**Abstract.** Large sample datasets are transforming hypothesis testing and model fidelity in the catchment sciences, but few  
15 large stream water chemistry datasets exist with complementary streamflow, meteorology, and catchment physiographic  
attributes. Here, we pair atmospheric deposition and water chemistry related information with the existing CAMELS  
(Catchment Attributes and Meteorology for Large-sample Studies) dataset. The newly developed dataset, CAMELS-Chem,  
comprises U.S. Geological Survey water chemistry data and instantaneous discharge over the period from 1980 through 2014  
in 506 minimally impacted headwater catchments. The CAMELS-Chem dataset includes 18 common stream water chemistry  
20 constituents: Al, Ca, Cl, Dissolved Organic Carbon, Total Organic Carbon, HCO<sub>3</sub>, K, Mg, Na, Total Dissolved Nitrogen  
[nitrate + nitrite + ammonia + organic-N], Total Organic Nitrogen, NO<sub>3</sub>, Dissolved Oxygen, pH (field and lab), Si, SO<sub>4</sub>, and  
water temperature. We also provide an annual wet deposition loads from the National Atmospheric Deposition Program over  
the same catchments that includes: Ca, Cl, H, K, Mg, and Total Nitrogen from deposition [precipitation NO<sub>3</sub> + NH<sub>4</sub>, dry  
deposition of particulate NH<sub>4</sub>, + NO<sub>3</sub>, and gaseous NH<sub>3</sub>], Na, NH<sub>4</sub>, NO<sub>3</sub>, SO<sub>4</sub>. We release a paired instantaneous discharge  
(and mean daily discharge) measurement for all chemistry samples. To motivate wider use by the larger scientific community,  
25 we develop three example analyses: 1. Atmospheric-aquatic linkages using atmospheric and stream SO<sub>4</sub> trends, 2. Hydrologic-  
biogeochemical linkages using concentration-discharge relations, and 3. Geological-biogeochemical linkages using  
weathering relations. The retrieval scripts and final dataset of > 412,801 individual stream water chemistry measurements are  
available to the wider scientific community for continued investigation.

## 1 Introduction

30 While hydrochemical datasets are increasingly available at continental scales, these datasets have often provided scientific  
insights focused on detailed knowledge of a single catchment rather than transformative knowledge across many catchments.

To address the need for ‘balancing breadth with depth’ (Gupta et al., 2014, Hubbard et al., 2020), the hydrological sciences have developed large sample size datasets that are of high quality and then made these available to the research community. One of the key advantages of aggregating and harmonizing data into larger sample size datasets is to test how model hypotheses reproduce observed behavior across variable conditions and sites to reduce the uniqueness of place-based issues that plague catchment science (Gupta et al., 2014) (Hubbard et al., 2020). As a result, several recent efforts have focused on generating and using datasets across the continental U.S. (CONUS) where observation networks are relatively dense. For example, the Model Parameter Estimation Experiment (MOPEX, Duan et al., 2006) dataset has been used to detect the effects of shifts from snow to rain on streamflow (Berghuijs et al. 2014) and to better diagnose the cause of catchment-scale water budgets (Brooks et al., 2015). Recent efforts have extended the record and detail of auxiliary data of older efforts (e.g. MOPEX) to develop longer-term streamflow and hydrometeorological forcing data for a larger number of minimally disturbed catchments, including the continental U.S (Newman et al.), Chile (Alvarez-Garreton et al., 2018), and Brazil (Chagas et al., 2020). In particular, Catchment Attributes for Large-Sample Studies (CAMELS, Newman et al., 2014) compile high quality streamflow measurement in 671 unimpaired catchments, as well as climate forcing datasets (e.g. daily precipitation and temperature) and physiographic properties (e.g. land cover, topography, etc., Addor et al., 2017). CAMELS has seen widespread adoption by the hydrological community as a benchmarking tool for hydrological models (Melsen et al., 2018; Mizukami et al., 2019; Pool et al., 2019), in the development of hydrological signatures and new information theory-based approaches, and the application of novel machine learning tools (Kratzert et al., 2018). However, the generation of matching datasets on stream water chemistry has not seen as much development.

