**Abstract.** Drought is a devastating natural disaster, where water shortage often manifests itself in the health of vegetation. Unfortunately, it is difficult to obtain high-resolution vegetation drought impact, which is spatially and temporally consistent. While remotely sensed products can provide part of this information, they often suffer from data gaps and limitations in spatial or temporal resolutions. A persistent feature among remote sensing products is tradeoffs between spatial resolution and revisiting times, where high temporal resolution is met by coarse spatial resolution and *vice versa*. Machine learning methods have been successfully applied in a wide range of remote sensing and hydrological studies. However, global applications to resolve drought impacts on vegetation dynamics still need to be made available, while there is significant potential for such a product to aid improved drought impact monitoring. To this end, this study predicted global vegetation dynamics based on the Enhanced Vegetation Index (*evi*) and the popular Random Forest algorithm (RF) at 0.1°. We assessed the applicability of RF as a gap filling and downscaling tool to generate spatial and temporal consistent global *evi* estimates. To do this, we trained an RF regressor with 0.1° *evi* data using a host of features indicative of water and energy balances experienced by vegetation and we evaluated the performance of this new product. Next, to test whether the RF is robust in terms of spatial resolution, we downscale global *evi*, the model trained on 0.1° data is used to predict *evi* at 0.01° resolution. The results show that the RF can capture global *evi* dynamics at both the 0.1° (RMSE: 0.02 - 0.4) and at the finer 0.01° (RMSE: 0.04 - 0.6) resolution. Overall errors were higher in the down-scaled 0.01° compared to the 0.1° product. Yet, relative increases remained small, thus demonstrating that RF can be used to create downscaled and temporally consistent *evi* products. Additional error analysis reveals that errors vary spatiotemporally, with underrepresented landcover types and periods of extreme vegetation conditions having the highest errors. Finally, this model is used to produce global spatially continuous *evi* products at both the 0.1° and 0.01° spatial resolution for 2003-2013 at an 8-day frequency.

## 20 1 Introduction

The impacts of natural hazards are felt on a local scale, but creating impactful risk management strategies requires a global view on the impacts and driving processes (Ward et al., 2020). Given its complex and multivariate nature, a global perspective is especially necessary when considering drought hazards and their impacts. Drought is one of the most disruptive natural hazards, causing negative repercussions on the environment, economy, and society, which can affect large areas and populations (Naumann et al., 2014; Vereinte Nationen, 2021). However, a universal definition of what constitutes a drought event remains

elusive, and as a result, we lack a comprehensive understanding of the direct and indirect effects of drought on the environment and society (Blauhut et al., 2016; Vogt et al., 2018; Sutanto et al., 2019). Remotely sensed products that monitor earth system responses during drought periods are one promising tool that can enable a global perspective on linking drought hazards and their impacts (AghaKouchak et al., 2015; West et al., 2019). However, they suffer from trade-offs between spatial and temporal resolution, where we either have high-resolution low frequency products or vice versa. The production of high-resolution spatially continuous products can facilitate a more holistic view of drought responses and management by incorporating more relevant fine-scale processes (Chen et al., 2022; Schneider et al., 2017).

Vegetation is involved in numerous drought-impact pathways and using remote sensing to track vegetation responses has been widely used (Zhang et al., 2021b; AghaKouchak et al., 2015). Drought disrupts terrestrial water and carbon cycles, which can reduce the integrity of ecosystem dynamics and associated ecosystem services (Banerjee et al., 2013; Crausbay et al., 2017; Han et al., 2018; Smith et al., 2020). More subtly, vegetation also affects the dynamics of drought propagation; Under favourable antecedent conditions, vegetation overshoot may exacerbate and facilitate the onset of rapid and intense droughts (Zhang et al., 2021b). Vegetation is also expected to play a crucial role in shaping drought resistance under future climate change (Vereinte Nationen, 2021). In the absence of such resistance, interventions to alleviate the negative impacts of disrupted ecosystem services can cost up to a billion dollars per drought event (Banerjee et al., 2013; Cammalleri et al., 2020). It follows that formulating appropriate responses to drought and alleviating the negative effects of ecosystem disruption during these periods requires accurate predictions.

In recent decades, numerous satellite-based vegetation indices have been developed (Li et al., 2021a). For example, the Enhanced Vegetation Index (*evi*), have proven to be an indispensable tool for monitoring vegetation at multiple scales, from the fine scale, such as crop patches (Moussa Kourouma et al., 2021; Sharifi, 2021) to the global scale (Huang et al., 2021; Vicente-Serrano et al., 2010). However, a persistent feature among these products are trade-offs between spatial resolution and revisiting times, where high temporal resolution is met by coarse spatial resolution and *vice versa*. For example, the Moderate Resolution Imaging Spectroradiometer (MODIS) captures the entire Earth with a high temporal resolution every 1 to 2 days (Zhao and Duan, 2020) with a maximum resolution of 250 m. Landsat and Sentinel-2 data have a higher spatial resolution, 10 and 30 m, but longer revisiting times of approximately 10 and 5 days, respectively (Zhu, 2017; Li et al., 2021a). Revisiting times for Landsat and Sentinel-2 are further prolonged when sensors or retrievals are interrupted by cloud cover, pollution in the atmosphere, or even technical issues. In addition to temporal frequency, temporal coverage is another important consideration. Coarser scale products are associated with older satellites and have more extended temporal coverage than the newer ones; MODIS products reach as far back as 1999 whereas Sentinel-2 products only go back to 2017. The ideal product for monitoring vegetation dynamics would have global coverage, little to no data gaps, and high spatial and temporal resolution.

Machine learning (ML) methods have been used for downscaling and gap filling purposes in remote sensing products and can be seen as one tool that can lead to the production of high-quality remote sensing products and thus alleviate the limitations around resolution and coverage current products exhibit (Zhu et al., 2022; Zeng et al., 2013). ML methods have been successfully applied to a wide range of drought-related (Hauswirth et al., 2021; Shamshirband et al., 2020; Tufaner and Özbeyaz, 2020; Shen et al., 2019; Das et al., 2020; Hauswirth et al., 2022) and remotely detected vegetation studies (Roy, 2021; Li et al.,

2021b; Reichstein et al., 2019). Compared to conventional statistical downscaling techniques, ML is considered the superior alternative; given that no strict statistical assumptions are required, complex and non-linear relationships are well captured and provide high precision (Ebrahimi et al., 2021).

One ML algorithm that has been widely applied for gap filling and downscaling in remote sensing data is the Random Forest Regressor (RF) (Zhang et al., 2021a; Fu et al., 2022; Liu et al., 2020; Wang et al., 2022). Gap-filling can be achieved by training a RF on available data and then use the model to predict values where data is sparse or missing (Wang et al., 2022). Using RF to downscale data involves establishing an RF at a coarse scale and predicting targets at finer resolutions by feeding the algorithm with high-resolution auxiliary data (Liu et al., 2020). These studies have highlighted that ML methods can accurately predict the dynamics of vegetation (Roy, 2021; Gensheimer et al., 2022). However, studies applying ML methods to global vegetation dynamics and assessing their suitability to investigate drought responses are less prominent, and it remains to be seen whether this approach is applicable at the global scale (Li et al., 2021b; Zhang et al., 2021b; Chen et al., 2021).

