Abstract

A deep learning model designed for time series predictions, the long short-term memory (LSTM) architecture is regularly producing reliable results in local and regional rainfall-runoff applications around the world. Recent large-sample-hydrology studies in North America and Europe have shown the LSTM to successfully match conceptual model performance at a daily timestep over hundreds of catchments. Here we investigate how these models perform in producing monthly runoff predictions in the relatively dry and variable conditions of the Australian continent. The monthly timestep matches historic data availability and is also important for future water resources planning, however it provides significantly smaller training data sets than daily time series. In this study, a continental-scale comparison of monthly deep learning (LSTM) predictions to conceptual rainfall-runoff model (WAPABA) predictions is performed on almost 500 catchments across Australia with performance results aggregated over a variety of catchment sizes, flow conditions, and hydrological record lengths. The study period covers a wet phase followed by a prolonged drought, introducing challenges for making predictions outside of known conditions — challenges that will intensify as climate change progresses. The results show that LSTMs matched or exceeded WAPABA prediction performance for more than two-thirds of the study catchments; the largest performance gains of LSTM versus WAPABA occurred in large catchments; the LSTM models struggled less to generalise than the WAPABA models (eg. making predictions under new conditions); and catchments with few training observations due to the monthly timestep did not demonstrate a clear benefit with either WAPABA or LSTM.

Key words ~~{6 max}~~: Hydrology and water resources, machine learning, deep learning, benchmarking, neural networks, process-based modelling LSTM

Major points

1. A deep learning model (single-layer LSTM) matched or exceeded performance of a WAPABA rainfall-runoff model in 69% of study catchments.
2. Monthly datasets contain enough information to train the LSTMs to this level.
3. Generalisation to new conditions was found to improve with use of the LSTM, with implications for modelling under climate change. WAPABA struggled in more catchments to make predictions under dry conditions after being trained on wet conditions than the LSTM did.

35 1. Introduction

36 With progressively variable climate conditions and the ever-increasing accessibility of hydrologic data, there comes the
37 opportunity to reconsider how available data is being used to efficiently predict streamflow runoff on a large scale.
38 Hydrological researchers are increasingly turning to emerging machine learning techniques such as deep learning to analyse
39 this increasing volume of data, due to the relative ease of extracting useful information from large datasets and producing
40 accurate predictions about future conditions without the need for detailed knowledge about the underlying physical systems.
41 ~~ML in some cases,~~ machine learning models have been ~~shown~~found to be capable of obtaining more information from
42 hydrological datasets than is abstracted with traditional models, due to their automatic feature engineering and ability to
43 effectively capture high-dimensional and long-term relationships ([Nearing et al., 2021](#), [Frame et al., 2021](#)). The continually
44 evolving machine learning field will continue to offer novel opportunities that can be harnessed for hydrological data
45 analyses, and it is important to understand how these methods relate to classical models. Here, ~~we benchmark~~
46 learning model is benchmarked against a traditional conceptual model over a large sample of catchments as a step towards a
47 general understanding of the use of deep learning models as a tool for the task of monthly rainfall-runoff modelling in
48 Australian catchments.

49 Deep learning models have been shown in many applications to provide accurate hydrological predictions and classifications
50 ([Kratzert et al., 2018](#), [Shen et al., 2021](#), [Reichstein et al., 2019](#), [Frame et al., 2022](#)). These models are particularly useful to
51 hydrological studies as they provide the potential to quickly add and remove predictors ([Shen, 2018](#)), scale to multiple
52 catchments ([Kratzert et al., 2019](#), ~~[Kratzert et al., 2018](#)~~, [Lees et al., 2021](#)), automatically extract useful and abstract information
53 from large datasets ([Reichstein et al., 2019](#), [Shen, 2018](#)), make predictions in areas with little or no data ([Kratzert et al.,](#)
54 [2019b](#), [Majeske et al., 2022](#), [Ouma et al., 2022](#), [Choi et al., 2022](#)), and extrapolate proficiently to larger hydrologic events
55 than are seen in the training dataset ([Frame et al., 2022](#), [Li et al., 2021](#), [Song et al., 2022](#)).

