based instruments are portable and therefore potentially field-deployable.

Especially the small measurement cavity size (35 mL) of wavelength-scanned cavity ring-

80 down spectroscopy (WS-CRDS) instruments makes them ideal for lab-scale experimental

setups as well as for small sensor designs. The spread of laser-based instruments has therefore

stimulated recent developments of a number of in situ methods for direct measurements of

water stable isotopes in various fields. Precipitation measurements were carried out via gas-

permeable ePTFE surgical tubings (Munksgaard et al., 2011). Soil column breakthrough

85 curves (Herbstritt et al., 2012) as well as analyses of precipitation and canopy throughfall in

parallel were achieved via small hydrophobic membrane contactors (Herbstritt et al., 2019).

The isotopic composition of pore water was analysed in lab-scale experiments via

hydrophobic microporous tubings (Rothfuss et al., 2013) as well as in natural soil profiles

with custom-made hydrophobic porous in situ water isotope probes (WIPs) (Volkman and

90 Weiler, 2014). Similar in situ probes were also used in tree stems in labelling experiments to

analyze the isotopic composition of xylem sap (Volkman et al., 2016a; Seeger and Weiler,

2021). The ‘[stem](#) borehole method’ (Marshall et al., 2020; [Kühnhammer et al., 2022](#)) is an

alternative way to obtain in situ samples of tree xylem water vapor. Measurements of the

isotopic composition of transpired water were conducted using leaf chambers (Wang et al.,

95 2012; Dubbert et al., 2014) or whole-plant chambers (Volkman et al., 2016b).

Feldfunktion geändert

Feldfunktion geändert

The isotopic composition of the liquid water of interest in all these in situ studies was inferred

from sampling and measuring a corresponding vapor phase. Water vapor of interest was either

withdrawn directly e.g. from soil profiles, out of tree boreholes, or exchange and equilibration

with a carrier gas through different types of hydrophobic membranes were facilitated.

100 However, operating laser-based analyzers at the study site requires power-consuming, heavy

and expensive equipment to be brought to the field with the risk of damages and the

disadvantage of relative immobility. Consequently, rough or remote terrains as well as spacious experimental designs, exceeding possible tubing lengths between in situ measurements and the isotope analyzer are virtually excluded with this approach. First attempts to overcome these obstacles by collecting discrete vapor samples under such circumstances into glass bottles were recently presented. In both approaches, the sampled vapor had to be diluted continuously during measurement, to compensate for negative pressure when sucked into the analyzer by releasing e.g. dry air into the rigid, fragile sampling flasks. The first approach (Havranek et al., 2020) can be seen as a proof of concept. In a follow-up, Havranek et al. (2022) describe a field application of their setup which requires considerable financial resources for the components in use, extensive technical know-how for construction as well as substantial effort for field installation of a limited number of flasks. Their recommended operation procedure requires long flushing times, leading to filling times per flask of more than one hour, which strongly reduces the sample throughput and thus the achievable temporal resolution. The second approach (Magh et al., 2022) partly resolved these issues but still relies on specialty tools, lacks reproducibility due to the small volume of sampled vapor and currently does not provide the data accuracy needed for natural abundance isotope assays. Further, a sophisticated calculation procedure is necessary for both approaches ([Havranek et al., 2020](#); [Magh et al., 2022](#)) to remove the effects of the initial pulse of water vapor during the start of the measurement phase.; [This initial pulse is mixed with pre-sample vapor](#) which clearly biases the obtained isotope data.

Therefore, the aim of this study is to develop a technique to collect discrete vapor samples in the field for subsequent lab-based analyses, that overcomes the aforementioned problems while still ensuring handiness as well as cost and time efficiency. [Specifically, we identified a way to prepare and measure calibration and validation vapor standards, necessary for processing unknown, field-collected vapor samples.](#) For this purpose, we varied the applied

gas flowrate through established non-destructive in situ water isotope probes (WIPs) to improve per-sample time consumption. We tested the diffusion-tightness and inertness of various commercially available gas sampling bags as well as custom-made inflatable containers comprising different materials and closing mechanisms. We identified the best performing bags and coupled it with WIPs in order to collect and temporarily store discrete vapor samples prior to lab-based isotope analyses. Also, we identified necessary preparatory steps to optimize the reproduction of in situ data.

135 Figure 1. Schematic of projected vapor sampling via in situ (a) soil- and (b) xylem-water isotope probes (modified from Volkman & Weiler, 2014 and Volkman et al., 2016a). The left part describes the intended field setting while the right part describes the intended laboratory setting: sampled vapor is first filled into appropriate, to-be-identified containers (X) and later analyzed in the lab via CRDS.

## 140 2 Methodology

### 2.1 Effect of changing gas throughflow rates on the isotopic composition

In the first part of this study we tried to optimize sample filling times. For this purpose we investigated the effect of varying gas flowrates through the to-be-employed in situ water

isotope probes (WIPs). Originally, ~~the size of the probes werewas optimized with their size~~  
145 ~~i.e. the contact area of the membranous tip, to work in facilitate isotopic equilibrium when~~ the  
applied flow rates had been set to match ~~the analyzer's~~ demand. ~~This prerequisite which~~  
becomes obsolete for the collection of discrete vapor samples. In the case of discrete vapor  
sampling through WIPs into air-tight containers, different, arbitrary flowrates can be selected,  
which inversely affect the filling times of the containers. ~~It is important that the contact area~~  
150 ~~relevant for vapor collection is consistent for all sample collections as isotope equilibrium~~  
~~cannot be expected anymore when the applied gas flowrates exceed the ones originally~~  
~~recommended (Volkman & Weiler, 2014).~~ For repeated analysis of a single vapor sample we  
found a total gas sample volume of 0.5 - 1 L to be sufficient (Gralher et al., 2021). Further, we  
aimed at sampling times in the field of no more than 5 minutes per sample. Therefore, flow-  
155 rates of both dry air through the WIP and the corresponding gas sampling rate into the  
containers were increased stepwise ~~in a lab experiment~~ up to 150 mL/min ~~which would yield~~  
~~0.75 L sample volume after a filling time of 5 min.~~ We also tested the effects of omitting the  
~~originally proposed~~ dilution ~~(Volkman & Weiler, 2014)~~ when increasing the throughflow  
rates. In order to keep the gas flow inside the WIP balanced between the inflowing carrier gas  
160 and the outflowing sampling gas and in doing so avoid over- or under-pressure, the sampling  
rates had to match the throughflow rates. For these tests a WIP was installed in an  
evaporation-shielded box filled with moist sand with a ~~stable liquid~~-water ~~stable~~ isotopic  
composition ~~of -9.64‰ and -66.84‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively, referenced to the~~  
~~VSMOW-SLAP scale (Craig, 1961)~~ and kept at a constant temperature of 20.8 °C. For precise  
165 isotope measurements we used dry synthetic air ('zero air') ~~as carrier gas.~~

Precise flowrates of the synthetic air from the pressurized gas bottle into the WIP were  
facilitated by a digital mass flow controller (PN 35828, Analyt MTC, Müllheim, Germany),  
while sampling at the same flowrate was facilitated by a small air pump (PN LP27-12, Pollin

Electronic GmbH, Pförring, Germany) where the pumping rate can be controlled manually via  
170 the applied voltage and controlled with a mass flow meter (PN 35808, Analyt MTC). The  
fractions of sampling rates exceeding the analyzer demand of ~ 35 mL/min were vented to air  
through an open split near the sample inlet port of the isotope analyzer (L2120-*i* or L2130-*i*,  
Picarro Inc., Santa Clara, CA, USA). The analyzer provided quasi-continuous (0.5 Hz)  
readings of water vapor mixing ratio (in ppmv), oxygen and hydrogen isotope readings (in  
175 ‰), and the spectral parameters ( $\delta^{18}O_{H_2O}$ ) indicating mixing with ambient air and,  
organic\_MeOHamp) indicating spectral interference from the bag material, which we also  
collected from room air on every day of bag measurements. This setup allowed for facilitating  
the demanded low and constant stream of gas to the analyzer while at the same time  
arbitrarily varying the gas flow through the attached WIP.