Indeed, some of the most important insights across Earth science disciplines over the last several decades derived from investigations that combined several datasets such as long-term stream chemistry data, stream discharge, hydroclimatology, and catchment properties (e.g. vegetation, geology, topography). For example, global analyses of CO<sub>2</sub> evasion from headwater streams have helped to quantify global fluxes (Gaillardet et al., 2018; Horgby et al., 2019; Lauerwald et al., 2015; Raymond et al., 2013). Changes in dissolved organic carbon (DOC) in stream water were partially related to changes in atmospheric deposition and acidity only viewable with longer records (Monteith et al., 2007). Stream flow and chemistry data, in particular combined(?) concentration and discharge data, have also been shown to illuminate subsurface flow paths and chemical vertical stratification (Stewart et al., 2022; Zhi and Li, 2020). Applying an integrative dataset in the Northeastern U.S., a recent study showed differential sensitivity of headwater catchments to reductions in SO<sub>4</sub> and NO<sub>3</sub> and resulting variations in stream DOC efflux (CITE Adler et al. 2021). Importantly, this study confirmed that much of the long-term recovery from acid rain is mediated by catchment-scale processes in variable soils and bedrock as well as variable hydrological and climatic forcings. Only by aggregating data across many catchments could these interacting factors affecting stream chemistry be determined because transferability from a small number of regional catchments is very limited (Clow et al, 1999; Garmo et al., 2014; Harpold et al., 2010). Long-term water chemistry datasets have also given insight into rock weathering and solute flux estimates. For example, Godsey et al. (2009) showed the ubiquity of ‘chemostasis’, where solute fluxes are primarily driven

by stream discharge and not variations in concentrations in 59 catchments but did not investigate the role of catchment properties or climate. More recent work using 2,186 catchments from the Global River Chemistry Dataset (GLORICH) began to illustrate the role of aridity and catchment properties in controlling the concentration-discharge (C-Q) relationship in key solutes (Godsey et al., 2019).

70

An opportunity exists to inform our understanding of the inter-relationships between water chemistry, hydrology, and biogeochemistry by developing new datasets that link stream chemistry to discharge and other catchment properties. A notable example is the GLORICH dataset that focuses on large, human impacted riverine systems and contains corresponding catchment properties and streamflow data from over 17,000 sampling locations (Hartman et al., 2019). However, GLORICH  
75 does not include complete observation of streamflow (and instead supplements with modeled data); its climate forcing datasets and catchment properties are scant, significantly limiting its application to process-based modeling and data analysis. As a result, we lack understanding on how stream chemistry responds to climatic forcings and catchment structure characteristics at the continental to global scales (Godsey et al., 2019). The continued development of large sample datasets that include stream chemistry has the potential to transform catchment science and address grand scientific challenges.

80

To enable and advance these (bio)geo-chemistry and catchment sciences, we compiled a new dataset that takes advantage of one of the most comprehensive collections of catchment attributes across the US i.e., CAMELS (Addor et al., 2017; Newman et al., 2014), and amended it with paired quality-controlled water chemistry data, instantaneous discharge, and atmospheric deposition data, hereafter referred to CAMELS-Chem. We harvested >412,801 individual water chemistry measurements  
85 from the U.S. Geological Survey (USGS) National Water Information System (NWIS), covering 506 catchments and 16 constituents, over the period from 1980 to 2014 as well as annual catchment-scale atmospheric deposition from a product developed by the National Atmospheric Deposition Program (NADP) for the same time period. The publicly released dataset also includes scripts that increase reproducibility and the potential to update the record with more current data. We first introduce the methods used to develop the CAMELS-Chem dataset (Section 2) and then summarize the availability and spatial  
90 patterns of key water chemistry constituents (Section 3). Finally, we develop example analyses using the large hydrochemistry dataset to demonstrate its utility for applications in (bio)geo-chemistry, ecology, and hydrology (Section 4).

