Abstract

Methodological advancements have been made in in situ observations of water stable isotopes that have provided valuable insights in ecohydrological processes. The continuous measurement capabilities of laser-based analyzers allow for high temporal resolutions and non-destructive, minimally invasive study designs of such in situ approaches. However, isotope analyzers are expensive, heavy, and require shelter and access to electrical power which impedes many in situ assays. Therefore, we developed a new, inexpensive technique to collect discrete water vapor samples in the field via diffusion-tight inflatable bags that can later be analysed in the lab. In a series of structured experiments, we tested different procedural settings, bag materials, and closure types for diffusion-tightness during storage as well as for practical handling during filling and extraction. To facilitate re-usage of sampling bags, we present a conditioning procedure using ambient air as primer. In order to validate our method, direct measurements through hydrophobic in situ probes were compared to repeated measurements of vapor sampled with our bags from the same source. All steps are summarized in a detailed SOP. This procedure represents the preparation and measurement of calibration and validation vapor standards necessary for processing of unknown, field-collected vapor samples in the foreseen application. Performing pertinent calibration procedures, accuracy was better than 0.4‰ for $\delta^{18}\text{O}$ and 1.9‰ for $\delta^2\text{H}$ after one day of storage. Our technique is particularly suitable in combination with minimal-invasive water vapor sampling in situ probes that have already been employed for soils and tree xylem. It is an important step towards minimally invasive monitoring of stable isotope distributions and also time-series in virtually undisturbed soils and trees without the need to have field-access to an analyzer. It is therefore a promising tool for many applications in eco-hydrology and meteorology.

1 Introduction

Analyses of stable isotope composition of hydrogen and oxygen ($\delta^2\text{H}$ and $\delta^{18}\text{O}$) in soils and plant water have proven to be powerful tools and are therefore widely employed in ecology, hydrology, and related disciplines. Stable isotopes of pore water have been used to provide insights into soil evaporation (Zimmermann et al., 1967;

Allison, 1982; Allison et al., 1983; Barnes and Allison, 1988; Walker et al., 1988) and groundwater recharge rates (Dincer et al., 1974; Saxena, 1984; Darling and Bath, 1988, Koeniger et al., 2016). They were used in soil hydrology to study unsaturated and saturated subsurface flow processes, mixing and residence times (Sklash and Farvolden, 1979; Buttle and Sami, 1990; McDonnell, 1990; Stewart and McDonnell, 1991; Gazis and Feng, 2004; Laudon et al., 2004; Garvelmann et al., 2012; Beyer et al., 2016), and to quantify evapotranspiration partitioning (Brunel et al., 1997; Hsieh et al., 1998; Yepez et al., 2005; Rothfuss et al., 2010; Wang and Yakir, 2000; Dubbert et al., 2013; Quade et al., 2019). Applications of water stable isotopes in ecology have allowed researchers to identify plant water sources (Dawson and Ehleringer, 1991), to describe water use patterns (Schwinning et al., 2002), and to determine competitive interactions (Ehleringer et al., 1991, Meißner et al., 2012). In plant physiology, insights into plant hydraulic architecture (Drake and Franks, 2003) were possible with isotope techniques, root water uptake was quantified (Rothfuss and Javaux, 2017; Fan et al., 2017; Seeger and Weiler, 2021) as well as hydraulic lift (Caldwell and Richards, 1989; Meunier et al., 2018).

Conventionally, measurements of pore water and tree xylem water isotope composition are obtained through destructive sampling of soil cores or manual collection of sapwood and subsequent water extraction for isotope ratio mass spectrometry (IRMS) analysis (Ehleringer et al., 2000, West et al., 2006) or Isotope Ratio Infrared Spectrometry (IRIS) (Baer et al., 2002; Gupta et al., 2009). These instruments allow for high measurement precision (Horita and Kendall, 2004), but are comparably expensive in the case of IRMS and generally require highly time-consuming and laborious sample pre-treatment (Kerstel and Gianfrani, 2008). A less expensive and overall more convenient approach relying on laser-based water stable isotope analyzers is the direct vapor equilibration laser spectrometry (DVE-LS) where samples of soil matrix, rocks or plant tissue are in equilibrium with a corresponding vapor phase (Wassenaar et al., 2008; Hendry et al., 2015; Gralher et al., 2021).

Although promising, the disadvantage is still that destructive soil sampling or harvesting of plant material generally prevents repeated samples from the exact same position. Additionally, repeated sampling of xylem imposes the risk of killing the tree or weakening it due to fungal infestation. Moreover, taking branch samples can be challenging or even impossible for tall trees. Generally, destructive sampling restricts the number of samples that can be obtained over time and space. This makes high-frequency or even continuous measurements difficult to sustain or simply infeasible. Number and spatiotemporal scope of lab-scale experimental setups as well as environmental isotope studies continued to expand, but were still limited by the available indirect observational techniques (West et al., 2010).

The growing distribution of laser-based water stable isotope analyzers in recent years also enabled minimal-invasive, direct, continuous, and simultaneous measurements of $\delta^2\text{H}$ and $\delta^{18}\text{O}$ of water vapor. Only herewith, time series observations from the same point became possible. Available IRIS instruments allow for measurements at a precision and accuracy comparable to that of IRMS (Berden et al., 2000; Baer et al., 2002; 65 Crosson, 2008; Kerstel and Gianfrani, 2008; Gupta et al., 2009). Importantly, laser-based instruments are portable and therefore potentially field-deployable. Especially the small measurement cavity size (35 mL) of wavelength-scanned cavity ring-down spectroscopy (WS-CRDS) instruments makes them ideal for lab-scale experimental setups as well as for small sensor designs. The spread of laser-based instruments has therefore stimulated recent developments of a number of in situ methods for direct measurements of water stable isotopes 70 in various fields. Precipitation measurements were carried out via gas-permeable ePTFE surgical tubings (Munksgaard et al., 2011). Soil column breakthrough curves (Herbstritt et al., 2012) as well as analyses of precipitation and canopy throughfall in parallel were achieved via small hydrophobic membrane contactors (Herbstritt et al., 2019). The isotopic composition of pore water was analysed in lab-scale experiments via hydrophobic microporous tubings (Rothfuss et al., 2013) as well as in natural soil profiles with custom-made 75 hydrophobic porous in situ water isotope probes (WIPs) (Volkman and Weiler, 2014). Similar in situ probes were also used in tree stems in labelling experiments to analyze the isotopic composition of xylem sap (Volkman et al., 2016a; Seeger and Weiler, 2021). The 'stem borehole method' (Marshall et al., 2020; Kühnhammer et al., 2022) is an alternative way to obtain in situ samples of tree xylem water vapor. Measurements of the isotopic composition of transpired water were conducted using leaf chambers (Wang et al., 80 2012; Dubbert et al., 2014) or whole-plant chambers (Volkman et al., 2016b).

The isotopic composition of the liquid water of interest in all these in situ studies was inferred from sampling and measuring a corresponding vapor phase. Water vapor of interest was either withdrawn directly e.g. from soil profiles, out of tree boreholes, or exchange and equilibration with a carrier gas through different types of hydrophobic membranes were facilitated.