56 The long short-term memory network (LSTM, ([Hochreiter and Schmidhuber, 1997](#))), is a deep learning model that is gaining
57 popularity in hydrology for daily time series predictions at individual basins or groups of basins due to its ability to efficiently
58 and accurately produce predictions without requiring assumptions about the physical processes generating the data. The
59 LSTM is a type of recurrent neural network (RNN), ~~Aan~~ an extension of the multilayer perceptron ~~that, the RNN~~ is specifically
60 designed for use with time series data through its sequential consideration of input data. The LSTM further extends the RNN
61 to incorporate gates and memory cells, allowing for input data to be remembered over much longer time periods and for
62 unimportant data to be forgotten from the network. LSTMs make predictions by taking into account both the short and long
63 temporal patterns in a time series as well as incorporating information from exogenous predictors. The data-driven detection
64 of intercomponent, spatial and temporal relationships by these deep learning models can be of particular benefit when
65 attempting to represent systems in which the physical characteristics are not well defined and the intervariable relationships
66 are complex.

67 The increasing popularity of the LSTM in hydrology is due to its ability to capture the short-term interactions between rainfall
68 and runoff, as well as the long-term patterns and interactions arising from longer-frequency drivers such as climate, catchment
69 characteristics, land use and changing anthropogenic activity. A growing number of publications are applying LSTMs to
70 hydrological simulations and comparing results to process-based or conceptual modelling results.

71 A gap exists in the literature concerning a comparison of LSTM models and conceptual models at a monthly time step over
72 a large sample of catchments. The conditions in which LSTMs or conceptual models may have an advantage for monthly
73 rainfall-runoff modelling, in a general sense, are not yet understood as most machine learning applications in hydrology are
74 individual-basin case studies ([Papacharalampous et al., 2019](#)) at a daily timestep or higher frequency (eg. [Li et al., 2021](#),

75 [Yokoo et al., 2022](#)). Though the LSTM has successfully matched conceptual model performance in ~~some-a-couple~~ large-
76 sample-hydrology studies at daily timesteps (eg. In the USA ([Kratzert et al., 2019b](#)) and the UK ([Lees et al., 2021](#))) it is yet
77 unknown how these models compare to conceptual models for monthly runoff predictions in relatively dry conditions such
78 as those characterised by Australian catchments.

79 Monthly hydrological models are important tools for water resources assessments as hydrologic data has historically been
80 recorded at a monthly or longer frequency ~~based on the schedule of manually-collected measurements. Furthermore, and~~ the
81 monthly timestep is often the most practical for water resources planning with many decisions requiring only monthly
82 streamflow predictions. With their simpler structure, fewer parameters and lower data requirements compared to daily models
83 ([Hughes, 1995](#), [Mouelhi et al., 2006](#)), monthly models are also useful tools to investigate uncertainty in rainfall-runoff model
84 structure ([Huard and Mailhot, 2008](#)) and ~~to-allow-the~~ support-~~of~~ probabilistic seasonal streamflow forecasting systems
85 ([Bennett et al., 2017](#)). Due to data availability, models designed to run on monthly timesteps can be used across much larger
86 areas, informing important large-scale water resources decision-making. For these reasons, generalisable models at monthly
87 timesteps are vital. However, the monthly timestep is traditionally a difficult one to model as it requires extracting both short
88 and long-term hydrologic processes ([Machado et al., 2011](#)). In a machine-learning context, the monthly time step differs
89 significantly from the daily time step as it drastically reduces the size of the data set available for model training (by a factor
90 of 30). As the convergence of machine learning algorithms typically improves with larger data sets, a central research question
91 of this paper is to explore the capacity of the LSTM algorithm to cope with the reduced amount of input data imposed by the
92 monthly time step.