This study aims to further our understanding on how well ML methods can be used to create vegetation products that are useful for global drought impact applications. This will allow us to quantify to what degree ML can be used for continuous drought monitoring, as well as for gap-filling of existing remote sensing products. We set out to establish whether ML methods can alleviate missing data and resolution limitations of remote sensing-based vegetation health products by linking vegetation condition (*evi*) with meteorological and hydrological data. This was done in three steps; first, assess whether ML is an appropriate tool to predict the condition of vegetation on a global scale and act as a gap filling tool. Second, to determine whether ML can be used to downscale vegetation conditions and predict values at spatial scales finer than those provided during training. High degrees of transferability between scales allow for further spatial up- or down-scaling of the RF in future applications while still providing robust results. Last, to explore how these products can be applied to drought impact studies, we investigated how well the ML-based vegetation maps predict vegetation status for different types of land cover and during drought periods.

## 2 Materials and Methods

The materials and methods are constructed so that each subsection corresponds to one of the objectives. We first have a look at an overview of the experimental approach used to assess how well an ML approach can be used as gap filling and downscaling tool. We then detail how we trained a RF and which data was used, followed by how we tested the gap-filling and downscaling capabilities in two separate sections. Last, the gap-filled and down-scaled products are stress tested by investigating how well they can be used to derive insights into global vegetation dynamics, specifically under drought conditions.

The relative abundance of remotely sensed vegetation data provides an opportunity to effectively establish the applicability of ML based methods for gap-filling and downscaling. In this study we relied on already assimilated data products to test the applicability of RF as a downscaling and gap-filling tool. To do this we first set out to train an RF in a subset of the available *evi* data at  $0.1^\circ$ . As a test of its gap-filling abilities, the model was then used to predict *evi* values at locations not seen during training. To determine how viable the RF is for downscaling, we predicted *evi* at the  $0.01^\circ$  resolution. Ideally, all data used in

this prediction would also be at 0.01°. However given the that this is not possible we provided it with 0.01° where possible and also provided it with data at 0.1° data where such high resolution data where not available.

## 2.1 Random Forest Regressor

### 2.1.1 Data Sources

The data sources (Table 1 and further information in the following subsections) described below were used to construct a 0.1° resolution dataset to train and test the ML model. The data set spans 10 years, from 2003 to 2013. The goal was to have all data at a 0.1° resolution, in cases where the resolution of the downloaded data was not, the relevant treatments are described below.

**Table 1.** Target variable (*evi*) and potential features with accompanying units, spatial resolution (Spat. Res.) and temporal resolution (Temp. Res.)

Name	Units	Spat. Res.	Temp. Res.	Reference
<b>Target Variable</b>				
<i>evi</i>	-	0.01°	8 day	Gao et al. (2000)
<b>Feature Variables</b>				
<i>lc</i>	-	500m	Yearly	Friedl, Mark and Sulla-Menashe, Damien (2019)
<i>elv</i>	m			
<i>hnd</i>	m	92m	Static	Yamazaki et al. (2019)
<i>aspect</i>	°			
<i>slope</i>	°			
<i>tp</i>	mm.day <sup>-1</sup>			
<i>t2m</i>	°C			
<i>swvl1</i>	-		Hourly	Muñoz-Sabater et al. (2021)
<i>stl1</i>	°C			
<i>pet</i>	mm.day <sup>-1</sup>	0.1°		Singer et al. (2021)
<i>spi1,spi3,...spi24</i>	-	0.1°	Monthly	this study
<i>spei1,spei3,...spei24</i>	-			

*evi* - Enhanced Vegetation Index, *lc* - Landcover Types, *elv* - Elevation, *hnd* - Height Above Nearest Drainage, *aspect* - Aspect, *slope* - Slope, *tp* - Total Precipitation, *t2m* - Two Meter Temperature, *swvl1* - Volumetric Soil Water Layer level 1, *stl1* - Soil Temperature layer level 1, *pet* - Potential Evapotranspiration, *spi1,... spi24* - Standardized Precipitation Index (1-month, ... 24-month), *spei1,... spei24* - Standardized Precipitation Evapotranspiration (1-month, ... 24-month). Highlighted rows indicate that features were dropped from further analysis after conducting feature selection prior to model fitting.

**Vegetation Index** - The reference data used in this study is the *evi* index. *evi* data provide the observational benchmark for the training and validation of the ML-based products created in this study. The *evi* can be used as an indicator of overall vegetation status and health, as it is sensitive to chlorophyll content and correlates with primary production, photosynthesis rates, and vegetation physiognomy (Box et al., 1989). Compared to the more widely used Normalized Difference Vegetation Index, *evi* is considered the superior index, as it is less sensitive to atmospheric conditions and saturation effects in areas of

dense vegetation (Gao et al., 2000). These data arise from the Moderate Resolution Imaging Spectroradiometer aboard the Terra and Aqua satellites. Sensors aboard Terra and Aqua are identical, and the 16-day composite images from each sensor are released 8-days apart. In this study, Google Earth Engine's python Application Program Interface (Gorelick et al., 2017) was used to access the terra (MOD13A2.006) and aqua (MYD13A2.006) *evi* data. These two products were combined to produce a quasi-eight-day time series (Didan, 2015, 2021). For the experimental setup used here, we required two sets of *evi* data, one at the 0.1° resolution, for training the RF and test its gap filling capability, and another at the 0.01° resolution to assess its downscaling abilities. The GEEMAP package was used to upscale the original 0.01° *evi* data to 0.1° (Wu, 2020).

**Feature Variables** - Global vegetation type patterns are largely driven by terrestrial water and energy balances (Hawkins et al., 2003). Similarly, the responses of vegetation to drought are regulated, in part, by water and energy availability (Xu et al., 2010). Consequently, a suite of data indicative of terrestrial water and energy balances was selected as potential input variables. These variables are introduced below, and Table 1 provides an overview.