## 180 2.2 Material ~~and closure type~~ selection

### 2.2.1 ~~Dry air inflation~~ Diffusivity and spectral interference

Rigid glass or steel bottles and cylinders conventionally used for gas sampling were excluded  
in our approach, since constant flow through the WIPs was needed in our setup and under-  
pressure at the analyzer during measurements has to be avoided. Commercially available  
185 gasbags with large volumes (~~2.5 L~~, 10 L) are available with reusable gas valves in opposite to  
bags with smaller volumes (0.5 L – ~~1~~ 2.5 L), which come with septa or other degrading  
closures. Hence, none of these combinations were suitable for our purposes, either due to  
their size or due to the type of closure. Other readily available gas sampling bags made of  
PTFE or laminated aluminum foil from a different supplier were available in appropriate sizes  
190 but were available only in minimum order quantities of 10. Their per-order costs ranged  
between €200 and €350 depending on bag material which were prohibitive for our purposes.  
Therefore, we ~~tested~~ investigated three different inflatable bags of different materials and  
reasonable sizes and combined them with different reclosable caps and valves (~~Tab-Table~~ 1).

195 | [Additionally, a 2.5 L commercially available gasbag was equipped with a stainless steel screw-lock valve and also tested.](#) Specifically, we ~~tested~~[evaluated](#) whether they were sufficiently reliable in terms of diffusion-tightness and chemical inertness, also focusing on easy handling. [The criteria for identifying reliable bags or bag material are summarized in a best-practice protocol \(SOP\) in the Appendix of this manuscript.](#)

200 | The different bag types were filled with pure N<sub>2</sub> (purity 99.996%) and analyzed immediately thereafter with a CRDS isotope analyzer (L2130-i, Picarro Inc., Santa Clara, CA, USA). We tested PE spoutbags (code 'PE-Sp', PN 1055) and single layer metalized spoutbags (code 'Al-Sp', PN 1050, both available from Daklapack Europe, Oberhausen, Germany), of which we replaced the original PE spout caps by caps with rubber septa. Filling and continuous vapor isotope analyses were facilitated through these septa via an infusion needle (ID = 1 mm)  
205 | assembled to a 1/8" perfluoroalkoxy alkane (PFA) tube. We also tested two kinds of 3-layer metalized zip bags with fill volumes of 1 L (PN: CB400-420BRZ, color: red) and 0.5 L (PN: CB400-310GZ, color: gold, both available from Weber Packaging GmbH, Göglingen, Germany). They were heat-sealed and equipped with silicone blots on the outside, which served as septa after 2 days of drying (code 'Al3-Sil' for the 1 L bag, code 'Al3g-Sil' for the  
210 | 0.5 L bag). The bags were filled and their content withdrawn for isotope analysis through the silicone septa again via an infusion needle assembled to a 1/8" PFA tube.

To improve handiness and simplify filling and sample analysis when using the 3-layer metalized bags, we tested two different types of valves as alternatives to our custom-made  
215 | silicone septa. [With a punching tool, a hole was applied to each bag for the respective diameter of the screw connections.](#) We fixed small pneumatic brass couplings (PN KDG M5 NW2,7, Landefeld, Kassel, Germany) on the 3-layer metalized 1 L zip bags (code 'Al3-PC'), which were then heat-sealed. The respective plug connector (PN KSGI M5 NW2,7, Landefeld, Kassel, Germany) was connected to a 1/8" PFA tube for filling and analysis. Also

220 stainless steel screw-lock gasbag valves with 6 mm hose fittings (PN 11701150, Linde, Pullach, Germany) were mounted on 0.5 L and on 1 L 3-layer metalized zip bags (codes ‘Al3s-GbV’ and ‘Al3-GbV’) after punching a 10 mm hole. For increased leak-tightness we mounted an additional, custom-made rubber washer between the valve and the inner wall of the bags which were then heat-sealed. For filling ~~and~~ as well as sample analysis the 6 mm hose fitting was adapted to a 1/8” PFA tube.

225 Table 1. Bag- and seal-type combinations and their properties tested for vapor sampling.

Code	Material	Bag style	Vol	Closure, cap or seal type	Inflation, filling, sampling via...
PE-Sp	PE	spoutbag	1 L	PE screw cap w/ rubber septum	Infusion needle and 1/8” PFA tube
Al-Sp	Al	spoutbag	1 L	PE screw cap w/ rubber septum	Infusion needle and 1/8” PFA tube
Al3g-Sil	Al 3ply gold	Zip bag	0.5 L	Silicone blot as septum	Infusion needle and 1/8” PFA tube
Al3-Sil	Al 3ply red	Zip bag	1 L	Silicone blot as septum	Infusion needle and 1/8” PFA tube
<u>plastigas®</u>	<u>Al 3ply silver</u>		<u>2.5 L</u>	<u>Stainless steel screw-lock valve</u>	<u>Hose fitting adapted to 1/8” PFA tube</u>
Al3-PC	Al 3ply red	Zip bag	1 L	Pneumatic brass coupling	Plug connector and 1/8” PFA tube
Al3-GbV	Al 3ply red	Zip bag	1 L	Stainless steel screw-lock valve	Hose fitting adapted to 1/8” PFA tube
Al3s-GbV	Al 3ply silver	Zip bag	0.5 L	Stainless steel screw-lock valve	Hose fitting adapted to 1/8” PFA tube

To detect gradual diffusive exchange of the bag content with ambient air or outgassing from the employed material, 3 to 5 replicates of each bag/valve combination were flushed with N<sub>2</sub> and evacuated twice before they were again filled with pure N<sub>2</sub>. They were then stored at ambient temperature and repeatedly analyzed over the course of four weeks. Measurement frequency was every two to three days during the first two weeks and one final time at the end of the fourth week, unless a bag/valve combination was found unsatisfactory earlier.

### 2.2.2 “Climate chamber” experiment

235 To further test the vulnerability of projected discrete vapor samples, i.e. to test if relative humidity outside of the bags can exchange with and thus flaw the sample inside the bag, we designed a small “climate chamber” which consisted of a plastic box (inner dimensions 57 cm × 37 cm × 32 cm) covered by a plastic lid with all holes and slits taped. We prepared six ‘Al3s-GbV’ bags filled with vapor from the same source (described in detail in 2.3). Three

bags were placed in the box straightforward while the other three were inserted in metal cans  
240 of the bags' size prior to placement in the box. Such metal cans are normally used for the  
transport and storage of glass bottles containing liquid water sampled for dissolved gases  
analysis. They are considered diffusion-tight when closed and sealed by means of metal lids,  
rubber seal rings, and metal clasps as we did. Inside the box we also placed an open bowl of  
water (ca. 350 mL) to quickly reach and then maintain a relative humidity near 100% over the  
245 course of the test which lasted three weeks. The box was deposited in the basement of our  
laboratory building to facilitate fairly stable temperature conditions. Temperature ( $^{\circ}\text{C}$ ) and  
relative humidity (%) inside the box were recorded every ten minutes with a CS215 probe  
connected to a CR200 logger (both from Campbell Scientific, Logan, UT, USA). These data  
were then converted to water vapor mixing ratios using Magnus' equation (Foken, 2008).  
250 Vapor concentration (ppmv) and isotope ( $\delta^{18}\text{O}$ ,  $\delta^2\text{H}$ ) data from the vapor source used for  
filling the bags, from the inside of the box after 20 days, and from all canned and un-canned  
~~the~~ bags after 20 days of storage inside the box were collected with a Picarro 2120-*i*.