93 ~~Some studies have already used the~~ ~~LSTMs have been used~~ to model the rainfall-runoff relationship at a monthly time step
94 in ~~a limited number of~~ localised studies, showing potential for this application on a broader scale. [Ouma et al. \(2022\)](#) used
95 monthly aggregated data due to low data availability in three scarcely-gauged basins the Nzoia River basin, Kenya. [Majeske](#)
96 [et al. \(2022\)](#) trained LSTMs with spatially- and temporally-limited data for three sub-basins of the Ohio River Basin, claiming
97 the daily timestep was superfluous and cumbersome in some conditions. [Lee et al. \(2020\)](#) found the LSTM adept at preserving
98 long-term memory in monthly streamflow at a single station on the Colorado River over a 97-year study without any
99 weakening of the short-term memory structure. [Yuan et al. \(2018\)](#) used a novel method for parameter calibration in an LSTM
100 for monthly rainfall-runoff estimation at a single station on the Astor River basin in northern Pakistan. [Song et al. \(2022\)](#)
101 found the LSTM better reproduced observed monthly runoff and simulated extreme runoff events than a physically-based
102 model at five discharge stations in the Yeongsan River basin in South Korea.

103 Large-sample hydrologic studies that assess methods on a large number of catchments are being increasingly called for in
104 the field of hydrology ([Papacharalampous et al., 2019](#), [Mathevet et al., 2020](#), [Gupta et al., 2014](#)). [Papacharalampous et al.](#)
105 [\(2019\)](#) compared the performance of a number of statistical and machine learning methods (no LSTM) on 2000 generated
106 timeseries and over 400 real-world river discharge timeseries and determined that the machine learning and stochastic
107 methods provided similar forecasting results. [Mathevet et al. \(2020\)](#) compared daily conceptual model performance (no
108 machine learning) for runoff prediction in over 2000 watersheds, determining that performance depended more on catchment
109 and climate characteristics than on model structure. [Kratzert et al. \(2018\)](#) found individual daily-scale LSTMs were able to
110 predict runoff with accuracies comparable to a baseline hydrological model for over 200 differently complex catchments.
111 ([Kratzert et al., 2019b](#)) found a global LSTM trained on over 500 basins in the United States with daily data produced better
112 individual catchment runoff predictions than conceptual and physically-based models calibrated on each catchment
113 individually. ([Lees et al., 2021](#)) produced a global LSTM to model almost 700 catchments in Great Britain, finding that this
114 model outperformed a suite of benchmark conceptual models, showing particular robustness in arid catchments and
115 catchments where the water balance does not close. ([Jin et al., 2022](#)) compared machine learning daily rainfall-runoff models

116 to process-based models for over 50 catchments in the Yellow River Basin in China. (Frame et al., 2021) found that a global
117 LSTM with climate forcing data performed similarly or outperformed a process-based model on over 500 US catchments,
118 and that in catchments where hydrologic conditions are not well understood the LSTM was a better choice.

119 This study aims to determine the ability of a simple machine learning model (a single-layer LSTM) to match or exceed the
120 performance of a conceptual monthly rainfall-runoff model (the WAPABA model (Wang et al., 2011)) for predicting runoff,
121 using inputs derived from easily accessible climate variables. The goal here is not to maximise LSTM performance to cutting-
122 edge machine learning standards, rather to ascertain the minimum performance level that a non-expert user might expect to
123 obtain from basic usage of an LSTM with the input data regularly used in a conceptual model. A frequently heard reason for
124 hydrological researchers not engaging machine learning approaches is the small data size associated with individual
125 catchment time series, and it is of interest to examine the lower limits of data availability required to fit an LSTM with
126 individual catchment monthly data sets.

127 A comparison is made on almost 500 basins across Australia, representing a wide variety of catchment types, hydro-climate
128 conditions, and with differing amounts of historical data. The prediction performance of the LSTM machine learning models
129 is compared to the WAPABA conceptual models for each individual catchment. The proportion of catchments in which the
130 runoff prediction performance of the conceptual model is met or exceeded by the machine learning model is determined.
131 Conditions under which the machine learning models or the conceptual models may have an advantage are investigated, such
132 as catchment size, flow level, and length of historical record. The central questions of this study are:

- 133 1) In general, do LSTMs match conceptual model prediction performance on Australian catchments?
- 134 2) Is the reduced number of data points due to the monthly time step an issue for training an LSTM?
- 135 3) Under what conditions is the LSTM of particular benefit or drawback? (eg. ~~c~~atchment size, flow level, amount of
136 training data, etc.)