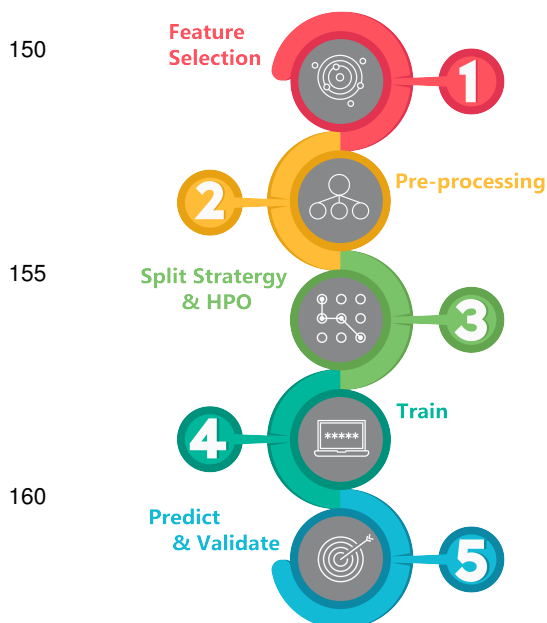

**Meteorology** - Hourly data for total precipitation (*tp*), two-meter temperature (*t2m*), volumetric soil moisture layer 1 (*swv1l*), and soil temperature layer 1 (*st1l*) were retrieved from the hourly ERA5-Land Reanalysis product by the European Centre for Medium-Range Weather Forecasts (Muñoz-Sabater et al., 2021). In addition, potential daily evaporation (*pet*) was acquired from Singer et al. (2021), *pet* is calculated following the Penman-Monteith formulation with ERA5-Land as the input data. All meteorological data were resampled to match the 8-day frequency of the *evi* data. *Tp* was aggregated by taking the cumulative sum of the previous 8 days, whereas the remainder of the variables were averaged over 8 day windows.

**Drought Indices** - Aside from short-term changes in water availability, it is also key to understand the long-term dynamics to identify drought legacy effects on the current vegetation states (Schwalm et al., 2017). To this end, the Standardised Precipitation Index (*spi*) (McKee et al., 1993) and Standardized Precipitation Evapotranspiration Index (*spei*) (Vicente-Serrano et al., 2010) were used to characterise these legacy effects. The *spi* and *spei* were calculated at the 1, 3, 6, 9, 12 and 24-month aggregation lengths. The different lengths of aggregation are related to types of drought: precipitation, soil moisture, and hydrological droughts. Precipitation and soil moisture droughts mostly correlate short-term deficits in soil water (1-3 months), and are important for vegetation with shallow roots; hydrological drought (6-12 months) can be a good proxy for impacts on shrubs, bushes and trees that have deeper roots and are likely to rely on local groundwater for water (12-24 months). In addition, the inclusion of drought indices allows for the characterisation of past climate memory effects on current vegetation growth (Reichstein et al., 2019; Schwalm et al., 2017) associated with past climatic conditions. The equations and steps for calculating *spi* and *spei* are detailed in Appendix A2.

**Landcover Types and Topography** - Land cover type is an important predictor of vegetation abundance and health (Meza et al., 2020). Here, the Moderate Resolution Imaging Spectroradiometer Yearly Land cover Types (MCD12Q1.006) were retrieved from the Google Earth Engine's Application Program Interface (Friedl, Mark and Sulla-Menashe, Damien, 2019). Given that the original data is at a spatial resolution of 500m, the GEEMAP package (Wu, 2020) was again used to upscale the data to 0.1° and 0.01°. In this product, landcover types are classified according to the International Geosphere-Biosphere Programme classification scheme. Barren land, deserts, permanent snow and water bodies were masked in all further analyses. It is important to note that the RF was supplied with the remainder 15 unique landcover types; however, these were collapsed

into eight broader classifications for brevity and clarity in the results, discussion and visualisations. To capture the variations in water and energy availability attributable to topographic effects, elevation (*elv*) and height from the nearest drainage basin (*hand*) were accessed from MERIT Hydro, a high-resolution global hydrography map (Yamazaki et al., 2019). Lastly, *slope* and *aspect* was calculated from *elv* using the relevant functions in `xarray-spatial` (Hoyer and Hamman, 2017). This data was upscaled from the original 92m resolution to  $0.1^\circ$  and  $0.01^\circ$  using the GEEMAP package (Wu, 2020).

## 2.1.2 Random Forest Model

165 **Figure 1.** The five sequential steps followed during the RF fitting and evaluation.

favour of *spei* (Fig. A1). *spi* and *aspect* were excluded from further analyses; features that were excluded are highlighted in Table 1.

170 **Pre-processing** - Given that the RF algorithm accepts 2-dimensional numeric arrays as input, the 3-dimensional data was processed so that each unique latitude and longitude was associated with a time series of each variable. The single categorical feature (*lc*) was converted to binary numeric. Each unique landcover type is assigned to a new feature, with 1 indicating presence and 0 indicating absence.

**Split Strategy and Hyper-parameter optimisation** - `HalvingRandomSearchCV` with a 3-fold cross-validation approach was applied to refine the number of estimators and maximum depth. This hyper-parameter optimisation provides the

While an abundance of ML approaches has been used to predict vegetation status, here the Random Forests Regressor (RF) was selected to link meteorology, land cover, topography, and drought inputs to vegetation health. RF is an ensemble method that fits many decision trees on different subsets of data. RF is advantageous given its relatively straightforward implementation, ability to incorporate categorical features, ability to easily identify causal links and limited risk of overfitting. The general pipeline used throughout consisted of five sequential steps (Fig. 1). Here, the RF was implemented in Python 3.9 (Rossum and Drake, 2010) under the `scikit_learn` framework (Pedregosa et al., 2011).

**Feature Selection** - In an attempt to include only relevant data in the ML model, the list of potential variables described in Section 2.1.1 and Table 1 was evaluated for their ability to provide meaningful information during model fitting. A pairwise Spearman rank correlation was calculated between all features to ensure that input data correlated with *evi*. Those variables that exhibited strong correlations were retained in further analysis, whereas variables that experienced weak correlations were excluded. *Aspect* did not exhibit strong correlations with *evi* (Fig. A1). Similarly, *spi* (at all aggregation times) did not correlate strongly with *evi*. In addition, *spi* and were closely correlated with *spei*, *spi* was excluded in

175 optimal configuration for the RF so that the critical vegetation dynamics are captured while simultaneously reducing the RF complexity and preventing over-fitting. The hyper-parameter optimisation focused on two parameter settings, namely, `Maximum_depth` and the `number_of_estimators`; the search space was 1-40 and 1-20, respectively. Increasing the `Maximum_depth` and `number_of_estimators` past 12 and 15, respectively, yielded only marginal increases in test scores (Fig. 2a). Given that only the risk of overfitting increases with increasing `Maximum_depth` and `number_of_estimators` and only marginal increases in test scores are observed past these points, 12 and 15 were identified as the optimal settings.

After determining optimal parameter settings, the data were split into training and validation sets. However, three-dimensional data could conceivably be split along the temporal dimension where the model is trained on all locations with only a subset of the temporal availability (i.e., temporal splitting), or the data can be split according to location where only a subset of the grid pixels are selected for training but over the entire available period (i.e., spatial splitting). Given that previous research has highlighted that RF performance is sensitive to spatial vs temporal splitting, this is especially true for extreme events such as droughts (Hauswirth et al., 2021). We conducted a cursory analysis to determine whether a temporal or spatial splitting approach better balances trade-offs between computational complexity and learning rates. Learning curves for cursory RF models using each splitting approach were quantified and compared. Each model was supplied with increasing training sizes, and test scores were calculated and plotted to visualise learning curves. This cursory analysis revealed that spatial splitting yields faster learning curves than the temporal splitting approach (Fig. 2b); therefore, spatial splitting was identified as the preferred approach.