### 2.3 Field ~~trial~~ application

We tested the reliability of the projected sampling procedure first in a laboratory experiment  
255 and later in the field using 'A13-GbV' bags. For this purpose, four evaporation-shielded boxes  
( $V = 18\text{ L}$ ) with moist sands with different water isotopic compositions were prepared and a  
WIP ~~in DDS mode~~ (Volkman & Weiler, 2014) was installed in each of the boxes to sample  
their soil water vapor. We used a low-weight sampling setup that provided a constant air flow  
of  $150\text{ mL/min}$  with the small pumps described above (section 2.1). The incoming stream of  
260 ambient air was dried by a 'Drierite' drying column (PN 26800, W. A. Hammond DRIERITE  
Co. Ltd., Xenia, OH 45385, USA) and directed ~~to~~ through the throughflow line into the  
porous tip of the WIP. The vapor generated inside the WIP was withdrawn through the  
sampling line by a second small pump with the same gas flow-rate. The stream of sampled

vapor was directed to the isotope analyzer (demanding 35 mL/min), using an open split for  
265 excess vapor (115 mL/min) near the analyzer's sample inlet port. Immediately after the direct  
measurement, the analyzer was disconnected and the setup was used for directing the entire  
gas stream into the bags. Additionally, ambient vapor data were collected with the isotope  
analyzer. Replicates of sampled vapor were filled in bags, which were then analyzed two  
hours later. Calibration was facilitated using in situ and bag measurements of those samples  
270 displaying ~~extreme~~ the highest and the lowest  $\delta^2\text{H}$  values, treating these in situ values de facto  
as standards. This selection was maintained for calibration of  $\delta^{18}\text{O}$  values, too, although that  
meant that the so-selected standards did not "bracket" the to-be-calibrated "samples" as is  
common best practice. The precision would be the standard deviation of repeated calibrated  
isotope readings of the samples displaying intermediate  $\delta^2\text{H}$  readings. The accuracy would be  
275 the deviation of the calibrated mean of replicates of the respective in situ measurements. Note  
that this led to the reproduction (validation) of the intermediate in situ values rather than  
liquid water values referenced to the VSMOW-SLAP scale (Craig, 1961). The derivation of  
liquid water values from vapor isotope observations has been described in Volkmann &  
Weiler (2014).

## 280 **2.4 Reusability of sampling bags**

### **2.4.1 Flushing attempts**

To test the reusability of the bags, we applied the following flushing procedure. 'A13-GbV'  
and 'A13s-GbV' bags were filled with pure  $\text{N}_2$ , evacuated immediately thereafter with a  
LABOPORT® diaphragm vacuum pump (N810.3 FT.18, KNF Neuberger GmbH,  
285 Munzingen, Germany) and filled again with pure  $\text{N}_2$ . On the next day they were evacuated  
again, filled with pure  $\text{N}_2$  again and evacuated one final time. After these preparatory steps, 3-  
5 bag replicates were used for sampling vapor from sources both isotopically different and  
identical to the ones that had been sampled before with the respective bags. The setup used

for this purpose was identical to the one described in Section 2.3 except that different  
290 diaphragm gas pumps (BOXER 22K, Boxer, Ottobeuren, Germany) were used. Vapor  
concentration and isotope data of the bags were recorded with a Picarro L2120-*i* 1, 3, and 7  
days after vapor sampling.

#### 2.4.2 Conditioning

We additionally tested ~~In order to further improve~~ the reusability of the bags ~~we by tested~~  
295 comparing two ways of conditioning previously used sampling bags. The first way was by  
filling a batch of bags with dry synthetic air, leave them filled for at least one day, analyze  
their vapor concentration and isotope signature with a Picarro L2120-*i*, evacuate them, fill  
them again, and repeat this cycle several times. The second way was identical except that  
moist, isotopically homogeneous air was used for filling and priming. In both cases the  
300 absolute vapor concentrations and the standard deviations (SD) of isotope readings from  
repeated batch measurements were considered as predictor for conditioning efficiency.  
Efficiency was then scrutinized by using the so-conditioned bags for collecting vapor samples  
from isotopically diverse sources (setup details in 2.3) followed by repeated analyses over the  
course of up to seven days. Mean vapor isotopic compositions of these sources were -20.41, -  
305 29.32, and -37.24 for  $\delta^{18}\text{O}$  and -84.95, -139.53, and -195.77 for  $\delta^2\text{H}$ . Again, calibration was  
facilitated using ~~in situ and~~ bag measurements of those ~~samples sources with samples~~  
~~displaying extreme~~ the highest and lowest isotope values and their respective in situ  
measurements. We report precision and accuracy as quality measures of the calibration  
process. The reported precision is the SD of the repeated calibrated isotope readings of the  
310 intermediate source which we consider as (validation standard) while the reported accuracy is  
the deviation of the calibrated mean of repeated measurements from the respective target  
value which are the isotope readings from the respective in situ measurements.

### 3 Results

#### 3.1 Effect of changing gas throughflow rates on the isotopic composition

315 With increasing flow-rates through the WIP, the vapor content originating from the source  
water decreased in the sampling gas (~~Figure~~ [Fig. 2](#)). At the same time, the isotopic  
composition for both isotope ratios under investigation changed, indicating that no  
equilibrium between the source water and the provided dry gas stream was established inside  
the WIP. Such kinetic fractionation effects could be observed at all flow-rates [exceeding the](#)  
320 [originally proposed equilibrium flowrate from Volkmann & Weiler \(2014\)](#). They were  
stronger for  $\delta^{18}\text{O}$  than for  $\delta^2\text{H}$ . The induced decreasing vapor contents were strongly  
correlated with decreasing isotopic signatures. In the case of the WIP operated ~~in-DDS mode~~  
with proportional dilution and throughflow rates, vapor content ranged from 10325 to 14432  
ppmv, while the concurrent uncalibrated isotope readings were in a range of -18.92‰ to -  
325 30.99‰ in the case of  $\delta^{18}\text{O}$  and -136.85‰ to -143.41‰ in the case of  $\delta^2\text{H}$ . The heaviest  
values of these ranges correspond to the settings originally proposed by Volkmann & Weiler  
(2014). These changes correspond to change rates of 0.241‰/(mL/min) for  $\delta^{18}\text{O}$  and  
0.131‰/(mL/min) for  $\delta^2\text{H}$ . Similar observations were made for the case when dilution was set  
to zero at higher flowrates. Here, the vapor content ranged from 12256 to 20041 ppmv while  
330 the uncalibrated isotope readings varied between -30.35‰ and -39.13‰ in the case of  $\delta^{18}\text{O}$   
and between -143.23‰ and -146.95‰ in the case of  $\delta^2\text{H}$ . Here, the changes correspond to  
change rates of 0.117‰/(mL/min) for  $\delta^{18}\text{O}$  and 0.049‰/(mL/min) for  $\delta^2\text{H}$ . Vapor was always  
sampled from the same liquid water source which had an isotopic composition of -9.64‰ and  
-66.84‰ for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ , respectively, referenced to the VSMOW-SLAP scale (Craig,  
335 1961). All coefficients of determination ( $R^2$ ) between vapor content and isotope readings were  
greater than 0.99. At the target flow-rate of 150 mL/min throughflow and 0 mL/min dilution  
vapor content was close to 12,000 ppmv at 20.8 °C ([Figure](#) [2](#)).