## 2 Materials and Methods

### 2.1 Data Sources

Two different data sources were identified for acquisition 1) NWIS instantaneous and daily mean discharge data and 2) NWIS  
95 water quality data for the (bio)geo-chemical records. NWIS time series data significantly reduce the need to resolve semantic and structural conflicts due to the data having already been normalized and quality controlled. NWIS data also have unique gauge identifiers for each observation reducing the complexity of merging the two datasets. The geographical coverage for the

dataset encompasses the gauge IDs of the original 671 CAMELS watersheds and uses the same temporal period of the CAMELS dataset from water years 1980 to 2014. The resulting data capture rendered a water quality record comprising 493 watersheds wherein 178 gauges did not have any associated water quality data. All 671 CAMELS gauges returned values for both instantaneous and daily mean discharge.

## 2.2 Applied Methods

The temporal and geographical span of this dataset posed two distinct data management needs: 1) the integration of a large amount of data from disparate data repository systems such that different gauges could be compared, and 2) an integrated data repository to group and browse large amounts of data.

Data integration required the development of processes for the acquisition and integration of the NWIS data; its transformation into appropriate subsets and subsequent storage of the transformed data was solved using a data integration process called Extract, Transform, and Load (ETL). ETL generally involves extracting data from outside sources (Figure 1), transforming the data to fit operational needs (which can include quality definitions) and loading the data into an end target (e.g., a database or data warehouse). ETL is an especially useful method in the creation and management of efficient and consistent databases and data warehouses. Moreover, ETL tools allow for the fast, straightforward, and reproducible loading of new (and reloading of old) datasets, which facilitates continuous data updates, and auditing of the data acquisition processes. For this project, Pentaho Data Integration (PDI) ETL (Pentaho Data Integration 2020) was used.

The second need, an integrated data repository, was solved by using an online transactional processing (OLTP) relational database management system (RDBMS). For the data repository, we selected Oracle's free and open-source database, PostgreSQL (PostgreSQL 2020). OLTP databases are optimized to prevent data anomalies by only storing data in one place and using keys to relate different tables and data to each other. A relational database provides fast query processing, enforces data integrity, provides detailed information about current data and schema, and a flexible platform to export data for external analysis. Statistics were calculated for key parameters such as probability of exceedance, standard deviation, low/medium/high flow conditions, mean daily and annual flow. These were used in the following figures and are also available as part of this data release.

## 2.3 Related Discharge Dataset

In addition to a daily average discharge, we solve several challenges to release an instantaneous discharge dataset. Approximately 93% of the samples in CAMELS-Chem have a paired daily discharge value; however, the coverage for paired instantaneous discharge values is lower at 15% because not all gauges provide hourly observations or they provide discharge only from a more recent part of the record. The biogeochemical sample time was adjusted forward/backward to pair with the closest quarter -hour (or sometimes hourly) instantaneous discharge observation. Missing time stamps for (bio)geo-chemical

130 sampling is more challenging to correct. We address this by using the fact that field technicians generally visit and sample once per day so the recorded time from one sample is as representative for all samples taken on that day. By assuming one sampling time every day per site we obtained another 397 instantaneous discharge (out of a total of 8,975 records without timestamps).

## 2.4 Wet Deposition Dataset

135 Wet deposition data were obtained from NADP for the period from 1985 until 2019. The data product is generally an inverse distance weighted interpolation of the wet deposition observations; more details are provided on their website. Data rasters were aligned with CAMELS catchment shape files to determine total watershed deposition for 9 species for a given year. Quantum GIS 3.12 was used to calculate total (mean) deposition for a given year by catchment. Minimum, maximum, and mean values were calculated for each catchment (Table 2).