**Figure 2.** (a) Evolution of RF performance during `HalvingRandomSearchCV` hyper-parameter optimization of: `maximum_depth` (blue) and `number_of_estimators` (red). (b) RF performance following the incremental increase of train set size using a location (red) based split approach compared to a temporal (blue) based split approach.

**Train** - For the final RF model, a spatial split with a (0.06:0.94) (train: predict) ratio was used to train the final model. A 0.06:0.94 split was chosen, and there was very little increase in performance past training sizes of 6% (Fig. 2b). `Maximum_depth` and `number_of_estimators` were set at 12 and 13, respectively. The parameters that were not subjected to hyper-parameter optimisation were set as follows: the `squared_error` criterion was used to measure the quality of the splits

in branches, the maximum `number_of_features` considered in each split was set at `auto`, and the minimum and maximum `samples_per_leaf_nodes` was set at 1 and 2, respectively.

## 2.2 Gapfilling *evi* using Random Forests

As a test of the RF gap-filling capabilities, we predicted *evi* for the 94% of the grid cells that were not used during training. The accuracy of these predictions was evaluated against the *evi* data obtained from MODIS. As a first-pass assessment of overall performance, the model was scored using default coefficient of determination ( $R^2$ ) scorer in the RF implementation of scikit. The model predictions were further evaluated by calculating the root mean squared error (RMSE) and Pearson correlation coefficients. These were calculated independently for each grid cell to provide information on the spatial variation of errors. Last, to gain insight into which features were the most essential for predicting *evi*, global feature importance was calculated using Shapley Additive exPlanations' (SHAP) TreeExplainer (Lundberg et al., 2020).

## 2.3 Downscaling *evi* using Random Forests

In this section, the focus shifted toward whether RF can be used to downscale global *evi* values, that is, whether a model trained on  $0.1^\circ$  can accurately predict *evi* at a finer  $0.01^\circ$  scale. To this end, a  $0.01^\circ$  data set was compiled. In cases where data were not at the  $0.01^\circ$  resolution, the nearest neighbour interpolation scheme from `xarray` (Hoyer and Hamman, 2017) was used to match the variables to the same spatial resolution. This data set was used as new input data to the already trained RF model to predict *evi* at the  $0.01^\circ$  scale. The evaluation approach for the downscaled values remained much the same, the overall model accuracy was assessed using ( $R^2$ ) and (RMSE), and Pearson correlation coefficients were calculated for each grid cell.

## 2.4 Applicability of ML informed vegetation status products during periods of drought

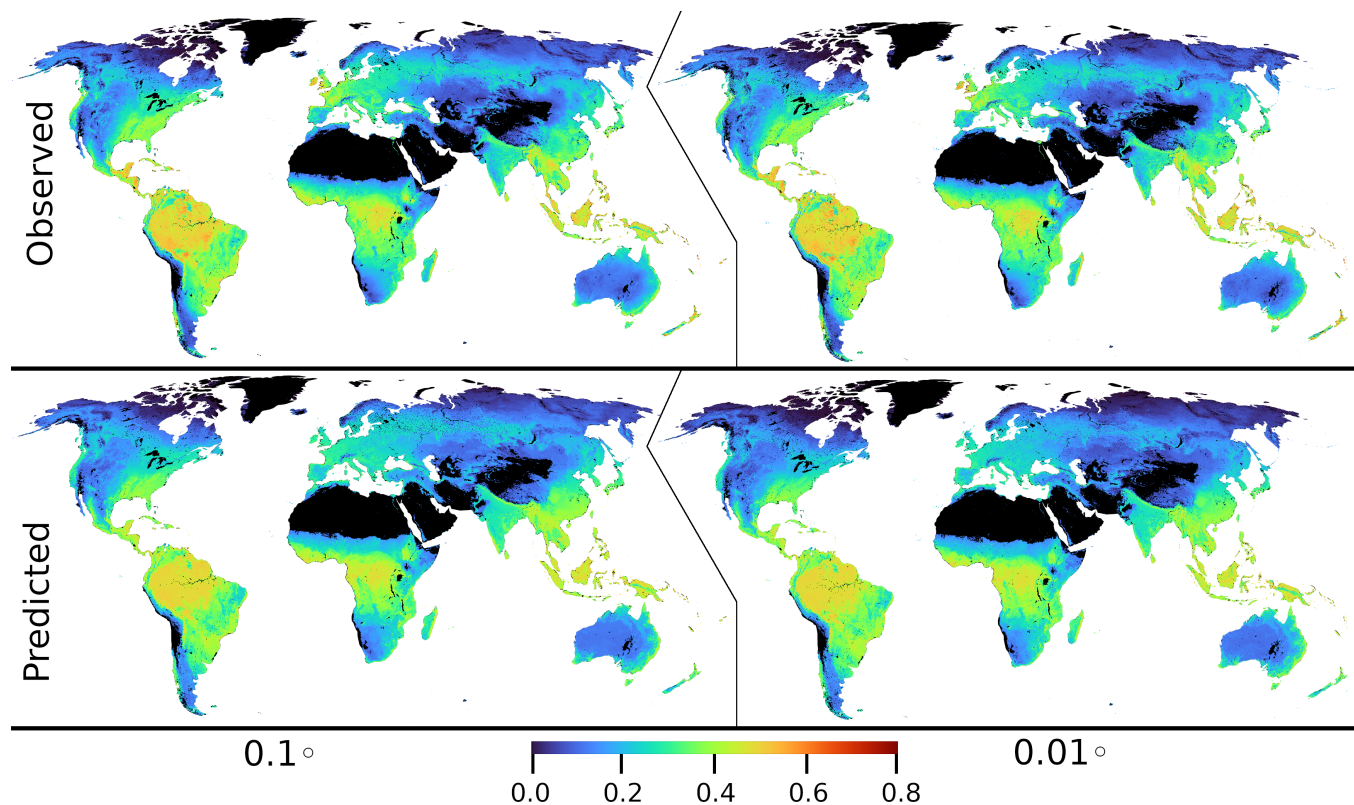

One noticeable shortcoming of the RF is its relatively poor ability to predict extreme values depending on the training selection (Hauswirth et al., 2021). To determine to what extent this may influence the generality of the two products mentioned above, we further investigated the accuracy of the predicted *evi* under low growing conditions by calculating the anomaly correlation coefficient (ACC; Eq. 1), where  $eviA_{i,j}$  denotes *evi* anomaly for the month  $j$  in year  $i$ ,  $\bar{evi}_{i,j}$  denotes the average *evi* of month  $j$  over 2003-2013;  $\sigma$  stands for the standard deviation of *evi* during the period. We use this metric to assess the applicability of the RF based  $0.1^\circ$  and  $0.01^\circ$  *evi* predictions against remotely sensed *evi*.