Figure 2. Scatterplot of water vapor isotopic composition (left:  $\delta^{18}\text{O}$ , right:  $\delta^2\text{H}$ ) and vapor content obtained by varying gas throughflow rates with (open symbols) and without (closed symbols) dilution at a constant temperature, illustrating the kinetic fraction effects with increasing flowrates through the probe. The numbers refer to the respective gas flowrates applied as throughflow/dilution or throughflow-only during the tests. The flowrates originally proposed by Volkman & Weiler (2014) facilitated equilibrium according to the design of the probe's tip size and the known instrument flowrate.

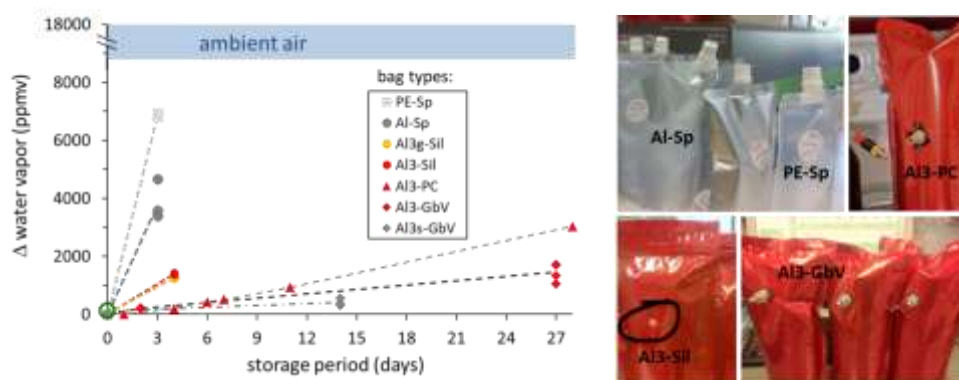

### 3.2 Material and closure type selection

#### 3.2.1 Dry air inflation Diffusivity and spectral interference

**Diffusion-tightness and long-term storage effects.** During the test for diffusion-tightness the water vapor content readings of the ambient air in the lab were in a range of 9000 – 18000 ppmv while inside the bags they were initially close to zero due to pure  $\text{N}_2$  inflation. Over time, these vapor pressure gradients were gradually levelled out with different rates. This is qualitatively evident from the different slopes of the dashed lines (Fig. 3). PE spout-bags 'PE-Sp' displayed the highest increase when after three days the vapor content had already increased by ~7000 ppmv. Vapor content readings in the metalized spout-bags 'Al-Sp' were ~4000 ppmv after three days. 3-layer metalized bags displayed the lowest vapor increase rate. Design and thus air-tightness of these bags differed only with the type of septum or valves

used. The vapor content readings in the bag-types with the silicon blot ('Al3-Sil') were ~1200 ppmv after four days.

360 Only for the better performing bag/valve combinations ('Al3-PC', 'Al3-GbV' and 'Al3s-GbV') we extended the vapor content measurements up to four weeks. After this period, mean vapor content readings in 'Al3-PC' and 'Al3-GbV' bags were ~3000 ppmv and ~1450 ppmv, respectively. Mean vapor content readings in 'Al3s-GbV' bags were ~420 ppmv after two weeks, which was the final value possible for this bag type due to its smaller volume.

365 Figure 3. Left panel: Time series of vapor content readings inside different bag types (closed symbols), initially filled with pure N<sub>2</sub> (green open circle). Right panel: Example pictures of tested sampling bags.

**Spectral interference of outgassing material.** In two bag types, deviations of the spectral parameters from the pure N<sub>2</sub> signal were found, which were also correlated with the respective isotope readings. The spectral line width variable indicative for gas composition ('h2o\_vy') is  $0.4309 \pm 0.0015$  ppm on our L2130-i analyzer for air containing oxygen at atmospheric levels, while it is  $0.4563 \pm 0.0049$  ppm for pure N<sub>2</sub>. Vapor concentration of bag-type 'Al3g-Sil' containing pure N<sub>2</sub>, was below 2000 ppmv and should therefore plot at a h2o\_vy value of about 0.46 ppm like the bags 'Al3-Sil' (same material but different color), but evolved towards 0.43 ppm. Simultaneously, apparent enrichment in heavy isotopes was

375

observed in 'Al3g-Sil' bags with an increase of around 80‰ in  $\delta^{18}\text{O}$  and 150‰ in  $\delta^2\text{H}$ , compared to samples stored in 'Al3-Sil' bags.

In ~~a~~ the commercially available 2.5 L plastigas® bag ~~(Linde)~~ equipped with a gasbag valve (PN 11701150, Linde) (combination not featured in Fig. 3), we observed an apparent  
 380 depletion in  $\delta^2\text{H}$  from -190‰ to -305‰ after 24h and to -360‰ after 72h. At the same time a spectral variable recorded on ~~our~~ the L2120-i analyzer, indicating potential contamination with organic compounds ('organic\_MeOHamp'), increased to  $0.00760 \pm 0.00014$  after 24h and to  $0.01005 \pm 0.00012$  after 72h. The initial value was  $0.00095 \pm 0.00026$  which was also  
 385 observed in ambient air. We therefore also excluded 'Al3g-Sil' and ~~2.5L~~ 'plastigas®' bags from further testing due to the observed spectral interferences. Further tests and isotope samplings in our study were conducted with 'Al3-GbV' or 'Al3-GbV' bags only. The performance of the different bag materials in the tests is summarized in Table 2. The protocol for testing bags and material properties and the respective target values for passing the tests can be found in Appendix A.

\* coupling corrosive

395 **3.2.2 “Climate chamber” experiment**

Temperature was quite stable inside the climate chamber, as intended. ~~It ranged,~~ ranging between 18.1°C and 16.3°C. Relative humidity rose to > 97% within 6 hours and maintained on average at 99.5% throughout the remaining observation period, which translated to vapor mixing ratios of  $19972 \pm 519$  ppmv. Mean vapor contents from the source were 14365 ppmv  
400 during filling and 12574 ppmv inside all bags after 20 days. Differences in mean vapor contents between canned and un-canned bags were smaller than the respective variations within the two batches. Isotope readings of all bags appeared to be enriched by 2.9‰ in  $\delta^{18}\text{O}$  and 15.0‰ in  $\delta^2\text{H}$  relative to the source, again with negligible differences between the two batches (data shown in ~~supplement~~ [Supplement Fig. S1](#)).

405 **3.3 Field ~~application trial~~**

When comparing all isotope data of the direct in situ sampling from the sand boxes in the field with the data from vapor sampled into the bags and measured 2 hours later, we found no systematic bias towards congruent enrichment or depletion in heavy isotopes. Instead, all [raw](#) isotope data of the bag measurements appeared to be shifted towards ambient air values by -  
410 0.6 to +1.6‰ for  $\delta^{18}\text{O}$  and +4 to -5‰ for  $\delta^2\text{H}$  relative to their respective in situ measurements. We used isotope readings of in situ and bag measurements from the samples displaying extreme  $\delta^2\text{H}$  values for calibration. Thereby, in situ values of the intermediate samples could be reproduced [by calibrated bag measurements](#) with a precision of 0.15‰ and an accuracy of 0.8‰ for  $\delta^{18}\text{O}$ . The respective numbers for  $\delta^2\text{H}$  were 0.76‰ and 2.89‰ ([Figure 4](#)).