85 However, operating laser-based analyzers at the study site requires power-consuming, heavy and expensive equipment to be brought to the field with the risk of damages and the disadvantage of relative immobility. Consequently, rough or remote terrains as well as spacious experimental designs, exceeding possible tubing lengths between in situ measurements and the isotope analyzer are virtually excluded with this approach. First attempts to overcome these obstacles by collecting discrete vapor samples under such circumstances into glass 90 bottles were recently presented. In both approaches, the sampled vapor had to be diluted continuously during

measurement, to compensate for negative pressure when sucked into the analyzer by releasing e.g. dry air into the rigid, fragile sampling flasks. The first approach (Havranek et al., 2020) can be seen as a proof of concept. In a follow-up, Havranek et al. (2022) describe a field application of their setup which requires considerable financial resources for the components in use, extensive technical know-how for construction as well as substantial effort for field installation of a limited number of flasks. Their recommended operation procedure requires long flushing times, leading to filling times per flask of more than one hour, which strongly reduces the sample throughput and thus the achievable temporal resolution. The second approach (Magh et al., 2022) partly resolved these issues but still relies on specialty tools, lacks reproducibility due to the small volume of sampled vapor and currently does not provide the data accuracy needed for natural abundance isotope assays. Further, a sophisticated calculation procedure is necessary for both approaches (Havranek et al., 2020; Magh et al., 2022) to remove the effects of the initial pulse of water vapor during the start of the measurement phase. This initial pulse is mixed with pre-sample vapor which clearly biases the obtained isotope data.

Therefore, the aim of this study is to develop a technique to collect discrete vapor samples in the field for subsequent lab-based analyses, that overcomes the aforementioned problems while still ensuring handiness as well as cost and time efficiency. Specifically, we identified a way to prepare and measure calibration and validation vapor standards, necessary for processing unknown, field-collected vapor samples. For this purpose, we varied the applied gas flowrate through established non-destructive in situ water isotope probes (WIPs) to improve per-sample time consumption. We tested the diffusion-tightness and inertness of various commercially available gas sampling bags as well as custom-made inflatable containers comprising different materials and closing mechanisms. We identified the best performing bags and coupled it with WIPs in order to collect and temporarily store discrete vapor samples prior to lab-based isotope analyses. Also, we identified necessary preparatory steps to optimize the reproduction of in situ data.

Figure 1. Schematic of projected vapor sampling via in situ (a) soil- and (b) xylem-water isotope probes (modified from Volkmann and Weiler, 2014 and Volkmann et al., 2016a). The left part describes the intended field setting while the right part describes the intended laboratory setting: sampled vapor is first filled into appropriate, to-be-identified containers (X) and later analyzed in the lab via CRDS.

2 Methodology

2.1 Effect of changing gas throughflow rates on the isotopic composition

In the first part of this study we tried to optimize sample filling times. For this purpose we investigated the effect of varying gas flowrates through the to-be-employed in situ water isotope probes (WIPs). Originally, the size of the probes was optimized i.e. the contact area of the membranous tip, to facilitate isotopic equilibrium when the applied flow rates had been set to match the analyzer's demand. This analyzer-immanent prerequisite becomes obsolete for the collection of discrete vapor samples. In the case of discrete vapor sampling through WIPs into air-tight containers, any other flowrate can be selected, which inversely affects the filling times of the containers. It is important that the contact area relevant for vapor collection is consistent for all sample collections as isotope equilibrium cannot be expected anymore when the applied gas flowrates exceed the ones originally recommended (Volkmann and Weiler, 2014). For repeated analysis of a single vapor sample we found a total gas sample volume of 0.5 - 1 L to be sufficient (Gralher et al., 2021). Further, we aimed at sampling times in the field of no more than 5 minutes per sample. Therefore, flowrates of both dry air through the WIP and the corresponding gas sampling rate into the containers were increased stepwise in a lab experiment up to 150 mL/min which would yield 0.75 L sample volume after a filling time of 5 min. We also tested the effects of

omitting the originally proposed dilution (Volkman and Weiler, 2014) when increasing the throughflow rates. In order to keep the gas flow inside the WIP balanced between the inflowing carrier gas and the outflowing sampling gas and in doing so avoid over- or under-pressure, the sampling rates had to match the throughflow rates. For these tests a WIP was installed in an evaporation-shielded box filled with moist sand with a water stable isotopic composition of -9.64‰ and -66.84‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively, referenced to the VSMOW-SLAP scale (Craig, 1961a) and kept at a constant temperature of 20.8 °C. For precise isotope measurements we used dry synthetic air ('zero air') as carrier gas.

Precise flowrates of the synthetic air from the pressurized gas bottle into the WIP were facilitated by a digital mass flow controller (PN 35828, Analyt-MTC, Müllheim, Germany), while sampling at the same flowrate was facilitated by a small air pump (PN LP27-12, Pollin Electronic GmbH, Pförring, Germany) where the pumping rate can be controlled manually via the applied voltage and controlled with a mass flow meter (PN 35808, Analyt-MTC). The fractions of sampling rates exceeding the analyzer demand of ~ 35 mL/min were vented to air through an open split near the sample inlet port of the isotope analyzer (L2120-*i* or L2130-*i*, Picarro Inc., Santa Clara, CA, USA). The analyzer provided quasi-continuous (0.5 Hz) readings of water vapor mixing ratio (in ppmv), oxygen and hydrogen isotope readings (in ‰), and the spectral parameters 'h2o_vy' indicating mixing with ambient air and 'organic_MeOHamp1' indicating spectral interference from the bag material, which we also collected from room air on every day of bag measurements. This setup allowed for facilitating the demanded low and constant stream of gas to the analyzer while at the same time arbitrarily varying the gas flow through the attached WIP.

2.2 Material selection

2.2.1 Diffusivity and spectral interference

Rigid glass or steel bottles and cylinders conventionally used for gas sampling were excluded in our approach, since constant flow through the WIPs was needed in our setup and under-pressure at the analyzer during measurements has to be avoided. Commercially available gasbags with large volumes (10 L) are available with reusable gas valves in opposite to bags with smaller volumes (0.5 L – 2.5 L), which come with septa or other degrading closures. Hence, none of these combinations were suitable for our purposes, either due to their size or due to the type of closure. Other readily available gas sampling bags made of PTFE or laminated aluminum foil from a different supplier were available in appropriate sizes but were available only in minimum order quantities of 10. Their per-order costs ranged between €200 and €350 depending on bag material which were prohibitive for our purposes. Therefore, we investigated three different inflatable bags of different materials and reasonable

sizes and combined them with different reclosable caps and valves (Table 1). Additionally, a 2.5 L commercially available gasbag was equipped with a stainless steel screw-lock valve and also tested. Specifically, we evaluated whether they were sufficiently reliable in terms of diffusion-tightness and chemical inertness, also focusing on easy handling. The criteria for identifying reliable bags or bag material are summarized in a best-practice protocol (SOP) in the Appendix of this manuscript.

The different bag types were filled with pure N₂ (purity 99.996%) and analyzed immediately thereafter with a CRDS isotope analyzer (L2130-*i*, Picarro Inc., Santa Clara, CA, USA). We tested PE spoutbags (code ‘PE-Sp’, PN 1055) and single layer metalized spoutbags (code ‘Al-Sp’, PN 1050, both available from Daklapack Europe, Oberhausen, Germany), of which we replaced the original PE spout caps by caps with rubber septa. Filling and continuous vapor isotope analyses were facilitated through these septa via an infusion needle (ID = 1 mm) assembled to a 1/8” perfluoroalkoxy alkane (PFA) tube. We also tested two kinds of 3-layer metalized zip bags with fill volumes of 1 L (PN: CB400-420BRZ, color: red) and 0.5 L (PN: CB400-310GZ, color: gold, both available from Weber Packaging GmbH, Güglingen, Germany). They were heat-sealed and equipped with silicone blots on the outside, which served as septa after 2 days of drying (code ‘Al3-Sil’ for the 1 L bag, code ‘Al3g-Sil’ for the 0.5 L bag). The bags were filled and their content withdrawn for isotope analysis through the silicone septa again via an infusion needle assembled to a 1/8” PFA tube.