$$eviA_{i,j} = \frac{evi_{i,j} - \bar{evi}_{i,j}}{\sigma} \quad (1)$$

### 3 Results

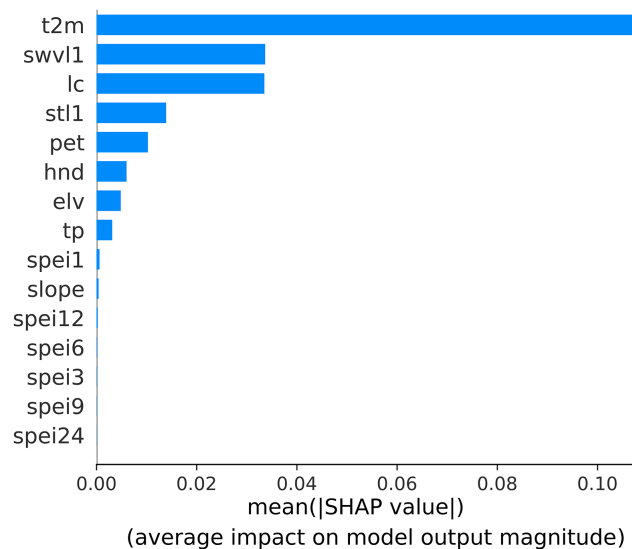

The results here are presented in three parts. First, the results of the model trained on the  $0.1^\circ$  data are presented; here, the focus is retained on the model's performance and ability to predict the status of the vegetation at the spatial resolution it is trained and act as a gap-filling tool. We also touch on which features are most important in predicting the status of the vegetation. Subsequently, we present the model's performance when used to downscale *evi* and predict  $0.01^\circ$  data. We explore how this module can be used to gain insight into global vegetation dynamics by assessing the accuracy of both products under drought conditions. A more general discussion on the quality of input data and comparisons with related studies is presented last.

**Figure 3.** Mean (2003 - 2013) observed (top) and mean predicted *evi* values by the model at the  $0.1^\circ$  (left) and  $0.01^\circ$  (right). Barren land, deserts, permanent snow, and water bodies were masked and represented by black.