137 The results of this large-sample analysis of LSTM performance over the Australian continent will assist in understanding
138 whether LSTMs are a justifiable alternative to conceptual models for monthly rainfall-runoff prediction in Australia and
139 similar environments, including if monthly data sets are sufficient to produce accurate predictions with the LSTM. Building
140 on the ~~se~~ results of this study, further benefits of deep learning could be harnessed through the creation of larger-scale models
141 that encompass climatic, hydrologic and anthropogenic patterns spanning multiple catchments, allowing for the sharing of
142 information under similar conditions and the potential transfer of knowledge between data-rich and data-scarce regions, or
143 models that blend conceptual models into the machine learning network structure.

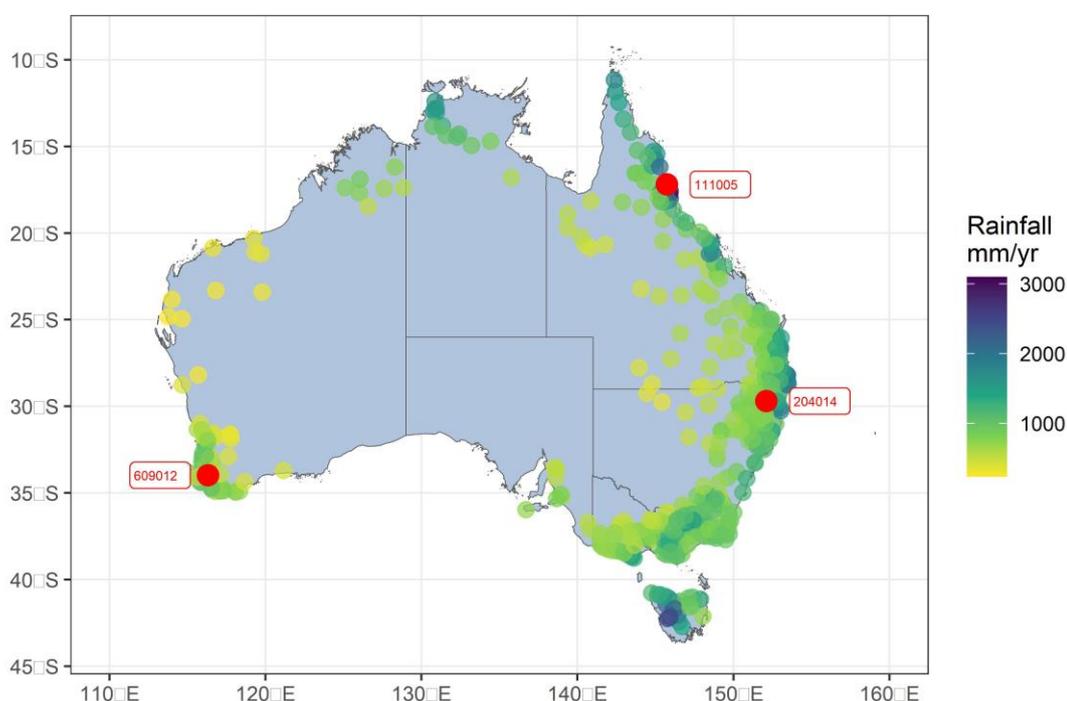

144 145 **2. Data and Methods**

146 **2.1. Data**

147 The catchment and climate data used in this study are from a dataset curated by Lerat et al. (2020) comprising a selection of
148 basins across Australia. The dataset spans all main climate regions of the continent, providing data from a variety of rainfall,
149 aridity and runoff regimes, as described in Table 1~~Table 1~~. Catchments where some data were marked as suspicious (e.g.
150 high flow data with large uncertainties, inconsistencies, suspected errors) or with more than 30% missing data were excluded.
151 This left 496 catchments in the study, with locations as shown in Figure 1~~Figure 1~~. The area of the individual catchments ranges
152 from approximately 5 km² to 120,000 km².