To improve handiness and simplify filling and sample analysis when using the 3-layer metalized bags, we tested two different types of valves as alternatives to our custom-made silicone septa. With a punching tool, a hole was applied to each bag for the respective diameter of the screw connections. We fixed small pneumatic brass couplings (PN KDG M5 NW2,7, Landefeld, Kassel, Germany) on the 3-layer metalized 1 L zip bags (code ‘Al3-PC’), which were then heat-sealed. The respective plug connector (PN KSGI M5 NW2,7, Landefeld, Kassel, Germany) was connected to a 1/8” PFA tube for filling and analysis. Also stainless steel screw-lock gasbag valves with 6 mm hose fittings (PN 11701150, Linde, Pullach, Germany) were mounted on 0.5 L and on 1 L 3-layer metalized zip bags (codes ‘Al3s-GbV’ and ‘Al3-GbV’) after punching a 10 mm hole. For increased leak-tightness we mounted an additional, custom-made rubber washer between the valve and the inner wall of the bags which were then heat-sealed. For filling as well as sample analysis the 6 mm hose fitting was adapted to a 1/8” PFA tube.

Table 1. Bag- and seal-type combinations and their properties tested for vapor sampling.

Code	Material	Bag style	Vol	Closure, cap or seal type	Inflation, filling, sampling via...
PE-Sp	PE	spoutbag	1 L	PE screw cap w/ rubber septum	Infusion needle and 1/8” PFA tube

Al-Sp	Al	spoutbag	1 L	PE screw cap w/ rubber septum	Infusion needle and 1/8" PFA tube
Al3g-Sil	Al 3ply gold	Zip bag	0.5 L	Silicone blot as septum	Infusion needle and 1/8" PFA tube
Al3-Sil	Al 3ply red	Zip bag	1 L	Silicone blot as septum	Infusion needle and 1/8" PFA tube
plastigas®	Al 3ply silver		2.5 L	Stainless steel screw-lock valve	Hose fitting adapted to 1/8" PFA tube
Al3-PC	Al 3ply red	Zip bag	1 L	Pneumatic brass coupling	Plug connector and 1/8" PFA tube
Al3-GbV	Al 3ply red	Zip bag	1 L	Stainless steel screw-lock valve	Hose fitting adapted to 1/8" PFA tube
Al3s-GbV	Al 3ply silver	Zip bag	0.5 L	Stainless steel screw-lock valve	Hose fitting adapted to 1/8" PFA tube

To detect gradual diffusive exchange of the bag content with ambient air or outgassing from the employed material, 3 to 5 replicates of each bag/valve combination were flushed with N₂ and evacuated twice before they were again filled with pure N₂. They were then stored at ambient temperature and repeatedly analyzed over the course of four weeks. Measurement frequency was every two to three days during the first two weeks and one final time at the end of the fourth week, unless a bag/valve combination was found unsatisfactory earlier.

2.2.2 “Climate chamber” experiment

To further test the vulnerability of projected discrete vapor samples, i.e. to test if relative humidity outside of the bags can exchange with and thus flaw the sample inside the bag, we designed a small “climate chamber” which consisted of a plastic box (inner dimensions 57 cm × 37 cm × 32 cm) covered by a plastic lid with all holes and slits taped. We prepared six ‘Al3s-GbV’ bags filled with vapor from the same source (described in detail in 2.3). Three bags were placed in the box straightforward while the other three were inserted in metal cans of the bags’ size prior to placement in the box. Such metal cans are normally used for the transport and storage of glass bottles containing liquid water sampled for dissolved gases analysis. They are considered diffusion-tight when closed and sealed by means of metal lids, rubber seal rings, and metal clasps as we did. Inside the box we also placed an open bowl of water (ca. 350 mL) to quickly reach and then maintain a relative humidity near 100% over the course of the test which lasted three weeks. The box was deposited in the basement of our laboratory building to facilitate fairly stable temperature conditions. Temperature (°C) and relative humidity (%) inside the box were recorded every ten minutes with a CS215 probe connected to a CR200 logger (both from Campbell Scientific, Logan, UT, USA). These data were then converted to water vapor mixing ratios using Magnus’ equation (Foken, 2008). Vapor concentration (ppmv) and isotope ($\delta^{18}\text{O}$, $\delta^2\text{H}$) data from the vapor source used for filling the bags, from the inside of the box after 20 days, and from all canned and un-canned bags after 20 days of storage inside the box were collected with a Picarro 2120-*i*.

2.3 Field trial

215 We tested the reliability of the projected sampling procedure first in a laboratory experiment and later in the field
using ‘Al3-GbV’ bags. For this purpose, four evaporation-shielded boxes ($V = 18$ L) with moist sands with
similar water contents but different water isotopic compositions were prepared and a WIP (Volkman and
Weiler, 2014) was installed in each of the boxes to sample their soil water vapor. We used a low-weight
sampling setup that provided a constant air flow of 150 mL/min with the small pumps described above (section
220 2.1). The incoming stream of ambient air was dried by a ‘Drierite’ drying column (PN 26800, W. A. Hammond
DRIERITE Co. Ltd., Xenia, OH 45385, USA) and directed through the throughflow line into the porous tip of
the WIP. The vapor generated inside the WIP was withdrawn through the sampling line by a second small pump
with the same gas flowrate. The stream of sampled vapor was directed to the isotope analyzer (demanding
35 mL/min), using an open split for excess vapor (115 mL/min) near the analyzer’s sample inlet port.
225 Immediately after the direct measurement, the analyzer was disconnected and the setup was used for directing
the entire gas stream into the bags. Additionally, ambient vapor data were collected with the isotope analyzer.
Replicates of sampled vapor were filled in bags, which were then analyzed two hours later. Calibration was
facilitated using in situ and bag measurements of those samples displaying the highest and the lowest $\delta^2\text{H}$ values,
treating these in situ values de facto as standards. This selection was maintained for calibration of $\delta^{18}\text{O}$ values,
230 too, although that meant that the so-selected standards did not “bracket” the to-be-calibrated “samples” as is
common best practice. The precision would be the standard deviation of repeated calibrated isotope readings of
the samples displaying intermediate $\delta^2\text{H}$ readings. The accuracy would be the deviation of the calibrated mean of
replicates of the respective in situ measurements. Note that this led to the reproduction (validation) of the
intermediate in situ values rather than liquid water values referenced to the VSMOW-SLAP scale (Craig, 1961a).
235 The derivation of liquid water values from vapor isotope observations has been described in Volkman and
Weiler (2014).

2.4 Reusability of sampling bags

2.4.1 Flushing attempts

To test the reusability of the bags, we applied the following flushing procedure. ‘Al3-GbV’ and ‘Al3s-GbV’
240 bags were filled with pure N_2 , evacuated immediately thereafter with a LABOPORT® diaphragm vacuum pump
(N810.3 FT.18, KNF Neuberger GmbH, Munzingen, Germany) and filled again with pure N_2 . On the next day
they were evacuated again, filled with pure N_2 again and evacuated one final time. After these preparatory steps,
3-5 bag replicates were used for sampling vapor from sources both isotopically different and identical to the ones

that had been sampled before with the respective bags. The setup used for this purpose was identical to the one
245 described in Section 2.3 except that different diaphragm gas pumps (BOXER 22K, Boxer, Ottobeuren,
Germany) were used. Vapor concentration and isotope data of the bags were recorded with a Picarro L2120-*i* 1,
3, and 7 days after vapor sampling.

2.4.2 Conditioning

We additionally tested the reusability of the bags by comparing two ways of conditioning previously used
250 sampling bags. The first way was by filling a batch of bags with dry synthetic air, leave them filled for at least
one day, analyze their vapor concentration and isotope signature with a Picarro L2120-*i*, evacuate them, fill them
again, and repeat this cycle several times. The second way was identical except that moist, isotopically
homogeneous air was used for filling and priming. In both cases the absolute vapor concentrations and the
standard deviations (SD) of isotope readings from repeated batch measurements were considered as predictor for
255 conditioning efficiency. Efficiency was then scrutinized by using the so-conditioned bags for collecting vapor
samples from isotopically diverse sources (setup details in 2.3) followed by repeated analyses over the course of
up to seven days. Mean vapor isotopic compositions of these sources were -20.41, -29.32, and -37.24 for $\delta^{18}\text{O}$
and -84.95, -139.53, and -195.77 for $\delta^2\text{H}$. Again, calibration was facilitated using bag measurements of those
samples with the highest and lowest isotope values and their respective in situ measurements. We report
260 precision and accuracy as quality measures of the calibration process. The reported precision is the SD of the
repeated calibrated isotope readings of the intermediate source which we consider as validation standard while
the reported accuracy is the deviation of the calibrated mean of repeated measurements from the respective target
value which are the isotope readings from the respective in situ measurements.