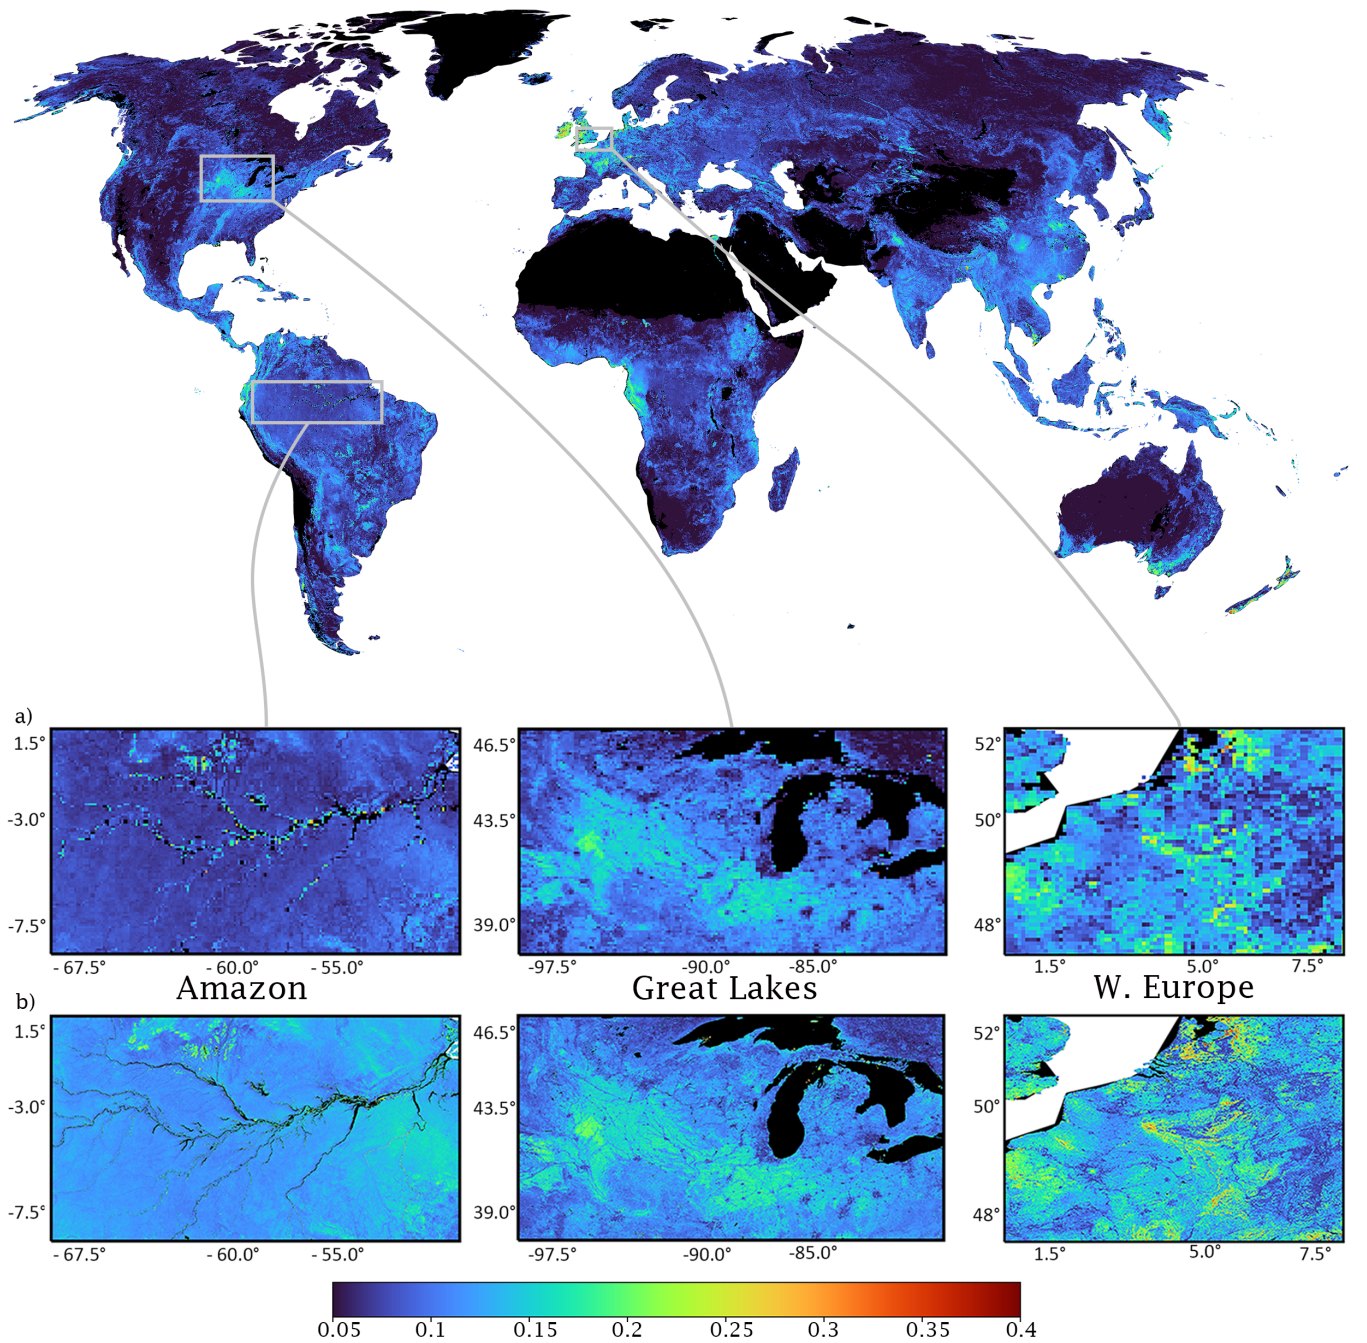

### 3.1 Gapfilling *evi* using Random Forests

230 The model was able to reproduce global vegetation patterns by correctly predicting high vegetation density in tropical forests and low vegetation density in arid and urban regions of the world (Fig. 3). SHapley Additive exPlanations values provided an understanding of the relative importance of each feature in predicting *evi*. The most important features were those associated with meteorology, landcover type and topography; drought indices proved to be a lower degree of information (Fig. 4).

**Figure 4.** Feature importance for the RF predicting *evi* at  $0.1^\circ$ . The features are ordered by level of importance, with higher mean SHAP values indicating higher importance.

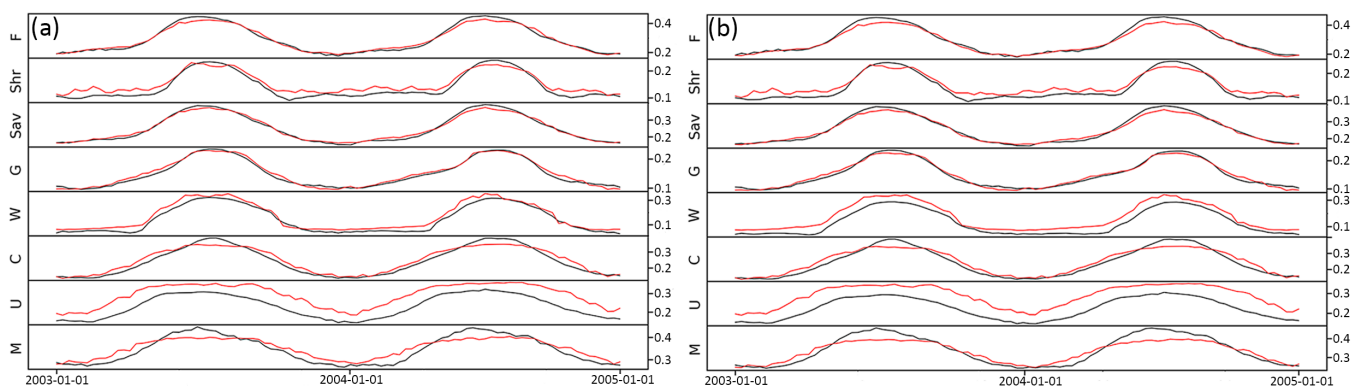

When trained on only 6% of the data, the RF was able to predict global *evi* accurately with a spatial resolution of  $0.1^\circ$  ( $R^2 = 0.86$ ; Fig. 3, 5, 6 & 7a). Looking more closely at the distribution of errors, less than 1% of grid cells showed negative correlations and more than 80% showed correlations higher than 0.5 (Fig. 7c) and RMSE ranged between 0.02 and 0.4 (mean:  $0.05 \pm 0.03$ ; Fig. 7d). However, it is important to note that the accuracy was neither spatially nor temporally uniform. Landcover types were an important feature in determining predictive ability. The predictions of *evi* in areas dominated by urban, mixed and crop landcover types showed the highest degree of error (Fig. 6a). On the contrary, the most natural types of land cover, such as forests and grasslands, were the most accurately represented by the model (Fig. 5a & 6a). For all types of land cover, 240 the periods of maximum and minimum *evi* were less accurately predicted than the intermediate periods (Fig. 6a). Predicted *evi* was consistently underestimated by the model in urban landcovers (Fig. 6a).

**Figure 5.** RMSE calculated for the Amazon Basin, Great Lakes and Western Europe for predicted *evi* values by the model at the (a) 0.1° and (b) 0.01°.

### 3.2 Downscaling *evi* using Random Forests

When the model trained with  $0.1^\circ$  data was used to predict *evi* at  $0.01^\circ$  spatial resolution, there was a slight drop in accuracy. The predictive capacity was still good but reduced compared to the  $0.1^\circ$  product, with a median  $R^2$  of 0.75 (Fig. 7b). Again, the RF was able to accurately capture spatial and temporal vegetation dynamics when supplied with  $0.01^\circ$  data (Fig. 3 & 6b). The errors also increased, the proportion of grid cells displaying negative correlations now being 5% (Fig. 7c) compared to less than 1% for the  $0.1^\circ$  product. RMSE ranged between 0.04 and 0.6 (mean:  $0.09 \pm 0.07$ ; Fig. 7d), with the majority of the grid cells exhibiting RMSE around 0.05. For the filling of the gap, the precision was dependent on the land cover, with urban mixed and crops performing the worst (Fig. 6b). Noticably, for urban landcover types the model consistently under-estimated *evi*.

**Figure 6.** Time series of average predicted (black) and observed (red) *evi*, per major land cover type at (a)  $0.1^\circ$  and (b)  $0.01^\circ$ . F=Forest, Shr=Shrubland, Sav=Savanna, G=Grassland, W=Wetlands, C=Crops, U=Urban, M=Mixed.

### 3.3 Accuracy under drought conditions

The ACC analysis revealed that the RF was still able to capture *evi* anomalies (Fig. 8), but to a lesser extent compared to overall performance (Fig. 7c). The majority of grid cells showed positive correlations, with less than 10% displaying negative correlations. At least 50% of grid cells exhibited an ACC of 0.25 for  $0.1^\circ$  compared to 45% when *evi* was predicted at  $0.01^\circ$  (Fig. 8). This indicates that for that 90% of the locations, the RF can reproduce anomalies from the average seasonal cycle and thus can be used to identify periods of negative or positive *evi* impacts resulting from droughts or more favourable growing conditions.

**Figure 7.** : (a) Scatter plot of observed and predicted *evi* at  $0.1^\circ$  and (b)  $0.01^\circ$ ; Cumulative distribution function for (c) Pearson Correlation Coefficients overall grid points at  $0.1^\circ$  (blue) and  $0.01^\circ$  (orange), (d) violin plot of RMSE for all grid points at  $0.1^\circ$  and  $0.01^\circ$

**Figure 8.** Cumulative distribution curves of anomaly correlation coefficients for *evi* predicted by a RF at  $0.1^\circ$  (blue) and  $0.01^\circ$  (orange).