140 **Table 1: The stream water chemistry datasets in the CAMELS-Chem dataset including the name, units, and description that includes the abbreviation used in this paper.**

Attribute	Name	Description	Units
Al	Aluminum	Water, filtered	mg/l
Ca	Calcium	Water, filtered	mg/l
Cl	Chloride	Water, filtered	mg/l
DOC	Dissolved Organic Carbon	Water, filtered	mg/l
TOC	Total Organic Carbon	Water, unfiltered	mg/l
HCO <sub>3</sub>	Bicarbonate	Water, filtered, field, inflection-point (incremental titration method)	mg/l
K	Potassium	Water, filtered	mg/l
Mg	Magnesium	Suspended sediment, total	mg/l
TDN	Total Dissolved Nitrogen	Water, filtered [nitrate + nitrite + ammonia + organic-N]	mg/l
TON	Organic Nitrogen	Water, unfiltered	mg/l
Na	Sodium	Water, filtered	mg/l
NO <sub>3</sub>	Nitrate	Water, filtered	mg/l
DO	Dissolved Oxygen	Water, unfiltered	mg/l
pH	pH	Water, unfiltered, field	std units
pH_l	pH	Water, unfiltered, laboratory	std units
Si	Silica	Water, filtered	mg/l

SO <sub>4</sub>	Sulfate	Water, filtered	mg/l
-----------------	---------	-----------------	------

145 **Table 2: NADP depositional dataset, denoting concentration for each constituent, including the name, units, and description that includes the abbreviation used in this paper. \*TN\_d denotes Total Nitrogen depositional observation [precipitation NO<sub>3</sub> + NH<sub>4</sub>, dry deposition of particulate NH<sub>4</sub>, + NO<sub>3</sub>, and gaseous NH<sub>3</sub>].**

Attribute	Name	Units
Ca	Calcium	mg/l
Cl	Chloride	mg/l
H	Hydrogen	mg/l
K	Potassium	mg/l
Mg	Magnesium	mg/l
*TN_d	Total Nitrogen	mg/l
Na	Sodium	mg/l
NH <sub>4</sub>	Ammonium	mg/l
NO <sub>3</sub>	Nitrate	mg/l
SO <sub>4</sub>	Sulfate	mg/l

### 3 Dataset Description

150 The CAMELS-Chem dataset comprises 17 water chemistry and property values (Table 1), instantaneous discharge, and annual wet deposition loads (Table 2). A comparison of the stream water and wet deposition constituents are provided in Table 3. The focus of CAMELS-Chem is stream water chemistry, which we organize into cations (Al, Ca, K, Mg, Na, Si), anions and nutrients (Cl, DOC, HCO<sub>3</sub>, NO<sub>3</sub>, SO<sub>4</sub>, TDN, TOC) and general water quality parameters (pH, DO, and water temperature). The additional wet deposition dataset can also be organized into cations (Ca, H, K, Mg, Na, NH<sub>4</sub>), anions (Cl, NO<sub>3</sub>, SO<sub>4</sub>), and TN. In the next two sections we describe and exemplify the scope and overall spatial patterns of the stream chemistry  
 155 (Section 3.1) and wet deposition data (Section 3.2) for a subset of 8 constituents (Table 2: Ca, DO, DOC, Na, NO<sub>3</sub>, pH, Si, SO<sub>4</sub>) and discharge. Information for other constituents is provided in the supplementary materials.

160 **Table 3: NADP depositional dataset, denoting concentration for each constituent, including the name, units, and description that includes the abbreviation used in this paper. \*TN\_d denotes Total Nitrogen depositional observation [precipitation NO<sub>3</sub> + NH<sub>4</sub>, dry deposition of particulate NH<sub>4</sub>, + NO<sub>3</sub>, and gaseous NH<sub>3</sub>].**

Source	Group	Water Chemistry or Property
--------	-------	-----------------------------

USGS NWIS Surface water chemistry	Cations	Al, Ca, Mg, Na, K, Si
	Anion and nutrients	Cl, DOC, HCO <sub>3</sub> , NO <sub>3</sub> , SO <sub>4</sub> , TDN, T
	General water quality	pH, DO, temperature
NADP wet deposition	Cations	Ca, K, Mg, Na, H (pH)
	Anions and nutrients	Cl, TN <sub>d</sub> , NO <sub>3</sub> , SO <sub>4</sub>