3 Results

265 3.1 Effect of changing gas throughflow rates on the isotopic composition

With increasing flowrates through the WIP, the vapor content originating from the source water decreased in the
sampling gas (Fig. 2). At the same time, the isotopic composition for both isotope ratios under investigation
changed, indicating that no equilibrium between the source water and the provided dry gas stream was
established inside the WIP. Such kinetic fractionation effects could be observed at all flowrates exceeding the
270 originally proposed equilibrium flowrate from Volkmann and Weiler (2014). They were stronger for $\delta^{18}\text{O}$ than
for $\delta^2\text{H}$. The induced decreasing vapor contents were strongly correlated with decreasing isotopic signatures. In
the case of the WIP operated with proportional dilution and throughflow rates, vapor content ranged from 10325

to 14432 ppmv, while the concurrent uncalibrated isotope readings were in a range of -18.92‰ to -30.99‰ in the case of $\delta^{18}\text{O}$ and -136.85‰ to -143.41‰ in the case of $\delta^2\text{H}$. The heaviest values of these ranges correspond to the settings originally proposed by Volkmann and Weiler (2014). These changes correspond to change rates of 0.241‰/(mL/min) for $\delta^{18}\text{O}$ and 0.131‰/(mL/min) for $\delta^2\text{H}$. Similar observations were made for the case when dilution was set to zero at higher flowrates. Here, the vapor content ranged from 12256 to 20041 ppmv while the uncalibrated isotope readings varied between -30.35‰ and -39.13‰ in the case of $\delta^{18}\text{O}$ and between -143.23‰ and -146.95‰ in the case of $\delta^2\text{H}$. Here, the changes correspond to change rates of 0.117‰/(mL/min) for $\delta^{18}\text{O}$ and 0.049‰/(mL/min) for $\delta^2\text{H}$. Vapor was always sampled from the same liquid water source which had an isotopic composition of -9.64‰ and -66.84‰ for $\delta^{18}\text{O}$ and $\delta^2\text{H}$, respectively, referenced to the VSMOW-SLAP scale (Craig, 1961a). All coefficients of determination (R^2) between vapor content and isotope readings were greater than 0.99. At the target flowrate of 150 mL/min throughflow and 0 mL/min dilution vapor content was close to 12,000 ppmv at 20.8 °C (Fig. 2).

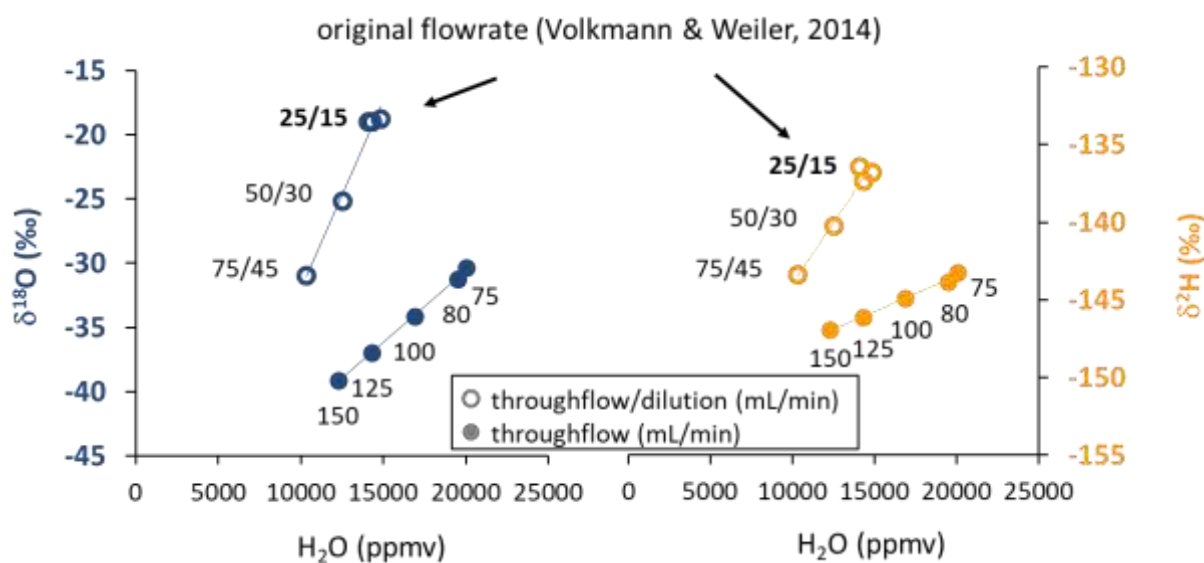

Figure 2. Scatterplot of water vapor isotopic composition (left: $\delta^{18}\text{O}$, right: $\delta^2\text{H}$) and vapor content obtained by varying gas throughflow rates with (open symbols) and without (closed symbols) dilution at a constant temperature. This pattern illustrates the kinetic fractionation effects with increasing flowrates through the probe. The numbers refer to the respective gas flowrates applied as throughflow/dilution or throughflow-only during the tests. The flowrates originally proposed by Volkmann and Weiler (2014) facilitated equilibrium according to the design of the probe's tip size and the known instrument flowrate.

3.2 Material selection

3.2.1 Diffusivity and spectral interference

Diffusion-tightness and long-term storage effects. During the test for diffusion-tightness the water vapor content readings of the ambient air in the lab were in a range of 9000 – 18000 ppmv while inside the bags they were initially close to zero due to pure N₂ inflation. Over time, these vapor pressure gradients were gradually levelled out with different rates. This is qualitatively evident from the different slopes of the dashed lines (Fig. 3). PE spout-bags ‘PE-Sp’ displayed the highest increase when after three days the vapor content had already increased by ~7000 ppmv. Vapor content readings in the metalized spout-bags ‘Al-Sp’ were ~4000 ppmv after three days. 3-layer metalized bags displayed the lowest vapor increase rate. Design and thus air-tightness of these bags differed only with the type of septum or valves used. The vapor content readings in the bag-types with the silicon blot (‘Al3-Sil’) were ~1200 ppmv after four days.

Only for the better performing bag/valve combinations (‘Al3-PC’, ‘Al3-GbV’ and ‘Al3s-GbV’) we extended the vapor content measurements up to four weeks. After this period, mean vapor content readings in ‘Al3-PC’ and ‘Al3-GbV’ bags were ~3000 ppmv and ~1450 ppmv, respectively. Mean vapor content readings in ‘Al3s-GbV’ bags were ~420 ppmv after two weeks, which was the final value possible for this bag type due to its smaller volume.