154 Table 14: Characteristics of the study catchments, over the period 1950-2020

Variable	Min	Q25	Median	Q75	Max
Catchment area (km ²)	4	180	449	1,456	119,000
Mean rainfall (mm/y)	237	691	887	1130	3097
Mean PET (mm/y)	918	1280	1500	1755	2321
Mean runoff (mm/y)	0.5	46	130	275	2213
Aridity index rainfall/PET (-)	0.11	0.44	0.61	0.81	2.61
Daily rainfall skewness (-)	2.4	4.8	5.9	7.4	16.7
Runoff coeff. Runoff/rainfall (-)	0.001	0.069	0.150	0.255	0.902
% zero flows in daily series	0.0	0.0	3.4	23.7	74.0

155

156 **Figure 14:** Locations of the 496 study catchments, coloured by mean annual rainfall. The three labelled catchments, which will be
 157 used as examples during the study, represent a wet catchment (111005 in Northern Queensland), a temperate catchment (204014
 158 in New South Wales), and a dry catchment (609012 in Western Australia).

159

160 Observed runoff data were collected from the Bureau of Meteorology’s Water Data online portal
 161 (<http://www.bom.gov.au/waterdata>), rainfall and temperature data are from the Bureau of Meteorology’s AWAP archive
 162 (Jones et al., 2009), and potential evapotranspiration data was computed by the Penman equation as part of the AWRA-L
 163 landscape model developed jointly by CSIRO and the Bureau of Meteorology (Frost et al., 2018). Rainfall, temperature and
 164 evapotranspiration are averaged from daily grids (5x5km) over each of the catchments.

165 The runoff records begin between January 1950 and September 1982, and end between October 2016 and June 2020. The
 166 number of runoff observations per catchment ranges from 425 to 846 with a median dataset size of 613 observations. The
 167 rainfall and potential evapotranspiration data cover the period from 1911 to 2020 continuously. The **resulting** dataset **therefore**
 168 consists of a set of 496 time series ranging from 37 to 70 years in length, with a median record length of 51 years.

169

170 2.1.1. Training and testing data split

171 The data set for each catchment is split into two portions for modelling — in machine learning these are referred to as
172 ‘training’ and ‘testing’ sets, corresponding to the traditional ‘calibration’ and ‘validation’ sets used in hydrologic modelling.
173 The training data set runs from January 1950 (or the start of the station’s record, if later) to December 1995 for all catchments.
174 The testing data set begins in January 1996 for all catchments and ends in July 2020 (or at the end of the station’s record, if
175 sooner). This split is chosen to divide the streamflow records into two relatively even periods, but also to distinguish an early
176 wet period from a testing period characterised by the Millennium Drought over south-eastern and eastern Australia (Van Dijk
177 et al., 2013). WAPABA and LSTM models were trained and evaluated using the same data splits, giving identical duration
178 and dataset size.

179 When split into training and testing sets at the beginning of January 1996, between 38% and 72% of the data from each
180 catchment becomes the training set. The length of the training data record for individual catchments ranges from 14 to 47
181 years, with the smallest data set used for training containing 172 observations. Typically in machine learning, a portion of
182 the training data is held back to be used during the model fitting process ~~to~~for monitoring ~~for~~ over-fitting and to signal early
183 stopping of training if necessary. Since the training data sets in this study are already small by machine learning standards,
184 this has not been done as it would reduce the number of training observations significantly, as well as lead to a smaller
185 training dataset than used in the WAPABA models. A sensitivity test has been performed to justify this choice, and it was
186 found that training the LSTMs with 20% of the training data reserved for this task (ie. with the data split into training: 64%,
187 validation: 16%, testing: 20%) produced no apparent benefit in prediction performance.

188 2.2. Models

189 2.2.1. Deep learning time series models (LSTMs)

190 The long short-term memory network, LSTM (Hochreiter and Schmidhuber, 1997), is an updated recurrent neural network
191 (RNN) specifically designed for deep learning with time series data. The inclusion of gates and memory cells increases the
192 length of time series the LSTM is able to process; three gates (input, output and forget gates) regulate the flow of information
193 into and out of the memory cell, determining which information from the past is to be retained and which can be forgotten.
194 In this way, each member of the LSTM output becomes a function of the relevant input at previous timesteps.

195 The LSTM network consists of an input layer, one or more hidden layers, and an output layer. The layers are connected by a
196 set of updatable weights, with the same weights applying to all timesteps of the data. Memory cells shadow each node on the
197 hidden layer, retaining important information over long time periods. Each node of the input layer represents a variable of
198 the input data set. Observations are fed into the network along with a pre-specified number of predictor values from previous
199 timesteps (known as the lookback length, or lag) which are cycled sequentially through the network. Network weights are
200 updated by backpropagating the gradient of the error between the modelled and observed outputs. For detailed information
201 on the mathematical functioning of the LSTM, see (Goodfellow et al., 2016) and (Kratzert et al., 2018).