## 4 Discussion

This study assessed whether the RF algorithm is an appropriate tool for predicting *evi* dynamics at the global scale. RF was  
260 evaluated for its ability to be used as a gap-filling and downs-scaling tool. The discussion is outlined as follows, first, the overall  
performance of the RF is discussed; after that its usefulness as a gap-filling or downscaling tool is critically evaluated. We then  
highlight important outcomes from applying the model during periods of drought. The importance of landcover types and input  
data accuracy in determining model accuracy is then discussed. Finally, the use of ML in drought monitoring of vegetation  
status touched on.

### 265 4.1 Overall performance

The RF successfully predicted *evi* at  $0.1^\circ$  scale from meteorological, topography, and landcover types as input data. Of these  
data, features related to water and energy balances were most important in predicting *evi*. The RF successfully captured annual  
vegetation growth cycles and was able to distinguish between the main global biomass with high accuracy. Error analysis  
revealed that prediction accuracy could have been more homogeneous across space and time and varied according to the  
270 growing season and land cover type. This behaviour can also be linked to the relative abundance of land cover types, where  
more dominant land cover types are simulated with higher accuracy.

### 4.2 Gapfilling *evi* using Random Forests

A promising aspect of this study is that the RF can accurately predict *evi* at unseen geographic locations when trained on  
relatively few data - only 6% in this case. It follows that this approach can be used to for gap-filling purposes and produce  
275 high-resolution vegetation indices from other satellite sources or be used in conjunction with satellite products. For example,  
Landsat and Sentinel-2 data produce high-resolution data vegetation products; however, retrievals are strongly affected by  
weather conditions, which results in data gaps. In addition, its relatively low orbiting altitude means that the spatial coverage  
for each pass over is low. The approach outlined in this study could be applied to Landsat and Sentinel-2, to produce continuous  
vegetation index data sets at the 30-10m spatial resolution. This approach has been previously used to impute missing values  
280 for other remote sensing products like land cover types (Holloway-Brown et al., 2021), leaf traits (Moreno-Martínez et al.,  
2018) and soil moisture (Nguyen et al., 2022) and can now be the extent to vegetation health or *evi*.

### 4.3 Downscaling *evi* using Random Forests

The RF accurately predicted *evi* at finer spatial scales than was trained, successfully predicting *evi* at a scale of  $0.01^\circ$  using high-  
resolution auxiliary data. However, it should be noted that this resulted in a reduction in precision compared to the  $0.1^\circ$  product.  
285 This is an expected result, given that *evi* at the  $0.01^\circ$  resolution will exhibit greater variances and more extreme values during  
periods of high and low growth. Scale-dependent drivers of vegetation dynamics may be another phenomenon that contributes  
to decreased precision when predicting *evi* at the  $0.01^\circ$  using a model trained at a coarser resolution. Meteorology has been  
shown to be tightly coupled to vegetation at the ecosystem scale but less so at finer scales, where biotic processes, such as

competition, herb ivory, disease, and fire, are more important (Franklin et al., 2020). When predicting *evi*, the relative increases  
290 in error remained small. This product can be of particular use in cases where the benefits of having high resolution long-term  
*evi* products outweigh the limitations associated with error increases. The product presented here can and should be used in  
further studies investigating global vegetation dynamics.

#### 4.4 Random Forests for predicting drought effects

Compared to the overall performance, the RF was less capable of capturing extreme values of *evi*. The increase in error among  
295 extreme values is a known limitation of the RF (Hauswirth et al., 2021). During RF training, an evaluation metric, in this case  
`squared_error`, is used to minimise the error for the model as a whole. In this scenario, optimal fits inevitably result in  
reduced errors for values close to the mean at the expense of inflated errors for the outliers (Ribeiro and Moniz, 2020). In the  
current study, this means that *evi* during normal growth periods is prioritised over periods of extremely low or high vegetation  
growth. Production of ML frameworks that accurately reproduce vegetation responses during extreme periods is an essential  
300 consideration for future research directives.

#### 4.5 Importance of Landcover Types and Input Data

Varying error according to landcover type in the  $0.1^\circ$  and  $0.01^\circ$  is expected for at least two reasons. The first relates to  
the inherent features of the RF algorithm itself, and the second to the environmental process that affects the dynamics of  
*evi*. A limitation of the RF algorithm is that when data is imbalanced, underrepresented groups are less well explained by  
305 the algorithm. Accordingly, accuracy varied according to a proportional abundance of landcover types (Jung et al., 2020).  
Dominant landcover types, such as forests and grasslands, displayed the least amount of error; in contrast, minority landcover  
types regions that have undergone human modification (i.e., urban areas and croplands) were associated with the highest error.  
Second, the features used in this study may not incorporate processes critical to vegetation status equally among landcover types  
(Moussa Kourouma et al., 2021). Forests, grasslands, and other natural ecosystems are closely coupled to natural weather  
310 processes. However, croplands and urban areas may be less influenced by weather and more influenced by anthropogenic  
manipulations of water and energy balances (Zhang et al., 2004; Hawkins et al., 2003; Tang et al., 2021). A potential solution  
to this problem is to rely on Extreme Gradient Boosted Decision Trees, which have been shown to provide more accurate  
predictions where data are imbalanced (Li et al., 2021b) or include information on human-water management to better represent  
drought responses (Wanders and Wada, 2015).

315 Landcover-specific variations in the model's ability to predict vegetation are an important outcome of this study. Apart from  
the statistical reasons detailed in the previous paragraph as potential mechanisms for this phenomenon, an additional, and most  
likely compounding explanation is that the data used to predict *evi* may be more relevant for some landcover types and levels  
of vegetation growth than others. For instance, vegetation status in urban areas and croplands shows weak correlation or high  
errors (Fig. 5 & 6). The meteorological data used here to predict *evi* may not be the only factor driving the vegetation dynamics  
320 in human-modified areas. It is possible that irrigation, harvesting, and water management influence vegetation. Indeed, vege-  
tation in urban areas have been shown to grow more rapidly and have a longer growing season than rural counterparts; this is

thought to be driven by higher temperatures, high concentration of airborne phosphorous and other aerosol pollutants (Sicard et al., 2018a, b; Pretzsch et al., 2017). In contrast, natural forests and grasslands show high levels of accuracy and correlations, thus suggesting that the data used here is appropriate for the machine learning models to capture vegetation dynamics. Similarly, poor accuracy in wetlands is not unexpected as wetland vegetation is primarily driven by water quality, salinity, and pH (Grieger et al., 2021). On the contrary, forests and grasslands show high accuracy when using meteorological variables, since these are important drivers of vegetation growth in these areas. Although not directly related to vegetation, Hauswirth et al. (2021) showed that by including water management practices in machine learning models, the predictions of groundwater head and stream flow were more accurately predicted.