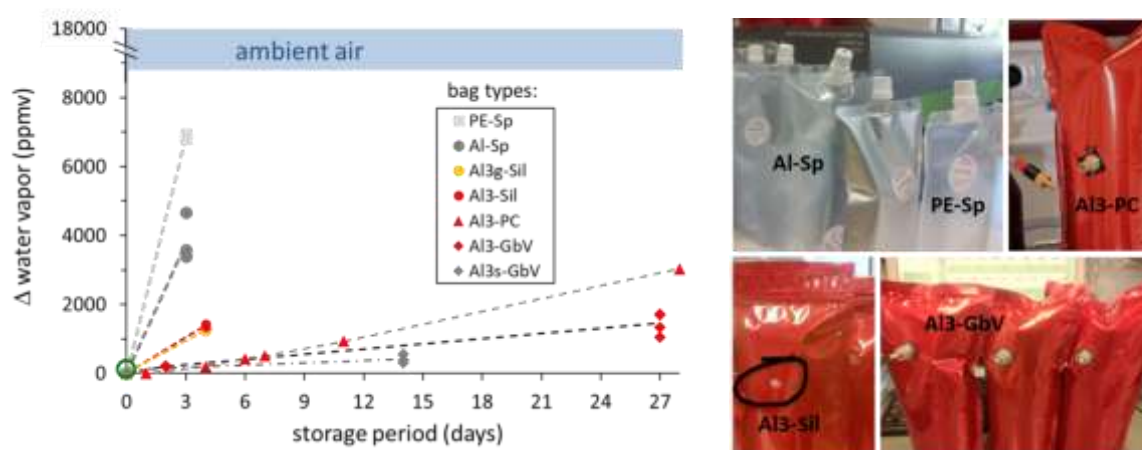

Figure 3. Left panel: Time series of vapor content readings inside different bag types (closed symbols), initially filled with pure N₂ (green open circle). Right panel: Example pictures of tested sampling bags.

Spectral interference of outgassing material. In two bag types, deviations of the spectral parameters from the pure N₂ signal were found, which were also correlated with the respective isotope readings. The spectral line width variable indicative for gas composition (‘h2o_vy’) is 0.4309 ± 0.0015 ppm on our L2130-*i* analyzer for air

containing oxygen at atmospheric levels, while it is 0.4563 ± 0.0049 ppm for pure N₂. Vapor concentration of
 315 bag-type ‘Al3g-Sil’ containing pure N₂, was below 2000 ppmv and should therefore plot at a h2o_vy value of
 about 0.46 ppm like the bags ‘Al3-Sil’ (same material but different color), but evolved towards 0.43 ppm.
 Simultaneously, apparent enrichment in heavy isotopes was observed in ‘Al3g-Sil’ bags with an increase of
 around 80‰ in δ¹⁸O and 150‰ in δ²H, compared to samples stored in ‘Al3-Sil’ bags.

In the commercially available 2.5 L plastigas® bag equipped with a gasbag valve (PN 11701150, Linde)
 320 (combination not featured in Fig. 3), we observed an apparent depletion in δ²H from -190‰ to -305‰ after 24h
 and to -360‰ after 72h. At the same time a spectral variable recorded on the L2120-*i* analyzer, indicating
 potential contamination with organic compounds (‘organic_MeOHamp1’), increased to 0.00760 ± 0.00014 after
 24h and to 0.01005 ± 0.00012 after 72h. The initial value was 0.00095 ± 0.00026 which was also observed in
 ambient air. We therefore also excluded ‘Al3g-Sil’ and ‘plastigas®’ bags from further testing due to the
 325 observed spectral interferences. Further tests and isotope samplings in our study were conducted with ‘Al3-GbV’
 or ‘Al3-GbV’ bags only. The performance of the different bag materials in the tests is summarized in Table 2.
 The protocol for testing bags and material properties and the respective target values for passing the tests can be
 found in Appendix A.

3.2.2 “Climate chamber” experiment

Temperature was quite stable inside the climate chamber, as intended. It ranged between 18.1°C and 16.3°C. Relative humidity rose to > 97% within 6 hours and maintained on average at 99.5% throughout the remaining observation period, which translated to vapor mixing ratios of 19972 ± 519 ppmv. Mean vapor contents from the source were 14365 ppmv during filling and 12574 ppmv inside all bags after 20 days. Differences in mean vapor contents between canned and un-canned bags were smaller than the respective variations within the two batches. Isotope readings of all bags appeared to be enriched by 2.9‰ in $\delta^{18}\text{O}$ and 15.0‰ in $\delta^2\text{H}$ relative to the source, again with negligible differences between the two batches (data shown in Supplement Fig. S1).

3.3 Field trial

When comparing all isotope data of the direct in situ sampling from the sand boxes in the field with the data from vapor sampled into the bags and measured 2 hours later, we found no systematic bias towards congruent enrichment or depletion in heavy isotopes. Instead, all raw isotope data of the bag measurements appeared to be shifted towards ambient air values by -0.6 to +1.6‰ for $\delta^{18}\text{O}$ and +4 to -5‰ for $\delta^2\text{H}$ relative to their respective in situ measurements. We used isotope readings of in situ and bag measurements from the samples displaying extreme $\delta^2\text{H}$ values for calibration. Thereby, in situ values of the intermediate samples could be reproduced by calibrated bag measurements with a precision of 0.15‰ and an accuracy of 0.8‰ for $\delta^{18}\text{O}$. The respective numbers for $\delta^2\text{H}$ were 0.76‰ and 2.89‰ (Fig. 4).

Figure 4. Isotope data from in situ measurements (filled symbols), raw bag measurements (orange and brown open symbols), and calibrated in situ data calculated from bag measurements (blue and cyan open symbols) using in situ (cyan closed symbols) and raw values (brown open symbols) of sources displaying extreme $\delta^2\text{H}$ values. Ambient vapor at that day is displayed as a blue open diamond.

355 **3.4 Reusability of sampling bags**

3.4.1 Flushing attempts

Generally, isotope data obtained from repeated measurements of the bags unanimously trended towards the values recorded previously from the respective sample bags. These trends increased over time and changes were proportional to the differences between current in situ and previous bag measurements on the individual bag
360 level. Such memory effects persisted although the bags had been evacuated and flushed three times with dry N_2 prior to vapor sampling. The trends were consistent for all tested bag types and appeared to be independent from concurrent ambient air values for both isotope ratios investigated (data shown in Appendix Table A1).

3.4.2 Conditioning

The two different conditioning methods (dry and moist) applied to previously used sample bags yielded contrary
365 results. Conditioning with dry synthetic air caused vapor content readings to decrease stepwise down to 324 ppmv (Figure 5a) while isotope signatures became more enriched (isotope data shown in Supplement Fig. S2). Their SDs generally decreased but remained above 2.9‰ for $\delta^{18}\text{O}$ and 18.8‰ for $\delta^2\text{H}$ (Figure 5b). In contrast, conditioning with moist air resulted in vapor content readings to decrease to 6740 ppmv, which was in the order of the level of conditioning. Isotope signatures of so-primed bags clustered around the conditioning values (data
370 shown in Supplement Fig. S3) with SDs decreasing to 0.05‰ for $\delta^{18}\text{O}$ and 1.07‰ for $\delta^2\text{H}$ after 4 to 5 steps (Fig. 5b).

Figure 5. Vapor content readings (a) and SDs of isotope readings (b) from vapor sampling bags, stepwise conditioned with dry synthetic air (light plus symbols) and moist air (dark cross symbols). Light and dark diamond symbols on vertical axes represent mean values of pre-conditioning sample measurements.

Re-using the conditioned bags for sampling vapor from isotopically diverse sources also yielded contrasting results. SDs of isotope readings in bag replicates after dry conditioning were larger than after moist conditioning. Repeated measurements generally resulted in a decline of measurement precision and accuracy of mean isotope values (Fig. 6). Comparing in situ values with bag measurements yielded no consistent picture in the case of dry conditioning (Fig. 6a) whereas in the case of moist conditioning a bias towards the conditioning values became evident which increased over time (Fig. 6b). One day after filling, raw isotope data of the bag measurements deviated by -0.6 to +1.6‰ for $\delta^{18}\text{O}$ and +4 to -5‰ for $\delta^2\text{H}$ relative to their respective in situ measurements. Calibration for reproduction of the intermediate in situ values worked better for moist- than for dry-conditioned bags. This refers to the precision as well as to the accuracy (Table 3).