### 3.1 Water Chemistry Constituents and Data Availability

While the lengths of discharge and climate records extend up to or greater than 30 years for many CAMELS-Chem catchments, the water chemistry data are not as continuous and spatially consistent (Figure 2 and S1). The total number of stream water samples varies substantially depending on the variable of interest, which should be taken into consideration when using this dataset. For example, the dataset has 34,704 total Si measurements from 477 catchments, compared to only 11,101 DOC measurements from 189 catchments (Figure 2). In general, weathering-related solutes (Si, Ca, K, Mg, Na) are more comprehensively sampled (i.e. longer records and more catchments) than biologically driven constituents (NO<sub>3</sub>, TDN, DOC). Temperature and DO are sampled more often because they are part of the standard USGS field measurements at the time of water chemistry sampling. Because USGS sampling foci varied over each decade, temporal biases in the sampling record exist. For example, many of the stream water constituents impacted by acid rain (e.g. SO<sub>4</sub>, Ca) were sampled less frequently starting in the late 1990's. In contrast, sampling frequency for many solutes related to local water quality issues (i.e. NO<sub>3</sub>, and K) have increased in recent decades (Figure 2). The NO<sub>3</sub> data are more focused in the Midwest and east coast where agriculture is generally more intense. In contrast, DOC observations highlight the location of long-term sites focused on minimally human-impacted catchments (e.g., USGS Hydrologic Benchmark Network) that have the most comprehensive sampling of all solutes (Gupta et al., 2014; Mast, 2013). We explore how the consistency of spatial and temporal sampling can affect analysis techniques and inferences in Section 4.

180

## 185 3.2 Atmospheric Deposition Dataset

Annual average atmospheric deposition maps developed by the National Atmospheric Deposition Program (NADP) are reported for each catchment (Figure 4). The wet deposition data are important to explain some water chemistry patterns. For example, Cl deposition near the coasts (Figure 3) is evident in higher streamflow Cl concentrations along the coast relative to more inland catchment (Figure 3). Conversely, atmospheric deposition of NO<sub>3</sub> is much higher in the Midwest and other places  
190 where anthropogenic inputs of fertilizer are high (Figure 4) and are consistent with patterns in stream chemistry (Figure 2). The annual resolution of the wet deposition data is sufficient to investigate trends in air and water quality (see example 4.3) and could be supplemented as additional datasets become available (i.e., total wet and dry deposition; Schwede et al., 2014).

## 4 Example Analyses Using CAMELS-Chem

We illustrate the research potential of CAMELS-Chem using three themes and examples: 1. by investigating trends in SO<sub>4</sub>  
195 deposition and stream chemistry over the continental U.S we show highlight atmospheric-aquatic linkages, 2. by investigating continental-scale C-Q relations we highlight hydrological and biogeochemical linkages, and 3. by investigating weathering patterns we highlight geological-biogeochemical linkages. Our goal for this section is to demonstrate the unique value of the CAMEL-Chem dataset, its potential limitations, and to motivate future work.

### 4.1 Trends in Atmospheric SO<sub>4</sub> Deposition and Stream Chemistry

#### 200 4.1.1 Background and Motivation

The Industrial Revolution caused a rapid increase in fossil fuel emissions, which introduced acid anions (SO<sub>4</sub>, NO<sub>3</sub>) in excess of background conditions leading to acidic precipitation throughout many industrialized regions (Newell & Skjelkvåle, 1997). The Clean Air Act in 1970 and subsequent amendment in 1990 led to major reduction in air pollution as apparent in progressively decreasing deposition amounts (Accessed September 20, 2020: <https://www.epa.gov/air-trends/sulfur-dioxide-trends>). These significant changes in atmospheric composition served as an experiment in stream chemistry response (Stoddard  
205 et al, 1990) and motivated several studies across the US and Europe. For example, Stoddard et al. (1990) showed that stream water acid anion concentration declined more in the 1990s than the 1980s and later research indicated that effects were larger in Europe than North America (Garmo et al., 2014). In the Northeastern U.S., SO<sub>4</sub> stream chemistry has generally responded to declines in SO<sub>4</sub> deposition (McHale et al., 2017; Siemion et al., 2018). However, catchment properties and flow regime  
210 were shown to impact the sensitivity of stream response to shifts in deposition (Clow et al., 2018; Murdoch et al., 2006). The lack of co-located long-term deposition data, stream water chemistry and discharge data, and catchment attributes hinders investigation of the legacy of effects of acid rain on stream chemistry at continental scales.