202 In this study, a separate LSTM is trained for each catchment. Input to the LSTMs are monthly averaged measurements of:
203 rainfall depth (P), potential evapotranspiration (E), average maximum daily temperature over the month, and net monthly
204 (effective) rainfall (P^*) computed for month t by summing daily effective rainfall, as shown here:

$$P_t^* = \sum_{d=0}^{d=\text{days}(t)} \max(0, P_d - E_d)$$

14

205 Standard scaling of the input data is performed per catchment as follows:

$$\tilde{X}_t = \frac{X_t - \mu_x}{\sigma_x}$$

2

206 where X_t is an input variable for month t , μ_x is its mean and σ_x its standard deviation over the training period. The target
207 variable for LSTM training is monthly average runoff. Observed runoff values are scaled by taking the square root and then
208 transforming to the range [-1,1] per catchment, as follows:

$$Y_t = 2 \frac{\sqrt{Q_t} - Y_0}{Y_1 - Y_0} - 1$$

3

209 where Q_t is the observed runoff for month t , and Y_0 and Y_1 are the minimum and maximum square root transformed flow
210 over the training period, respectively. The square root transform is chosen to be conceptually consistent with the objective
211 function of the WAPABA model calibration (as described below, mean absolute error of the square roots of flows). Note that
212 the same scaling constants ($\mu_x, \sigma_x, Y_0, Y_1$) used during LSTM training are also applied to LSTM inputs and targets for the
213 testing period. Using scaling constants only derived from the training data ensures that the training process is not
214 incorporating any information from the testing data set.

215 The loss function used for training the LSTM is the mean absolute error (MAE) performed on the transformed runoff, as
216 follows:

$$L = \sum_t |Y_t - \hat{Y}_t|$$

4

217 where \hat{Y}_t is the output of the network for month t and Y_t is the transformed runoff for the same month.

218 Hyperparameters, or parameters controlling the LSTM training algorithm, were selected after a grid search ([over 1016](#)
219 [separate runs](#)) on a randomly selected catchment (14207) with a good length data record and tested on a small additional
220 subset of catchments. [As the purpose of this study was not to optimise catchment-specific predictions results, a more](#)
221 [comprehensive hyperparameter search by catchment was deemed unnecessary.](#) The hyperparameter space searched was:
222 initial learning rate δ_0 (1e-3 to 1e-4), sequence (lookback or lag) length (6, 9, 12, 15, 18, 21, 24 months) and number of
223 hidden nodes (10, 20, 30, 40, 50, 60). The hyperparameter set that performed the best predictions over the training period
224 [was](#) selected for use in all LSTMs: 10 nodes on a single hidden layer, run with a sequence length 6 months, and an initial
225 learning rate δ_0 of 0.0001. Subsequent to this hyperparameter search ~~on one catchment, we investigated on all catchments~~
226 ~~the the~~ effect of raising the initial learning rate for faster convergence while using input and recurrent dropout to prevent
227 overfitting [was investigated on all catchments](#). Empirically, and counter to our intuition, this never improved training
228 performance [and](#) so ~~thean~~ initial learning rate δ_0 of 0.0001 was [retainedkept](#). The learning rate was allowed to vary during
229 training with a patience of 3 epochs without improvement before multiplying by a factor of 0.2 to obtain a new learning rate.
230 The dataset was divided into 400 steps-per-epoch for training; data was sent through the model in batches with a weight
231 update after each (an epoch, or iteration, is concluded when the entire dataset has been run through the model once). The
232 LSTM training was implemented using a gradient descent algorithm run for a maximum of 100 epochs. Training was set to
233 stop early if the training error failed to decrease over 5 consecutive epochs. The LSTMs were implemented with Tensorflow

234 in Python. ~~The code was designed to, using use~~ numeric seeds to ~~ensure~~ have reproducible outcomes, ~~which is often not the~~
 235 ~~default behavior of many components of Tensorflow or other deep learning frameworks.~~