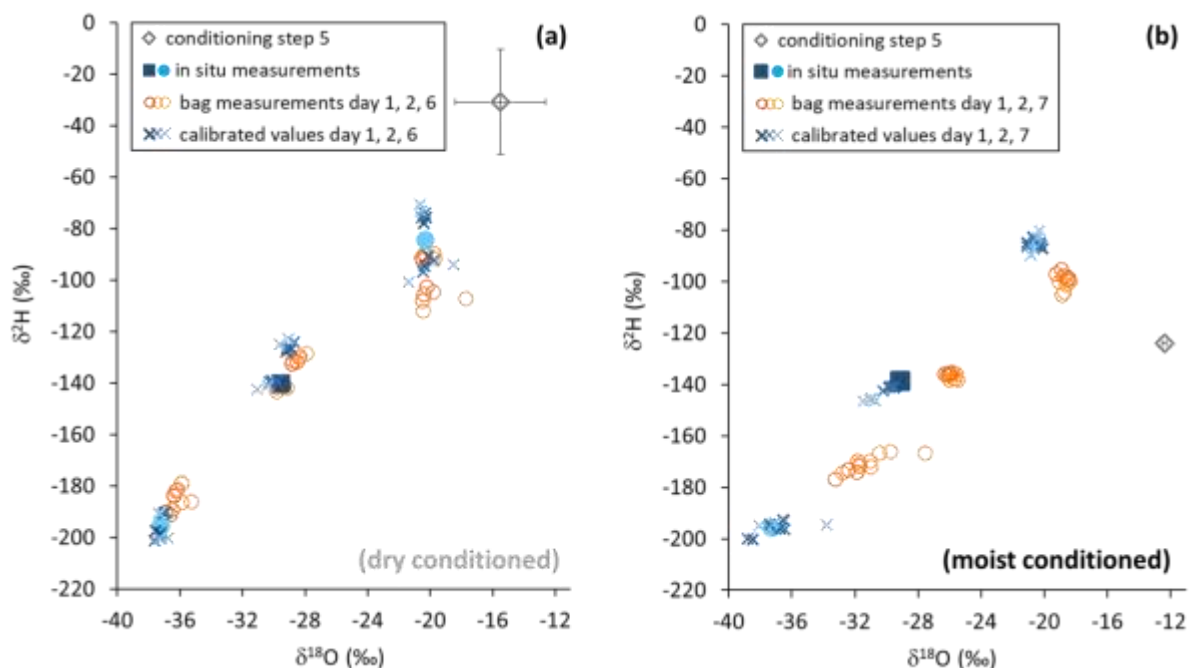

Figure 6. Isotope data from in situ measurements (filled symbols), gasbag measurements (open circles), and in situ data calculated from gasbag measurements (asterisks) after conditioning with a dry (a) and moist atmosphere (b). Pre-sampling levels are represented by gray diamonds. Note that error bars (black) are smaller than the symbol in the case of moist conditioning (b).

Table 3. Conditioning effects on vapor stable isotope measurements from re-used sampling bags.

Day after sampling	Analysis iteration	Dry atmosphere conditioning				Moist atmosphere conditioning			
		$\delta^{18}\text{O}$ (‰)		$\delta^2\text{H}$ (‰)		$\delta^{18}\text{O}$ (‰)		$\delta^2\text{H}$ (‰)	
		precision	accuracy	precision	accuracy	precision	accuracy	precision	accuracy
1	1	0.58	-0.10	6.71	-7.16	0.25	0.41	0.41	1.93
2	2	0.70	-0.02	8.14	-7.89	0.30	0.70	0.75	2.59
6	3	0.87	0.51	10.36	-7.40				
7	3					0.30	1.91	0.40	7.18

395 4 Discussion

Gas flowrate effects. The goal of this study was to facilitate storage of in situ sampled vapor without sensitive and costly analytical equipment in the field. The main applications we had in mind were high frequent, minimally invasive in situ isotope measurements of water vapor in soils and plant tissue as recently performed by e.g., Volkman and Weiler (2014), Volkman et al. (2016a), Seeger and Weiler (2021), or Gessler et al.

400 (2022). Their setups were based on applying stable, yet low gas flowrates to their WIPs. These flowrates resulted in continuous vapor samples assumed to be in isotopic equilibrium with the liquid water of interest. They had been carefully adjusted to the employed analyzers' demands. However, in the intended absence of an analyzer this necessity becomes obsolete. Therefore, we first tested the effect of higher gas flowrates on the obtained vapor isotope signatures. We did so in order to facilitate shorter filling times that would allow for higher filling
405 frequencies of any containers of sufficient volume (0.5 – 1 L) needed to collect and store vapor samples prior to lab-based analyses.

Incidentally, we also tested the necessity of isotope equilibrium for water vapor sampling using WIPs. We found that also under non-equilibrium conditions, in-situ isotope values originating from wet sand standards with equal matrix potentials could be reproduced with a very good precision and accuracy. We attribute this to the fact that
410 all employed WIPs had been constructed equal in size. This resulted in consistent gas transit and vapor pick-up times inside the tips as well as consistent relevant soil contact area which is the vapor collection area. This expands the findings of previous studies which aimed at facilitating equilibrium conditions when sampling water vapor from soils or stem boreholes (Volkman and Weiler, 2014; Marshall et al., 2020). This also means that our approach may not be suitable for application together with the stem borehole method as the tree stem diameters
415 will likely be variable thus not allowing for consistent gas transit and vapor pick-up times. By using identical WIPs throughout our experiment as well as for standards and samples in the foreseen application, potential isotope fractionation effects induced by the membrane are eliminated in the calibration process. Such membrane-induced fractionation effects have been observed before during across-membrane collection of vapor for liquid water isotope determination (Herbstritt et al., 2012). Further, non-equilibrium conditions as encountered in this
420 study did not require any extra correctional efforts. Mathematically, the applied calibration routine is identical to the case of the direct vapor equilibration method (Wassenaar et al., 2008; Hendry et al., 2015, Gralher et al., 2021) or even routine, automated liquid water isotope analyses (Werner and Brand, 2001). Nonetheless, we are aware that differences in matrix potential among samples or relative to the co-prepared standards in the foreseen application may result in differences in the deviation from isotope equilibrium values when applying high
425 flowrates as we did. This would require extra post-processing measures besides our straightforward calibration process. However, such tests were outside the scope of this study. Potentially, if time permits, low flowrates facilitating equilibrium could be a workaround ideally superseding such measures.

Although pure N₂ as a carrier gas would have been cheaper, we used synthetic air in order to maintain a consistent nitrogen-to-oxygen mixing ratio. This helped to avoid gas matrix effects previously demonstrated for

430 CRDS instruments (Gralher et al., 2016). We found that gas flowrates higher than the ones previously applied
(Volkman and Weiler, 2014; Volkman et al., 2016a) immediately resulted in incomplete equilibrium between
the liquid water under investigation and the obtained vapor sample (Fig. 2). This became evident by decreasing,
below-saturation vapor contents as well as lighter isotope readings. On the other side, we found that even the
highest gas flowrates applied in this study (150 mL/min) still yielded vapor concentrations (~12000 ppmv @
435 21°C) that are high enough to be within the analyzer's optimum measurement range and thus enable sufficiently
precise isotope measurements for resolving natural variations (Picarro Document Library, 2021). At the same
time, a dilution of the obtained vapor stream is obsolete under such settings as the low obtained vapor
concentrations impose no risk of condensation. Of course, field sites being sampled for vapor while enduring
temperatures that are much higher than the lab temperature might yield too high vapor concentrations. Then even
440 higher flow rates or the re-application of a dilution flow is necessary for compensation to avoid condensation and
thus un-correctable isotope fractionation. This implies that like for other indirect, minimally invasive methods
(Volkman and Weiler, 2014; Magh et al., 2022) knowledge about the temperature or maintenance of its
consistency at the points of vapor sampling is mandatory for interpreting the obtained isotope data. Cases where
temperature differs considerably among sampling sites and/or the site of calibration standard preparation require
445 additional correction schemes considering the temperature-dependencies of water-vapor isotope fractionation.
This could be facilitated either via mathematical approaches based on the dependencies described e.g., by
Majoube (1971) or via empirical approaches derived from sets of calibration standards that were collected while
intentionally being subjected to different, controlled temperatures. Calibration standards can be prepared e.g., by
installing WIPs in evaporation-shielded, sand-filled boxes wetted with water of known isotopic composition as
450 detailed in Volkman and Weiler (2014).