#### 4.1.2 Analysis and Findings

215 CAMELS-Chem provides new potential to analyze the effects of acid deposition on long-term stream chemistry trends across  
a range of hydrological conditions. Many (but not all) sites have >100 SO<sub>4</sub> stream samples spanning over 20 years of record  
(Figure 2). Our analyses of the flow duration curves (FDC, divided into terciles of probability of exceedance < 0.33) show  
that bias towards part of the flow regime when SO<sub>4</sub> samples is common and depends on the location of interest (Figure 5).  
For example, some streams in central Arizona and North Dakota have no low flow samples (FDC>66%), whereas streams in  
Oregon and Washington tend to have more moderate flows (33%>FDC<66%) than high flows (FDC<33%; Figure 5).

220

We performed a Mann-Kendall test to investigate trends in atmospheric SO<sub>4</sub> deposition and resulting trends in stream water  
chemistry (Hirsch et al., 1984). Our results are in agreement with previous findings of declining SO<sub>4</sub> deposition following the  
1990 Clear Air Amendments (Figure 5, Stoddard et al., 2003). As expected, plotting trends in SO<sub>4</sub> stream chemistry and wet  
deposition just after the Clean Air Act (Figure 5a) show a predominance of decreasing trends in SO<sub>4</sub> deposition and  
225 corresponding decreasing trends in SO<sub>4</sub> stream chemistry. Wet deposition trends remain decreasing in the following two  
decades (1995-2005 and 2005-2015), but with much response in SO<sub>4</sub> stream chemistry. This initial analysis provides a starting  
point for hypothesis testing - for example, on the role of catchment attributes that are shown for the dominant geology in Figure  
5a-c. Furthermore, we hope to motivate more sophisticated statistical and machine learning techniques to investigate coupled  
trends in solutes and the role of climate physiographic information as predictor variables.

#### 230 4.2 Concentration-Discharge Relationships

##### 4.2.1 Background and Motivation

Concentration-discharge (C-Q) relationships are routinely used to compute solute loads for mass budgets (Cohn et al., 1989)  
and have been used to infer catchment effects on biogeochemical cycling (Basu et al., 2010, Musolff et al., 2015). When  
event-scale data is not available, routine sampling can be used to compute a log-log C-Q relationship to understand whether  
235 concentration has a clear dependency on discharge. The log-log C-Q relationship is considered chemostatic if the regression  
slope is near zero, implying that export of that solute is negligibly influenced by discharge (Godsey et al., 2009, Underwood  
et al., 2017, Zhi and Li, 2020).

This chemostatic relation is more likely for geogenic solutes, like Si and Ca, and less so for biogenic solutes, like nutrients,  
240 with large anthropogenic or natural legacy effects (Musolff et al., 2015). Recent work by Godsey et al., (2019) suggests that  
groundwater and fast chemical reactions buffer C-Q relationships towards chemostasis, but that the baseline concentrations  
reflect catchment differences in geology, land use, etc. Godsey et al. (2019) also found that nutrients can be chemostatic, but  
their long-term mean concentrations correlated more to land use than climate. Moreover, sampling bias occurring at high and  
low streamflow (Figure 5, as well as rising and falling limb of hydrograph, season, etc.) may bias effects towards chemostatic

245 behavior (Zhi et al., 2019). These efforts with CAMELS-Chem show the value of large-sample datasets for inferring C-Q relations and their uncertainty.