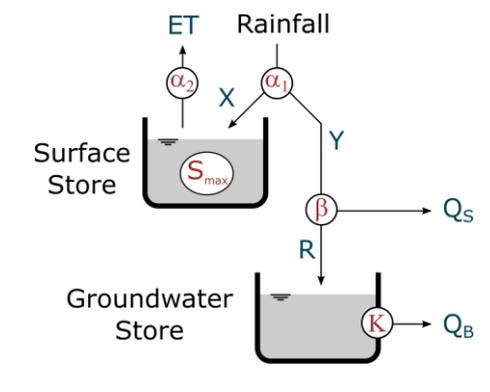

236 2.2.2. WAPABA rainfall-runoff models

237 The WAPABA model is a conceptual monthly rainfall-runoff model introduced by Wang et al. (2011). The model is an
 238 evolution of the Budyko framework proposed by Zhang et al. (2008) where water fluxes are partitioned using parameterised
 239 curves. The model uses two inputs, mean monthly rainfall and potential evapotranspiration, and operates in five stages. First,
 240 input rainfall is split between effective rainfall that will eventually leave the catchment, and catchment consumption that
 241 replenishes soil moisture and evaporates. Second, catchment consumption is portioned between soil moisture replenishment
 242 and actual evapotranspiration. Third, effective rainfall is partitioned between surface water (fast) and groundwater (slow)
 243 stores. Fourth, the groundwater store is drained to provide a baseflow contribution. Fifth, the surface water and baseflow are
 244 added to obtain the final simulated runoff for the month. The model has five parameters described in [Table 2](#) ~~Table 2~~ [which](#)
 245 [interact as depicted in Figure 2.](#)

246 Table 2 WAPABA model parameters

Name	Description	Unit	Minimum	Maximum
alpha1	Exponent of the catchment consumption/effective rainfall curve	Dimensionless	1.0	10.0
alpha2	Exponent of the soil moisture storage/evapotranspiration curve	Dimensionless	1.0	10.0
Beta	Partition between groundwater recharge and surface runoff	Dimensionless	0.0	1.0
Smax	Maximum water-holding capacity of soil store	mm	5.0	6000.0
Inverse K	Inverse of groundwater store time constant	1/day	0.000274	1.0

247

248

249 **Figure 2: WAPABA model schematic**

250 A separate WAPABA model is run for each study catchment. The WAPABA models were trained (calibrated) and tested
 251 (validated) over the same periods as the LSTMs: 1950 to 1995 inclusive for training, and 1996 to June 2020 for testing. [The](#)
 252 [model was calibrated with a warm-up period of 2 years to avoid possible bias associated with initial values.](#) WAPABA
 253 parameters were optimized over the training period using the Shuffle Complex Evolution algorithm (Duan et al., 1993) with
 254 the Swift software package (Perraud et al., 2015). The objective function used for the WAPABA models is the same as the
 255 one used for LSTM, i.e. the mean absolute error (MAE) on the square root of runoff (see Equation 4).

256 2.3. Performance evaluation

257 Predictions from the conceptual (WAPABA) and machine learning (LSTM) models for all catchments are compared to
258 observed runoff, assessing each model's predictive capabilities on the set of catchments. Runoff prediction performance is
259 reported here using the following metrics.

260 The Nash Sutcliffe Efficiency (NSE, [Nash and Sutcliffe, 1970](#)) is the most often used performance metric in hydrology. It
261 can be considered a normalised form of mean squared error (MSE) and is defined as:

$$NSE = 1 - \frac{\sum_t (Q_{obs}^t - Q_{mod}^t)^2}{\sum_t (Q_{obs}^t - \mu_{obs})^2} = 1 - \frac{E}{V} \quad 5$$

262 where Q_{obs}^t and Q_{mod}^t are the observed and modelled discharges for month t , respectively, and μ_{obs} is the average observed
263 discharge over the training or testing period. The ratio of the sum of squared errors, $E = \sum_t (Q_{obs}^t - Q_{mod}^t)^2$, to the variance,
264 $V = \sum_t (Q_{obs}^t - \mu_{obs})^2$, is subtracted from a maximum score of 1. An NSE closer to 1 indicates better predictive capability
265 of the model, and an NSE less than 0 indicates the model mean squared error is larger than the observation variance.