The changes in isotope readings and thus deviations from equilibrium were smaller for $\delta^2\text{H}$ than for $\delta^{18}\text{O}$ in
absolute numbers (10.1‰ vs. 20.21‰, respectively) (Fig. 2) and even more so in relation to naturally occurring
isotope variations, where changes usually exhibit an 8:1 ratio in meteoric waters (= slope of the GMWL, Craig,
1961b). Therefore, in situ isotope assays relying on discrete vapor sampling for later analysis with a setup
455 similar to the one foreseen here, have to ensure precise control of the applied gas flowrates for samples and co-
measured standards in order to comply with the paramount Principle of Identical Treatment (Werner and Brand,
2001). If the isotope ratio under investigation is optional, we recommend interpreting hydrogen rather than
oxygen isotope ratios given the lower susceptibility regarding gas flow rate effects and thus a more favorable
signal-to-noise ratio. In this context, it is quite convenient that labeling studies are more cost-efficient when
460 using deuterium as tracer rather than oxygen-18 (Magh et al., 2022).

Flowrates through the probes, exceeding previously recommended settings (Volkman and Weiler, 2014) immediately resulted in changes of vapor concentration and isotope readings (Fig. 2). Hence, both the previous recommended and our newly selected settings require precise control of flowrates as any uncertainty in flowrate settings translates to systematic errors in isotope readings. These errors are considerably higher at lower flowrates and higher for $\delta^{18}\text{O}$ than for $\delta^2\text{H}$. Aiming at lower flowrates in order to reliably achieve equilibrium readings appeared impractical in our study for two reasons. Firstly, the employed analyzer's gas flow demand defines the minimum total gas flow. A workaround applying higher dilution flowrates would yield varying vapor concentrations and thus vapor concentration effects as can be seen from the different isotope readings observed for 75mL throughflow rate with or without dilution (Fig. 2) thus potentially introducing additional errors. And secondly, applying lower flow rates contradicts the study aim of shorter filling times and thus higher sample collection frequencies and achievable temporal resolution.

Material and closure type selection. Our purpose was to find an inexpensive, yet reliable vapor sample container as an alternative to commercially available gasbags, which we found to be insufficient for our purposes either due to their large size or due to their degrading closure type. Therefore, we had inflated also other types of sample bags with pure, dry nitrogen gas. We found that only those combining laminated aluminum (Al) foil bodies and metal screw-lock valves yielded useful barriers against ambient vapor pressures (Fig. 3). These bags are mass products, originally produced for storing food or cosmetics and are much cheaper than existing diffusion-tight containers from specialized suppliers. All other tested combinations of bag materials and locks failed to prevent intrusion of ambient air which is crucial for the storage of vapor samples. This corresponds to the finding of a previous study where Al-laminated bags also performed best in avoiding evaporation from soil samples (Gralher et al., 2021). Although the number of water molecules of these samples were three magnitudes higher than in our study we were not surprised to find Al-laminated bags again ranking best in material suitability.

Interestingly, not only the material but also the color of the material coating the diffusive barrier appeared to play a role. Clearly, different colors are a result of different chemical complex formulas used in the production and dyeing process. Unfortunately, they seem to come with different outgassing properties and spectral interference potentials regarding the intended isotope analyses. This issue always needs to be checked in advance. The presence of certain organic compounds in a given gas sample may flaw laser-based isotope readings (Brand et al., 2009; Hendry et al., 2011), some of which can be identified by changes in the spectral parameter readings of the CRDS isotope analyzer.

In the “climate chamber” experiment, we actually sampled vapor in order to test how its concentration would change when the container is subjected to extreme moisture conditions over a longer time period. Unexpectedly, we found that vapor concentrations slightly decreased over time (Fig. S1). This clearly contradicted the applied vapor concentration gradient relative to ambient conditions. Further, the extent of decrease was not affected by the canning of some of the containers as typically proposed for sampling water for dissolved gas analyses. Therefore, we argue that not only were the employed containers sufficiently diffusion-tight against ambient meteorological forcings but also a fraction of the sampled vapor must have been absorbed by the inside coating of the containers (which had been repeatedly flushed with a dry atmosphere prior to vapor sampling). We can only speculate that mixing with previously absorbed vapor led to the observed, fairly uniform enrichment in heavy isotopes for both, $\delta^{18}\text{O}$ and $\delta^2\text{H}$. Presumably, the increase in vapor concentration inside Al-laminated bags following pure nitrogen gas inflation in the first part of the material tests (Fig. 3) was mainly due to release of previously absorbed vapor rather than via diffusive intrusion from ambient.

Field trial. This “conditioning” effect from previous filling or exposures would also explain why isotope data from the field-derived samples unanimously appeared to shift towards ambient air in dual-isotope space (Fig. 4). This was likely because all bags used for this part of our study had been freshly prepared. In doing so, during valve installation they had all been exposed to the same ambient air (in the lab) with a homogenous vapor isotopic composition. Apparently, that air was isotopically quite similar to the one recorded during the filling of the field samples. The proportional, systematic shift of isotope values allowed for a robust calibration scheme to be applied. This scheme used in situ and bag measurements of those samples displaying extreme $\delta^2\text{H}$ values. It reproduced the intermediate in situ isotope values representative for sampling of the bags with a precision sufficient for resolving naturally occurring variations of meteoric waters. The observed discrepancies between in situ and bag measurements indicate that the Principle of Identical Treatment needs to be followed also in terms of ambient vapor isotopic composition when preparing a batch of sample bags for the collection of unknown samples as well as co-measured standards. Additionally, we recommend using bags of identical size and inflating them to the same volume in order to maintain a uniform ratio of sample volume to internal wall area.

Reusability of sampling bags. Initially, we had used dry air or pure nitrogen gas in an attempt to erase the signal of previous fillings and thus avoid carryover effects when reusing the sampling bags. However, this procedure did not produce the desired outcome. Repeated measurements from identically filled bags still displayed a clear isotope pattern of the previous fillings (Fig. A2). The range of this pattern must be associated with the measurement uncertainty if the latest filling had been an unknown sample and would thus prevent

resolving natural isotope variations. It was established before the first measurement after five days and then seemed to persist.

Therefore, we tried to find a different, easy-to-implement flushing or conditioning routine that would repeatedly enable precise vapor isotope measurements using our sampling bags. For this purpose, we systematically compared the impact of dry to moist conditioning on the measurement precision and accuracy of vapor from isotopically diverse sources. From experience, we knew that room air vapor isotope signatures are usually quite persistent on shorter timescales as necessary for filling batches of sampling bags using high-flowrate devices such as vacuum pumps. Using this unlimited resource, we were able to establish a conditioning routine that is easy to reproduce and enables the precise reproduction of in situ isotope values following impertinent calibration schemes (Table 3). In this context, the low SD of isotope readings from moist-conditioned bags proved to be a far better predictor of conditioning efficiency than the low vapor concentration of dry-conditioned bags. We therefore recommend conditioning entire batches of sample bags simultaneously with a moist, isotopically homogeneous atmosphere prior to each isotope sampling campaign.

Further, we emphasize that for any given vapor sample an isotopic shift must be expected between collection and subsequent, lab-based analysis. This shift became apparent e.g., during field application (Fig. 4) and the conditioning procedure (Fig. 6). It is characteristic and implicit to our method. However, it is proportional relative to the priming signal. Herewith, it becomes manageable through co-measuring calibration standards, prepared in identically pre-treated bags.