415

Figure 4. Isotope data from in situ measurements (filled symbols), raw bag measurements (orange and brown open symbols), and calibrated in situ data calculated from bag measurements (blue and cyan open symbols) using in situ (cyan closed symbols) and raw values (brown open symbols) of sources displaying extreme δ<sup>2</sup>H values. Ambient vapor at that day is displayed as a blue open diamond.

420

### 3.4 Reusability of sampling bags

#### 3.4.1 Flushing attempts

Generally, isotope data [obtained from repeated measurements of the bags](#) unanimously trended towards the values recorded previously from the respective sample bags. These trends increased over time and changes were proportional to the differences between current in situ and previous bag measurements on the individual bag level. [Such memory effects persisted although the bags had been evacuated and flushed three times with dry N<sub>2</sub> prior to vapor sampling.](#) The trends were consistent for all tested bag types and appeared to be independent from concurrent ambient air values for both isotope ratios investigated (data shown in

425

430 [supplement-Appendix Fig. S2A1](#)).

### 3.4.2 Conditioning

The two different conditioning methods (dry and moist) applied to previously used sample bags yielded contrary results. Conditioning with dry synthetic air caused vapor content readings to decrease stepwise down to 324 ppmv (Figure 5a) while isotope signatures became more enriched (isotope data shown in [sSupplement Fig. S32](#)). Their SDs generally decreased but remained above 2.9‰ for  $\delta^{18}\text{O}$  and 18.8‰ for  $\delta^2\text{H}$  (Figure 5b). In contrast, conditioning with moist air resulted in vapor content readings to decrease to 6740 ppmv, which was in the order of the level of conditioning. Isotope signatures of so-primed bags clustered around the conditioning values (data shown in [sSupplement Fig. S43](#)) with SDs decreasing to 0.05‰ for  $\delta^{18}\text{O}$  and 1.07‰ for  $\delta^2\text{H}$  after 4 to 5 steps (Fig. 5b).

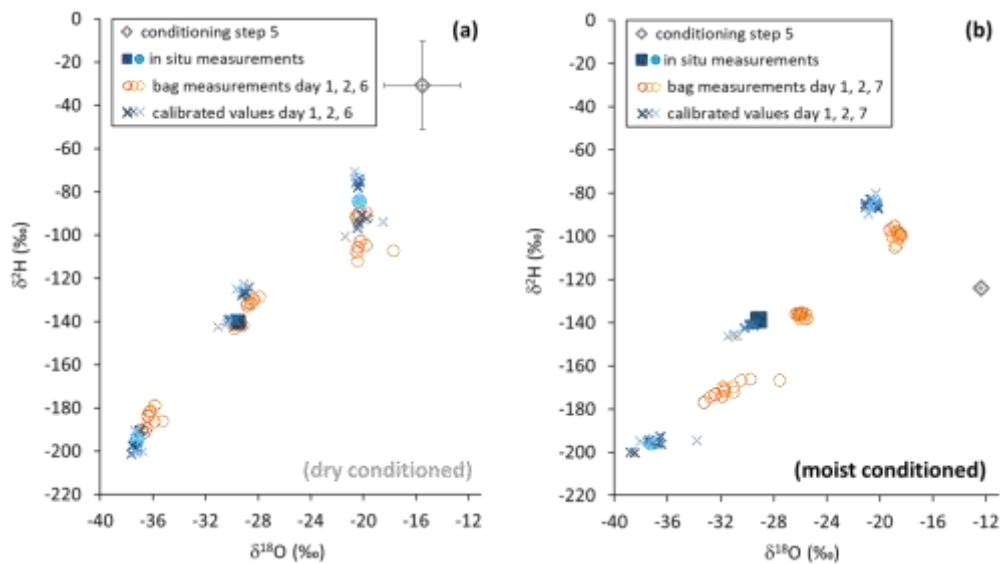

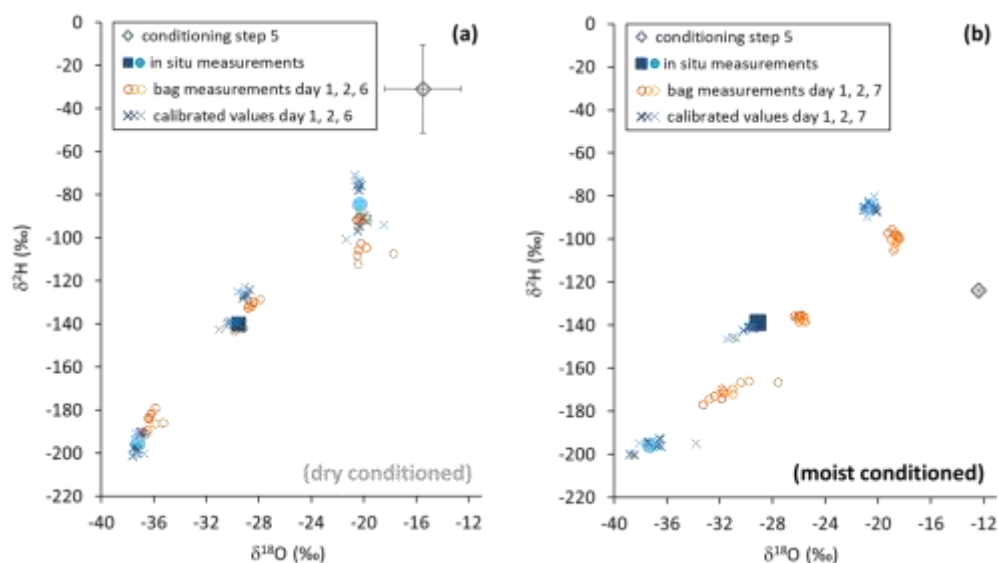

Figure 5. Vapor content readings (a) and SDs of isotope readings (b) from vapor sampling bags, stepwise conditioned with dry synthetic air (light plus symbols) and moist air (dark cross symbols). Light and dark diamond symbols on vertical axes represent mean values of pre-conditioning sample measurements.

Re-using the conditioned bags for sampling vapor from isotopically diverse sources also yielded contrasting results. SDs of isotope readings in bag replicates after dry conditioning were larger than after moist conditioning. Repeated measurements generally resulted in a decline of measurement precision and accuracy of mean isotope values (Fig. 6). Comparing in

455

situ values with bag measurements yielded no consistent picture in the case of dry conditioning (Fig. 6a) whereas in the case of moist conditioning a bias towards the conditioning values became evident which increased over time (Fig. 6b). [One day after filling, raw isotope data of the bag measurements deviated by -0.6 to +1.6‰ for  \$\delta^{18}\text{O}\$  and +4 to -5‰ for  \$\delta^2\text{H}\$  relative to their respective in situ measurements.](#) Calibration for reproduction of the intermediate in situ values worked better for moist- than for dry-conditioned bags. This refers to the precision as well as to the accuracy ([Tab. Table 23](#)).

460

Figure 6. Isotope data from in situ measurements (filled symbols), gasbag measurements (open circles), and in situ data calculated from gasbag measurements (asterisks) after conditioning with a dry (a) and moist atmosphere (b). Pre-sampling levels are represented by gray diamonds. Note that error bars (black) are smaller than the symbol in the case of moist conditioning (b).

465

Table 23. Conditioning effects on vapor stable isotope measurements from re-used sampling bags.