One other possibility is that uncertainty in the input data prevents more accurate predictions by the model. The temperature of ERA5-Land is known to show weaker correlations with the observed data in the tropics compared to more northern and southern latitudes (Muñoz-Sabater et al., 2021). When considering the quality of land cover data used here, some inconsistencies may affect the ability of the RF to accurately predict *evi*. For example, when croplands are smaller than the pixel size used in MODIS, these croplands are incorrectly assigned as natural vegetation. Furthermore, temperate evergreen needleleaf forests are misclassified as broadleaf evergreen forests, and some grassland areas are classified as savannas. The relatively poor predictive performance in mixed landcover types further reiterates the need to provide models with appropriate input data sources where strong signals are present.

#### 4.6 The use of ML in drought monitoring

This study shows that ML can be used for drought monitoring at high spatial and temporal resolutions, however there are trade-offs when it comes to using machine learning for vegetation drought impact monitoring. ML based *evi* estimates can be used to assess the potential impact of droughts on vegetation, however this ML based estimates still require meteorological input dataset. The ML model also needs to be trained on actual remotely sensed *evi* observations to identify the relationship between these meteorological variables and vegetation drought impacts. This inherently makes the ML based estimates as good as the remotely sensed product, and as long as no reliable alternative exists it will be difficult to fully replace remotely sensed *evi* observations. However, there is an added benefit of having continuous high resolution global coverage derived from a ML based *evi* estimate. Finally, the ML-based estimates also allow us to extrapolate the *evi* records to historical periods for which meteorological data exist but satellite remotely sensing was not yet available or use as post-processing in hydrological model simulations to directly estimate drought impacts.

## 5 Conclusions

The results from this study reveal that the RF is an appropriate method for predicting *evi* at the global scale, at the  $0.1^\circ$  and downscaled  $0.01^\circ$  resolution. In general, RF was capable of predicting *evi* dynamics with high accuracy; global patterns of vegetation and temporal dynamics were well captured. However, it is essential to note that higher errors were associated with under-represented landcover types and periods of extreme vegetation growth, such as drought periods. Lower accuracy for

underrepresented classes in unbalanced data sets and a hampered ability to predict extreme values is a common criticism of the  
355 RF. In accordance with this study, landcover types that account for a smaller fractional cover of the earth's surface, and periods  
of extreme vegetation growth, were associated with the highest error. Predicting *evi* at a finer resolution resulted in increased  
errors. This is attributable to higher variances in the  $0.01^\circ$  product compared to  $0.1^\circ$  and it is important to note that the relative  
increases remained small.

The results here also highlight the use of RF for efficiently and accurately predicting missing data and downscaling, ulti-  
360 mately allowing for the production of spatially continuous *evi* data at very high spatial and temporal resolutions. Toward this  
end, this study produces spatially continuous *evi* product at  $0.1^\circ$  and  $0.01^\circ$  resolution, which could be used to fill existing gaps  
in satellite observations or in conjunction with satellite data to have improved monitoring of drought impacts on vegetation.  
These results add to the current body of research showing that RF is a powerful technique for predicting the temporal and  
spatial dynamics of vegetation from remote sensor data (Roy, 2021; Staben et al., 2018; Wang et al., 2021). For example, (Roy,  
365 2021) successfully use machine learning to predict *evi* at a more local scale. On a more global scale, (Han et al., 2023) provides  
an example on how a similar approach to the one used here can produce global high-resolution soil moisture. Apart from ML  
based methods, this current work adds to the number of already available tools (reviewed in Peng et al. 2017) that can be used  
for gap-filling and downscaling of remotely sensed vegetation data.

This study adds to previous research efforts that have successfully applied the RF in predicting vegetation status. Here the  
370 RF was used to produce a global spatial and temporally continuous *evi* product at  $0.1^\circ$  and  $0.01^\circ$ , with a median  $R^2$  of 0.86  
& 0.75, respectively. The approach outlined in this study could be applied to Landsat and Sentinel-2, to produce continuous  
vegetation index data sets at the 30-10m spatial resolution. The RF algorithm is a powerful technique for predicting temporal  
and spatial vegetation dynamics from remote sensor data, as well as those using RF for gap filling purposes on remote sensing  
products. The novelty of this product, compared to previous studies, is that it has global coverage, high spatial and high  
375 temporal resolution.

## Appendix: A1. Feature Selection

**Figure A1.** Correlation Matrix of pairwise Spearman rank correlation coefficients between all potential variables

## Appendix: A2. Drought Indices Calculations

For the calculation of  $spi$ :

$$x = \sum_i^m tp_i \quad (A1)$$

390 where  $i$  is the month in question and  $m = i - scale$ .

For the calculation of  $spei$ :

$$x = \sum_i^m D_i \quad (A2)$$

where:  $D_i = tp_i - pet_i$  and

$$x_{i,j}^k = \begin{cases} \sum_{l=13-k+j}^{12} tp_{i-j,l} + \sum_{l=1}^j tp_{i,l}, & \text{if } j < k \\ \sum_{l=j-k+1}^j tp_{i,l}, & \text{if } j \geq k \end{cases} \quad (A3)$$

395 This time series is then fitted to a gamma distribution taken the following steps:

First  $\alpha$  and  $\beta$  fitting parameters as calculated as:

$$\hat{\alpha} = \frac{1}{4A} \left( 1 + \sqrt{1 + \frac{4A}{3}} \right) \quad (\text{A4})$$

Where  $A = \ln(\bar{x}) - \frac{\sum \ln(x)}{n}$  with  $n$  being number of observations.

$$\hat{\beta} = \frac{\bar{x}}{\alpha} \quad (\text{A5})$$

400 The gamma distribution probability density (Eq. A6) function with respect to  $x$  and including the calculated estimates for  $\alpha$  and  $\beta$  can be inserted to produce an equation for the cumulative probability of a value for (Eq. A7).

$$g(x) = \frac{1}{\beta^\alpha \Gamma(\alpha)} x^{\alpha-1} e^{-\frac{x}{\beta}} \quad (\text{A6})$$

where  $\alpha$  is the shape parameter and  $\beta$  is the scale parameter and  $\Gamma(a) = \int_0^\infty y^{a-1} e^{-y} dy$

$$G(x) = \frac{1}{\beta^\alpha \Gamma(\alpha)} \int_0^x t^{\alpha-1} e^{-\frac{t}{\beta}} dt \quad (\text{A7})$$

405 then substituting  $t$  for  $\frac{x}{\beta}$  results in the incomplete gamma distribution (Eq. A8)

$$G(x) = \frac{1}{\Gamma(\hat{\alpha})} \int_0^{\frac{x}{\beta}} t^{\hat{\alpha}-1} e^{-t} dt \quad (\text{A8})$$

Values of the incomplete gamma function can be computed using Eq. A9

$$H(x) = q + (1 - q)G(x) \quad (\text{A9})$$

410 Finally, values computed from Eq. A9 are transformed into the standard normal distribution to yield the *spi* and *spei* at the relevant time scales. These calculations were completed using the relevant algorithms in the `climate_indices` python package (Adams, 2021) using *tp*, *pet*, and *t2m* detailed in Section 2.1.2.