Our conditioning routine was performed manually and its efficiency checked after every conditioning iteration. However, we are confident that it can be easily automated for future applications and its efficiency eventually assumed reliably without measurements as a matter of experience. Further, it seems that for the SD being a meaningful parameter for conditioning efficiency, the conditioning time steps need to match the projected sample storage time. This also calls for automating the conditioning procedure.

Our aim was to develop a low cost solution as funding might not always be available and we wanted to avoid the high per-unit costs of commercially available gas sampling bags. Moreover, diffusion-tight bags from e.g. Analyt-MTC are made from plastic coated aluminum foil (Analyt-MTC Products, 2015), similar to the ones we used in our study. Therefore, similar adsorption issues must be expected due to the interior coating of the diffusive barrier. This means that before being readily available some kind of conditioning procedure would also have to be applied, even when re-using commercially available bags. Also, for any other sampling vessel a

550 potential user will have to verify the suitability in a way similar to the one we describe: in terms of diffusion tightness, contamination, as well as adsorptive disturbances from the inner layer of the vessel material itself.

So far, we are satisfied with the outcome of our tests and the achievable precision and accuracy. Nonetheless, we are aware that our method is not yet ready to go and further tests are needed before unknown, field-collected samples can be processed. This refers not only to the issue of potential temperature discrepancies between
555 samples and standards. Moreover, resulting differences in vapor concentration must be considered which likely induce additional challenges. The proportionality of the memory effect observed in this study, e.g. after applying the moist-air conditioning procedure was likely because we were able to facilitate a consistent ratio of collected sample size and vapor reservoir absorbed to the bags' inner walls expressible e.g. in water vapor mole fractions. The effect of changes of this ratio has not been tested yet nor has a mathematical correction scheme accounting
560 for this issue been found. Further, we are aware that the effort that needs to be put into assembling the necessary components as well as into pre-sample-collection tests and conditioning might still have a deterring effect on potential users of our method. The same probably holds for the costly alternatives available in the market for collecting gas samples into flexible containers that would at least dispense with the assembly efforts. In this context, we admit that the option to use inexpensive off-the-shelf components as employed by e.g. Magh et al.
565 (2022) is certainly appealing. Also, the option to reliably reproduce vapor isotope values after one or more weeks of storage remains a worthwhile goal.

On the other hand, we believe that the otherness of our method also holds several advantages relative to previous approaches for the collection and analysis of discrete vapor samples. In contrast to Havranek et al. (2020, 2022), the non-automation allows for maximum temporal flexibility regarding experimental designs. The spatial
570 distribution of sampling sites is not limited by connectivity to a central sampling system and associated tubing lengths. As all employed components are small and light-weight, they can easily be deployed even in terrains that are rather difficult to access. In contrast to Magh et al. (2022), the achieved precision and accuracy (Table 3) allow for the resolution of even fine-scaled environmental isotope variations. Practically, our method does not require any tools, not to mention specialty tools during handling or refurbishing of crimp-sealed glass bottles and
575 the lack of consumables such as septa makes it cost-efficient. The combination of the screw-lock mechanism and a sufficiently large sample volume is forgiving as it allows for multiple measurements from one sample bag. Also, flushing and re-filling are possible without wearing of the closing mechanism. Using evacuated, inflatable containers renders any in-field flushing obsolete thus reducing sampling time and increasing feasible temporal resolution. Further, it eliminates the risk of breaking glass during transport and handling. Finally, our method

580 does not require additional gas sources during analysis and allows for directly interpretable measurement readings without the need to identify the relevant isotope data section via derivation of the vapor concentration readings.

5 Conclusions

We present a new method for the collection of discrete water vapor samples in the field and subsequent storage
585 and isotope analysis in the lab. After systematic material testing (Appendix Table A1), we identified a combination of inflatable bag and closure type that guarantees air-tightness and avoids sample contamination by material outgassing. Similar tests are necessary also for commercially available gas sampling bags. Our custom-made method uses off-the-shelf components only and is easy to use, cost-efficient, sustainable and allows for multiple measurements. Further, it allows for direct interpretation of the obtained isotope results. The achieved
590 precision and accuracy are not only suitable for labelling experiments but also sufficient for resolving natural variations of water stable isotope signatures. Preparation and co-measurement of calibration standards are indispensable for our approach in order to correct for the implicit shift of the obtained isotope signal, induced by the mandatory conditioning procedure. We are convinced that the conditioning procedure can be automated, which would further reduce the per-sample workload when re-using sampling bags. The presented approach
595 allows for collecting vapor samples from soil matrix and plant tissues in remote settings without an isotope analyzer in the field. The method therefore widens the applicability of minimally invasive in situ approaches of matrix-bound water stable isotope observations. Hence, we are confident that our method will open new observatory paths and thus contribute to novel insights in hydrology, soil science, plant physiology and related disciplines. Future tests will have to find ways of dealing with discrepancies in temperature, vapor concentration,
600 or matrix potential among samples during collection and relative to co-prepared standards.

6 Appendix A: Protocol for identifying appropriate sampling bags

The procedure of testing and the requirements that had to be fulfilled in our study by the tested gas sampling bags are summarized in the protocol. Any other material or commercially available bags can also be evaluated by passing this protocol.

605 Table A1: Suggested test protocol to identify suitable gas sampling bags for isotopic vapor.

	Properties tested	Filling bags with:	Aim	Observed instrument variable *L2120-i **L2130-i	Target value for passing test
Test 1	Diffusivity	dry N ₂	Identify mixing with ambient air	Water content: 'H2O' spectral gas matrix variable: 'h2o_y_eff_a'* 'h2o_vy'**	< 1000 after 2 weeks ~1.03* ~0.46**
	Spectral interference		Identify substances spectrally interfering with measurements, thus flawing isotope readings	Water content: 'H2O' Stable isotopes: 'd18O' 'd2H' spectral gas matrix variable: 'h2o_y_eff_a'* 'h2o_vy'** organic contamination: 'MeOHampl'* 'CH4_conc'**	< 1000 after 2 weeks ~1.03* ~0.46** ~0.00095* ~-0.00012**
Test 2	Reliability Only conducted when tests for diffusivity and spectral interference were passed	Vapor from 3 different sources with known isotopic composition	Evaluate isotope measurement in respective bag type by calibrating intermediate validation standard with known and observed values of two calibration standards (heavy, light)	Water content: 'H2O' Stable isotopes: 'd18O' 'd2H'	similar for all 3 standards Calibrated values should match known values with deviations < 0.4 ('d18O') and < 2.0 ('d2H') or better
Test 3 (optional)	Conditioning for re-use of bags	Room air (repeatedly)	Homogenize memory effect across entire sampling bag batch to make it manageable via pertinent calibration schemes	Water content: 'H2O' Stable isotopes: 'd18O' 'd2H'	~5000-20000 SD of whole batch of bags << 0.4 ('d18O') << 2.0 ('d2H') (see Fig. 5)

Appendix B: Memory effects in re-used bags.

610 In re-used bags, we observed isotope data consistently trending towards the values recorded previously from the respective sample bags, although evacuated and flushed three times with dry N₂. These 'memory effects' were proportional to the differences between the current and the previous bag measurement (Fig. B1).

Figure B1. Dual isotope plot of gasbag measurements of re-used bags 5 days (open squares) and 10 days (open triangles) after all of them being filled with a constant flowrate of 150 mL/min via a WIP from one single isotopic reservoir (filled dot). The different colors indicate the differing isotopic levels of the previous samples, stored in the respective bags.

Author contribution

BH, SS, MR and MW designed the first part (material selection, field trial) of the experiments, BH and SS carried them out. BH and BG designed the second part (climate chamber, conditioning procedure) of the experiments and carried them out. BH, BG and MW analysed and interpreted the data. BH and BG prepared the manuscript with contributions from all co-authors.

Acknowledgments

The authors thank Janine Heitzmann for her tireless commitment in the lab during material testing.