Day after sampling	Analysis iteration	Dry atmosphere conditioning				Moist atmosphere conditioning			
		$\delta^{18}\text{O}$ (‰)		$\delta^2\text{H}$ (‰)		$\delta^{18}\text{O}$ (‰)		$\delta^2\text{H}$ (‰)	
		precision	accuracy	precision	accuracy	precision	accuracy	precision	accuracy
1	1	0.58	-0.10	6.71	-7.16	0.25	0.41	0.41	1.93

#### 4 Discussion

470

**Gas flow-rate effects.** The goal of this study was to facilitate storage of in situ sampled vapor without sensitive and costly analytical equipment in the field. The main applications we had in mind were high frequent, minimally invasive in situ isotope measurements of water vapor in soils and plant tissue as recently performed by e.g., Volkman & Weiler (2014), Volkman et al. (2016a), Seeger & Weiler (2021), or Gessler et al. (2021). Their setups were based on

475 | applying stable, yet low gas\_flow-rates to their WIPs. These flowrates resulted in continuous  
vapor samples assumed to be in isotopic equilibrium with the liquid water of interest. They  
had been carefully adjusted to the employed analyzers' demands. However, in the intended  
absence of an analyzer this necessity becomes obsolete. Therefore, we first tested the effect of  
higher gas\_flow-rates on the obtained vapor isotope signatures. We did so in order to facilitate  
480 | shorter filling times that would allow for higher filling frequencies of any containers of  
sufficient volume (0.5 – 1 L) needed to collect and store vapor samples prior to lab-based  
analyses.

Incidentally, we also tested the necessity of isotope equilibrium for water vapor sampling  
using WIPs. We found that also under non-equilibrium conditions, in-situ isotope values  
485 | could be reproduced with a very good precision and accuracy. We attribute this to the fact that  
all employed WIPs had been constructed equal in size. This resulted in consistent gas transit  
and vapor pick-up times inside the tips as well as consistent relevant soil contact area which is  
the vapor collection area. This expands the findings of previous studies which aimed at  
facilitating equilibrium conditions when sampling water vapor from soils or stem boreholes  
490 | (Volkmann & Weiler, 2014; Marshall et al., 2020). This also means that our approach may  
not be suitable for application together with the stem borehole method as the tree stem  
diameters will likely be variable thus not allowing for consistent gas transit and vapor pick-up  
times. By using identical WIPs throughout our experiment as well as for standards and  
samples in the foreseen application, potential isotope fractionation effects induced by the  
495 | membrane are eliminated in the calibration process. Such membrane-induced fractionation  
effects have been observed before during across-membrane collection of vapor for liquid  
water isotope determination (Herbstritt et al., 2012). Further, non-equilibrium conditions as  
encountered in this study did not require any extra correctional efforts. Mathematically, the  
applied calibration routine is identical to the case of the direct vapor equilibration method

500 | [\(Wassenaar et al., 2008; Hendry et al., 2015, Gralher et al., 2021\) or even routine, automated](#)  
| [liquid water isotope analyses \(Werner & Brand, 2001\).](#)

Although pure N<sub>2</sub> as a carrier gas would have been cheaper, we used synthetic air in order to maintain a consistent nitrogen-to-oxygen mixing ratio. This helped to avoid gas matrix effects previously demonstrated for CRDS instruments (Gralher et al., 2016). We found that gas\_flow rates higher than the ones previously applied (Volkman & Weiler, 2014; Volkman et al., 505 2016) immediately resulted in incomplete equilibrium between the liquid water under investigation and the obtained vapor sample (Fig. 2). This became evident by decreasing, below-saturation vapor contents as well as lighter isotope readings. On the other side, we found that even the highest gas\_flow-rates applied in this study (150 mL/min) still yielded 510 vapor concentrations (~12000 ppmv @ 21°C) that are high enough to be within the analyzer's optimum measurement range and thus enable sufficiently precise isotope measurements for resolving natural variations (URL1). At the same time, a dilution of the obtained vapor stream is obsolete under such settings as the low obtained vapor concentrations impose no risk of condensation. Of course, field sites being sampled for vapor while enduring temperatures that 515 are much higher than the lab temperature might yield too high vapor concentrations. Then even higher flow rates or the re-application of a dilution flow is necessary for compensation to avoid condensation and thus un-correctable isotope fractionation. This implies that like for other indirect, minimally invasive methods (Volkman & Weiler, 2014; Magh et al., 2022) knowledge about the temperature or maintenance of its consistency at the points of vapor 520 sampling is mandatory for interpreting the obtained isotope data. Cases where temperature differs considerably among sampling sites and/or the site of calibration standard preparation require additional correction schemes considering the temperature-dependencies of water-vapor isotope fractionation. This could be facilitated either via mathematical approaches based on the dependencies described e.g., by Majoube (1971) or via empirical approaches

525 derived from sets of calibration standards that were collected while intentionally being  
subjected to different, controlled temperatures. Calibration standards can be prepared e.g., by  
installing WIPs in evaporation-shielded, sand-filled boxes wetted with water of known  
isotopic composition as detailed in Volkmann & Weiler (2014).

The changes in isotope readings and thus deviations from equilibrium were smaller for  $\delta^2\text{H}$   
530 than for  $\delta^{18}\text{O}$  in absolute numbers (10.1‰ vs. 20.21‰, respectively) and even more so in  
relation to naturally occurring isotope variations, where changes usually exhibit an 8:1 ratio in  
meteoric waters (= slope of the GMWL, Craig, 1961). Therefore, in situ isotope assays  
relying on discrete vapor sampling for later analysis with a setup similar to the one foreseen  
here, have to ensure precise control of the applied gas flow-rates for samples and co-measured  
535 standards in order to comply with the paramount Principle of Identical Treatment (Werner  
and Brand, 2001). If the isotope ratio under investigation is optional, we recommend  
interpreting hydrogen rather than oxygen isotope ratios given the lower susceptibility  
regarding gas flow rate effects and thus a more favorable signal-to-noise ratio. In this context,  
it is quite convenient that labeling studies are more cost-efficient when using deuterium as  
540 tracer rather than oxygen-18 (Magh et al., 2022).

Flowrates through the probes, exceeding previously recommended settings (Volkmann &  
Weiler, 2014) immediately resulted in changes of vapor concentration and isotope readings  
(Fig. 2). We therefore argue that neither the previous recommended nor our newly selected  
settings result in complete isotopic equilibrium. Hence, both settings require precise control of  
545 flowrates as any uncertainty in flowrate settings translates to systematic errors in isotope  
readings. These errors are considerably higher at lower flowrates and higher for  $\delta^{18}\text{O}$  than for  
 $\delta^2\text{H}$ . Aiming at lower flowrates in order to reliably achieve equilibrium readings appears  
impractical for two reasons. Firstly, the employed analyzer's gas flow demand defines the  
minimum total gas flow. A workaround applying higher dilution flowrates would yield

550 varying vapor concentrations and thus vapor concentration effects as can be seen from the different isotope readings observed for 75mL throughflow rate with or without dilution (Fig. 2) thus potentially introducing additional errors. And secondly, applying lower flow rates contradicts the study aim of shorter filling times and thus higher sample collection frequencies and achievable temporal resolution.

555 **Material and closure type selection.** Our purpose was to find an inexpensive, yet reliable vapor sample container as an alternative to commercially available gasbags, which we found to be insufficient for our purposes either due to their large size or due to their degrading closure type. Therefore, we had inflated also other types of sample bags with pure, dry nitrogen gas. We found that only those combining laminated aluminum (Al) foil bodies and  
560 metal screw-lock valves yielded useful barriers against ambient vapor pressures (Fig. 3). These bags are mass products, originally produced for storing food or cosmetics and are much cheaper than existing diffusion-tight containers from specialized suppliers. All other tested combinations of bag materials and locks failed to prevent intrusion of ambient air which is crucial for the storage of vapor samples. This corresponds to the finding of a previous study  
565 where Al-laminated bags also performed best in avoiding evaporation from soil samples (Gralher et al., 2021). Although the number of water molecules of these samples were three magnitudes higher than in our study we were not surprised to find Al-laminated bags again ranking best in material suitability.