#### 4.2.2 Analysis and Findings

The CAMELS-Chem dataset offers potential to resolve C-Q relationships by improving discharge estimates and pairing with substantial existing physiographic information. Here we repeat the methods and analysis of Godsey et al. (2019) to show similar event-scale (i.e. instantaneous water chemistry and discharge) C-Q slopes across the overlapping solutes (Figure 6). The existing physiographic data compiled by (Addor et al., 2017) allows us to easily filter by the aridity index to match the previous analysis of Godsey et al. 2019. Arid catchments were defined as those in which potential evapotranspiration was greater than actual evapotranspiration, the reverse was used to determine humid catchments. In general, the findings for CONUS sites are consistent with the global-scale analysis of Godsey et al. (2019), showing near-chemostatic behavior of DOC and Si. In contrast to Godsey et al. (2019), Na for the CAMELS sites shows more pronounced negative slopes in arid catchments than in humid catchments. This analysis could be expanded to include additional solutes, or physiographic data, in more complex statistical or machine learning based approaches that attempt to infer association with biogeochemical process and uncertainty due to irregular and limited sampling.

260 The CAMELS-Chem dataset has several advantages in this C-Q analysis: 1) instantaneous (hourly) discharge data were used to supplement the NWIS database and 2) 30-year daily discharge records are a reference for C-Q ranges. Because Q values are more likely to change over daily periods at high flows than low flows, instantaneous discharge measurements are more critical on high flow days than low flow days. Instantaneous discharge during the chemistry sampling can be > 50% higher or lower than the daily mean discharge for a range of important solutes, despite little overall bias (Figure S4). Thus, the CAMELS-Chem discharge data could improve accuracy in previous C-Q analysis that rely on daily measured or modeled discharge data. The 30-year daily discharge records can be used to assess the degree of discharge variation covered by chemistry sampling dates. We show this as the percent of the long-term FDC covered by the minimum and maximum discharge during sampling in Figure 7. While many sites cover > 90% of the FDC, like those in the upper Midwest, other locations cover less than 50% of the FDC, like many of the Gulf Coast sites. The response of the concentration discharge relationship can be different at high and low flows (Li et al., 2020). The diverse number of samples with uneven collection dates, as well as the lack of discharge variation during solute sampling, suggest that future work should explore C-Q uncertainty estimates using more sophisticated statistical techniques with CAMELS-Chem.

## 4.3 Weathering Response

### 4.3.1 Background and Motivation

275 Weathering (i.e. the breakdown of bedrock and regolith) involves key physical and chemical processes that shape the critical zone and provide important nutrients for all ecosystems. Weathering of silicate minerals regulates global atmospheric CO<sub>2</sub> levels over geologic time scales (Spence and Telmer, 2002), and weathering of carbonate rocks modulate CO<sub>2</sub> levels at the human to century time scales (Martin, 2018). Riverine composition is often used as an indicator for weathering rates and to draw conclusions on implications at larger scales. A classic example is the study by Gaillardet et al. (1999) where 60 of the world largest rivers were used to show a strong role of bedrock lithology on weathering rates from Si effluxes. To display the impact of major rock classes (i.e. silicates, carbonates, evaporites) on riverine composition, the use of molar ratios for geogenic species (Ca/Na, Mg/Na, HCO<sub>3</sub>/Na) instead of absolute concentrations is useful, because large differences in concentrations between solid and liquid phases make comparisons difficult. CAMELS-Chem provides complete and co-sampled water chemistry datasets, with known lithology, making these types of weathering analyses possible across CONUS.