570 Interestingly, not only the material but also the color of the material coating the diffusive barrier appeared to play a role. Clearly, different colors are a result of different chemical complex formulas used in the production and dyeing process. Unfortunately, they seem to come with different outgassing properties and spectral interference potentials regarding the intended isotope analyses. This issue always needs to be checked in advance. The presence of certain organic compounds in a given gas sample may flaw laser-based isotope readings

575 (Brand et al., 2009; Hendry et al., 2011), some of which can be identified by changes in the spectral parameter readings of the CRDS isotope analyzer.

In the “climate chamber” experiment, we actually sampled vapor in order to test how its concentration would change when the container is subjected to extreme moisture conditions over a longer time period. Unexpectedly, we found that vapor concentrations slightly  
580 decreased over time (Fig. S1). This clearly contradicted the applied vapor concentration gradient relative to ambient conditions. Further, the extent of decrease was not affected by the canning of some of the containers as typically proposed for sampling water for dissolved gas analyses. Therefore, we argue that not only were the employed containers sufficiently diffusion-tight against ambient meteorological forcings but also a fraction of the sampled  
585 vapor must have been absorbed by the inside coating of the containers (which had been repeatedly flushed with a dry atmosphere prior to vapor sampling). We can only speculate that mixing with previously absorbed vapor led to the observed, fairly uniform enrichment in heavy isotopes for both,  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$ . Presumably, the increase in vapor concentration inside Al-laminated bags following pure nitrogen gas inflation in the first part of the material tests  
590 (Fig. 3) was mainly due to release of previously absorbed vapor rather than via diffusive intrusion from ambient.

**Field application trial.** This “conditioning” effect from previous filling or exposures would also explain why isotope data from the field-derived samples unanimously appeared to shift towards ambient air in dual-isotope space (Fig. 4). This was likely because all bags used for  
595 this part of our study had been freshly prepared. In doing so, during valve installation they had all been exposed to the same ambient air (in the lab) with a homogenous vapor isotopic composition. Apparently, that air was isotopically quite similar to the one recorded during the filling of the field samples. The proportional, systematic shift of isotope values allowed for a robust calibration scheme to be applied. This scheme used in situ and bag measurements of

600 those samples displaying extreme  $\delta^2\text{H}$  values. It reproduced the intermediate in situ isotope values representative for sampling of the bags with a precision sufficient for resolving naturally occurring variations of meteoric waters. The observed discrepancies between in situ and bag measurements indicate that the Principle of Identical Treatment needs to be followed also in terms of ambient vapor isotopic composition when preparing a batch of sample bags  
605 for the collection of unknown samples as well as co-measured standards. Additionally, we recommend using bags of identical size and inflating them to the same volume in order to maintain a uniform ratio of sample volume to internal wall area.

**Reusability of sampling bags.** Initially, we had used dry air or pure nitrogen gas in an attempt to erase the signal of previous fillings and thus avoid carryover effects when reusing  
610 the sampling bags. However, this procedure did not produce the desired outcome. Repeated measurements from identically filled bags still displayed a clear isotope pattern of the previous fillings (Fig. [S2A2](#)). The range of this pattern must be associated with the measurement uncertainty if the latest filling had been an unknown sample and would thus prevent resolving natural isotope variations. It was established before the first measurement  
615 after five days and then seemed to persist.

Therefore, we tried to find a different, easy-to-implement flushing or conditioning routine that would repeatedly enable precise vapor isotope measurements using our sampling bags. For this purpose, we systematically compared the impact of dry to moist conditioning on the measurement precision and accuracy of vapor from isotopically diverse sources. From  
620 experience, we knew that room air vapor isotope signatures are usually quite persistent on shorter timescales as necessary for filling batches of sampling bags using high-flowrate devices such as vacuum pumps. Using this unlimited resource, we were able to establish a conditioning routine that is easy to reproduce and enables the precise reproduction of in situ isotope values following impertinent calibration schemes ([Tab. Table 23](#)). In this context, the

625 low SD of isotope readings from moist-conditioned bags proved to be a far better predictor of  
conditioning efficiency than the low vapor concentration of dry-conditioned bags. We  
therefore recommend conditioning entire batches of sample bags simultaneously with a moist,  
isotopically homogeneous atmosphere prior to each isotope sampling campaign.

Further, we emphasize that for any given vapor sample an isotopic shift must be expected  
630 between collection and subsequent, lab-based analysis. This shift became apparent e.g.,  
during field application (Fig. 4) and the conditioning procedure (Fig. 6). It is characteristic  
and implicit to our method. However, it is proportional relative to the priming signal.  
Herewith, it becomes manageable through co-measuring calibration standards, prepared in  
identically pre-treated bags.

635 Our conditioning routine was performed manually and its efficiency checked after every  
conditioning iteration. However, we are confident that it can be easily automated for future  
applications and its efficiency eventually assumed reliably without measurements as a matter  
of experience. Further, it seems that for the SD being a meaningful parameter for conditioning  
efficiency, the conditioning time steps need to match the projected sample storage time. This  
640 also calls for automating the conditioning procedure.

[Our aim was to develop a low cost solution as funding might not always be available and we  
wanted to avoid the high per-unit costs of commercially available gas sampling bags.  
Moreover, diffusion-tight bags from e.g. Analyt-MTC are made from plastic coated aluminum  
foil \(<https://analyt-mtc.de/files/50/Produkte/4/Probenahme.pdf>, in German\), similar to the  
645 ones we used in our study. Therefore, similar adsorption issues must be expected due to the  
interior coating of the diffusive barrier. This means that before being readily available some  
kind of conditioning procedure would also have to be applied, even when re-using  
commercially available bags. Also, for any other sampling vessel a potential user will have to  
verify the suitability in a way similar to the one we describe: in terms of diffusion tightness.](#)

650 contamination, as well as adsorptive disturbances from the inner layer of the vessel material  
itself.

So far, we are satisfied with the outcome of our tests and the achievable precision and  
accuracy. Nonetheless, we are aware that our method is not yet ready to go and further tests  
are needed before unknown, field-collected samples can be processed. This refers not only to  
655 the issue of potential temperature discrepancies between samples and standards. Moreover,  
resulting differences in vapor concentration must be considered which likely induce  
additional challenges. The proportionality of the memory effect observed in this study, e.g.  
after applying the moist-air conditioning procedure was likely because we were able to  
facilitate a consistent ratio of collected sample size and vapor reservoir absorbed to the bags'  
660 inner walls expressible e.g. in water vapor mole fractions. The effect of changes of this ratio  
has not been tested yet nor has a mathematical correction scheme accounting for this issue  
been found. Further, we are aware that the effort that needs to be put into assembling the  
necessary components as well as into pre-sample-collection tests and conditioning might still  
have a deterring effect on potential users of our method. The same probably holds for the  
665 costly alternatives available in the market for collecting gas samples into flexible containers  
that would at least dispense with the assembly efforts. In this context, we admit that the option  
to use inexpensive off-the-shelf components as employed by e.g. Magh et al. (2022) is  
certainly appealing. Also, the option to reliably reproduce vapor isotope values after one or  
more weeks of storage remains a worthwhile goal.

670 On the other hand, weWe believe that the otherness of our method also holds several  
advantages relative to previous approaches for the collection and analysis of discrete vapor  
samples. In contrast to Havranek et al. (2020, 2022), the non-automation allows for maximum  
temporal flexibility regarding experimental designs. The spatial distribution of sampling sites  
is not limited by connectivity to a central sampling system and associated tubing lengths. As

675 all employed components are small and light-weight, they can easily be deployed even in  
terrains that are rather difficult to access. In contrast to Magh et al. (2022), the achieved  
precision and accuracy ([Tab-Table 23](#)) allow for the resolution of even fine-scaled  
environmental isotope variations. Practically, our method does not require any tools, not to  
mention specialty tools during handling or refurbishing of crimp-sealed glass bottles and the  
680 lack of consumables such as septa makes it cost-efficient. The combination of the screw-lock  
mechanism and a sufficiently large sample volume is forgiving as it allows for multiple  
measurements from one sample bag. Also, flushing and re-filling are possible without  
wearing of the closing mechanism. Using evacuated, inflatable containers renders any in-field  
flushing obsolete thus reducing sampling time and increasing feasible temporal resolution.  
685 Further, it eliminates the risk of breaking glass during transport and handling. Finally, our  
method does not require additional gas sources during analysis and allows for directly  
interpretable measurement readings without the need to identify the relevant isotope data  
section via derivation of the vapor concentration readings.

## 5 Conclusions

690 We present a new method for the collection of discrete water vapor samples in the field and  
subsequent storage and isotope analysis in the lab. After systematic material testing, we  
identified the optimum combination of inflatable bag and closure type that guarantees air-  
tightness and avoids sample contamination by material outgassing. Our custom-made method  
uses off-the-shelf components only and is easy to use, cost-efficient, sustainable and allows  
695 for multiple measurements. Further, it allows for direct interpretation of the obtained isotope  
results. The achieved precision and accuracy are not only suitable for labelling experiments  
but also sufficient for resolving natural variations of water stable isotope signatures.  
Preparation and co-measurement of calibration standards are indispensable for our approach  
in order to correct for the implicit shift of the obtained isotope signal, induced by the

700 mandatory conditioning procedure. We are convinced that the conditioning procedure can be automated, which would further reduce the per-sample workload when re-using sampling bags. The presented approach allows for collecting vapor samples from soil matrix and plant tissues in remote settings without an isotope analyzer in the field. The method therefore widens the applicability of minimally invasive in situ approaches of matrix-bound water  
 705 stable isotope observations. We are therefore confident that our method will open new observatory paths and thus contribute to novel insights in hydrology, soil science, plant physiology and related disciplines. [Future tests will have to find ways of dealing with temperature and vapor concentration discrepancies among samples during collection and relative to co-prepared standards.](#)

710 **6 Appendix A: Protocol for identifying appropriate bags**

[The procedure of testing and the requirements that had to be fulfilled in our study by the tested gas sampling bags are summarized in the protocol. Any other material or commercially available bags can also be evaluated by passing this protocol.](#)

[Table A1: Suggested test protocol.](#)

	<u>Properties tested</u>	<u>Filling bags with:</u>	<u>Aim</u>	<u>Observed instrument variable</u> <u>*L2120-i **L2130-i</u>	<u>Target value for passing test</u>
<u>Test 1</u>	<u>Diffusivity</u>	<u>dry N<sub>2</sub></u>	<u>Identify mixing with ambient air</u>	<u>Water content:</u> <u>'H2O'</u> <u>spectral gas matrix variable:</u> <u>'h2o_y_eff_a'*</u> <u>'h2o_vy'***</u>	<u>&lt; 1000 after 2 weeks</u>  <u>~1.03*</u> <u>~0.46**</u>
	<u>Spectral interference</u>		<u>Identify substances spectrally interfering with measurements, thus flaving isotope readings</u>	<u>Water content:</u> <u>'H2O'</u> <u>Stable isotopes:</u> <u>'d18O'</u> <u>'d2H'</u> <u>spectral gas matrix</u>	<u>&lt; 1000 after 2 weeks</u>

				<u>variable:</u> <u>'h2o_y_eff_a'</u> * <u>'h2o_vy'</u> ** <u>organic contamination:</u> <u>'MeOHamp'</u> * <u>'CH4_conc'</u> **	<u>~1.03*</u> <u>~-0.46**</u>  <u>~-0.00095*</u> <u>~-0.00012**</u>
Test 2	<u>Reliability</u>  <u>Only</u> <u>conducted</u> <u>when tests for</u> <u>diffusivity and</u> <u>spectral</u> <u>interference</u> <u>were passed</u>	<u>Vapor from</u> <u>3 different</u> <u>sources with</u> <u>known</u> <u>isotopic</u> <u>composition</u>	<u>Evaluate isotope</u> <u>measurement in</u> <u>respective bag type</u> <u>by calibrating</u> <u>intermediate</u> <u>validation standard</u> <u>with known and</u> <u>observed values of</u> <u>two calibration</u> <u>standards (heavy,</u> <u>light)</u>	<u>Water content:</u> <u>'H2O'</u> <u>Stable isotopes:</u> <u>'d18O'</u> <u>'d2H'</u>	<u>similar for all 3</u> <u>standards</u>  <u>Calibrated</u> <u>values should</u> <u>match known</u> <u>values with</u> <u>deviations</u> <u>&lt; 0.4 ('d18O')</u> <u>and</u> <u>&lt; 2.0 ('d2H')</u> <u>or better</u>
Test 3 (optional)	<u>Conditioning</u> <u>for re-use of</u> <u>bags</u>	<u>Room air</u> <u>(repeatedly)</u>	<u>Homogenize</u> <u>memory effect</u> <u>across entire</u> <u>sampling bag batch</u> <u>to make it</u> <u>manageable via</u> <u>pertinent calibration</u> <u>schemes</u>	<u>Water content:</u> <u>'H2O'</u>  <u>Stable isotopes:</u> <u>'d18O'</u> <u>'d2H'</u>	<u>~5000-20000</u>  <u>SD of whole</u> <u>batch of bags</u> <u>&lt;&lt; 0.4 ('d18O')</u> <u>&lt;&lt; 2.0 ('d2H')</u> <u>(see Fig. 5)</u>

715

**Appendix B: Memory effects in re-used bags.**

In re-used bags, we observed isotope data consistently trending towards the values recorded previously from the respective sample bags, although evacuated and flushed three times with dry N<sub>2</sub>. These 'memory effects' were proportional to the differences between the current and the previous bag measurement (Fig. A1).

720

Figure A1. Dual isotope plot of gasbag measurements of re-used bags 5 days (open squares) and 10 days (open triangles) after all of them being filled with a constant flowrate of 150 mL/min via a WIP from one single isotopic reservoir (filled dot). The different colors indicate the differing isotopic levels of the previous samples, stored in the respective bags.

### Author contribution

BH, SS, MR and MW designed the first part (material selection, field trial) of the experiments, BH and SS carried them out. BH and BG designed the second part (climate chamber, conditioning procedure) of the experiments, and carried them out. BH, BG and MW analysed and interpreted the data. BH and BG prepared the manuscript with contributions from all co-authors.

### Acknowledgments

The authors thank Janine Heitzmann for her tireless commitment in the lab during material testing. This work was partly funded by the priority program SPP 1685 “Ecosystem Nutrition: Forest Strategies for limited Phosphorus Resources” of the German Research Foundation

(DFG; contract numbers: GE 1090/10-1 and WE 4598/7-2) and the University of Freiburg through the Open Access Publishing funding program.