### 285 4.3.2 Analysis and Findings

CAMELS-Chem has sufficient data on the dissolved load of geogenic species to be used in a regional scale weathering study across variable lithology and climate. We display these molar ratios of stream water composition for all CAMELS-Chem sites (with a sample number larger than 5) as a function of bedrock lithology including igneous, metamorphic and sedimentary rocks (Fig 5). We included only samples in the lower tercile of daily discharge values because the low flow discharge is more likely from longer residence groundwater that carries the weathering signal. The lower tercile encompasses more Ca and Mg samples than Na and HCO<sub>3</sub> samples based on overall sampling frequency (Figure 9). Similar to previous studies (Gaillardet et al. 1999), we observe organization as a function of lithology, with catchments underlain by carbonate plotting in the upper right (i.e., high Ca/Na, Mg/Na, and HCO<sub>3</sub>/Na ratios) and unconsolidated sediments plotting in the lower left (e.g., low Ca/Na, Mg/Na, and HCO<sub>3</sub>/Na ratios). These results are consistent with the high weathering rates of carbonates, where even small amounts of carbonate lithology lead to significant shifts to higher Ca/Na (calcite endmember) and Mg/Na (presence of dolomite) ratios. Although beyond the scope of this work, CAMELS-Chem gives sufficient samples to provide uncertainty estimates in Figure 8, particularly given the uneven number of samples and distribution across solutes (Figure 9). CAMELS-Chem also allows consideration of catchment properties to better understand connections to climate, hydrology, and other physiographic effects. For example, we visualize the baseflow index to show generally higher baseflow in carbonates-underlain catchments (Figure 8), which is consistent with fractures and highly conductive conduits that are common in carbonate aquifers (Hartmann et al., 2014). In contrast, unconsolidated sediments tend to have low weathering rates and low baseflow index (Figure 8). The control of lithology on geogenic species concentrations needs to be taken into account when investigating other processes, like baseline concentrations found in the C-Q relationships (i.e. Godsey et al. 2019), particularly when using a single or small number of catchments to infer large-scale response. CAMELS-Chem includes these important data on

305 lithology across many catchments, which we hope motivates the low-temperature geochemistry research community to take another look at weathering processes across CONUS.

## 5 Summary and Conclusions

We developed and released the CAMELS-Chem dataset comprising > 44,000 water chemistry measurements, corresponding instantaneous discharge, and wet deposition data. The dataset has several advantages because it is paired with  
310 hydrometeorological and hydrological modeling data (Newman et al., 2014), as well as catchment physiographic properties (Addor et al. 2017). In addition, the consistency of USGS water chemistry analysis increases the comparability of the dataset across regions and decades, which is a well-recognized problem (Godsey et al., 2019; Niu et al., 2018).

CAMELS-Chem has several limitations that were prominently illustrated through examples. In general, the sampling  
315 frequency and chemical variables of interest are not consistent over time, reflecting changing priorities and budgets within the USGS. This may require subsetting the data into the catchments with longer records or using new machine learning and statistical techniques that can take advantage of sparse data within a larger data analysis. The CAMELS-Chem dataset shows that bi-weekly or coarse water sampling reflects somewhat random discharge conditions on the flow duration curve (Figure S4). An advantage of CAMELS-Chem would be to use long-term discharge to constrain and propagate uncertainty in water  
320 chemistry-based flux and modeling efforts.

We illustrate several basic applications of CAMELS-Chem to motivate future research efforts across a variety of fields. One advantage of a comprehensive dataset such as CAMELS-Chem is to target new measurement campaigns that either extend long-term records, add new chemical species, or add new sites all together. These long-term records should guide future large-  
325 scale sampling campaigns and/or new gauges. For example, consistent co-sampling of solutes across the streamflow regime provides more information than limited discharge conditions, which should be paired with regional or larger-scale consistency in the variables of interest. Another exciting application of CAMELS-Chem is use in ‘big data’ applications of advanced statistical or machine learning tools that are focused on specific research questions. For example, large data approaches can develop new predictive tools for ungauged locations to help with water quality management (Zhi et al., 2020) or make process  
330 inferences and improve predictive models (Nearing et al., 2020). All of the research directions take advantage of the many unique aspects of CAMELS-Chem, which bodes well for its adoption and use by a variety of scientific disciplines.

## Code and Data Availability

Data are made available on this google drive with plans to publish a more permanent place in the next round of reviews.