266 The NSE metric alone cannot provide an accurate description of model performance due to its focus on high flow regime
267 ([Schaeffli and Gupta, 2007](#)). The reciprocal NSE focuses the error metric on low flows ([Pushpalatha et al., 2012](#)) by comparing
268 the reciprocals of the observed and modelled flows. It is calculated as:

$$RecipNSE = 1 - \frac{\sum_t \left(\frac{1}{(Q_{obs}^t + 1)} - \frac{1}{(Q_{mod}^t + 1)} \right)^2}{\sum_t \left(\frac{1}{(Q_{obs}^t + 1)} - \frac{1}{(\mu_{obs} + 1)} \right)^2} \quad 6$$

269 The Kling-Gupta efficiency (KGE, [Gupta et al., 2009](#)) provides an alternative to metrics based on sum of squared error
270 such as the two previous ones, by equally weighting measures of bias of the mean, variability, and correlation into a single
271 metric as follows:

$$KGE = 1 - \sqrt{\left(1 - \frac{\mu_{sim}}{\mu_{obs}}\right)^2 + \left(1 - \frac{\sigma_{sim}}{\sigma_{obs}}\right)^2 + (1 - \rho)^2} \quad 7$$

272 where μ_x and σ_x are the mean and the standard deviation and ρ is the Pearson correlation coefficient between the simulated
273 and observed data.

274 Finally, **B**ias is a measure of consistent under-forecasting or over-forecasting of the mean, defined as:

$$Bias = \frac{\mu_{sim} - \mu_{obs}}{\mu_{obs}} \quad 8$$

275 Comparison of performance metrics between catchments using normalised indexes

276 When comparing metrics across model types and catchments, a normalised difference in NSE values is used. The NSE metric
277 can reach into large negative values in dry catchments when the variance of the observations is very small compared to the
278 model errors ([Mathevet et al., 2006](#)), as can be seen from Equation 5. Differences between large negative values of NSE have
279 a much smaller implication than the same absolute difference between values of NSE closer to 1. To allow for a comparison
280 between the WAPABA and LSTM models at catchments of various aridities, the normalised difference in NSE is calculated
281 following [Lerat et al. \(2012\)](#):

$$Diff_NSE_{norm} = \frac{NSE_2 - NSE_1}{(1 - NSE_1) + (1 - NSE_2)} = \frac{NSE_2 - NSE_1}{2 - (NSE_1 + NSE_2)} \quad 9$$

282 where NSE_1 and NSE_2 are the NSE values corresponding to the two models to be compared. Substituting in $NSE = 1 - \frac{E}{V}$
 283 from Equation 5 into Equation 9, the normalised difference in NSE can be seen to represent a percentage difference in the
 284 sum of squared errors between the two models being compared:

$$Diff_NSE_{norm} = \frac{NSE_2 - NSE_1}{2 - (NSE_1 + NSE_2)} = \frac{E_1 - E_2}{E_1 + E_2} \quad 10$$

285 A similar formula is applied to reciprocal NSE and KGE. The normalised difference between the bias for two models is
 286 calculated as:

$$Diff_Bias_{norm} = \frac{|Bias_1| - |Bias_2|}{|Bias_1| + |Bias_2|} \quad 11$$

287 To simplify the comparison of model results across the large number of catchments, model performances at each catchment
 288 are classified as similar if the normalised difference between WAPABA and LSTM metrics lies within +/- 0.05 at that
 289 catchment, following [Lerat et al. \(2020\)](#). Therefore in this paper, a ‘similar’ NSE denotes that the sum of squared errors of
 290 the WAPABA and LSTM models at an individual catchment differ by no more than 5%. For differences greater than this,
 291 the catchments are classified by the model type producing the higher metric. The selection of the threshold of 0.05 was based
 292 on the recommendations of ([Lerat et al., 2020](#)) and the authors’ experience relative to the use of the NSE, KGE and bias
 293 metrics.

294

295 3. Results

296 For each of the study catchments, a WAPABA model and an LSTM model have been trained using monthly data over the
 297 training period, and the prediction performance of the models are evaluated here on monthly data from the testing period
 298 (data unseen by the model during training) using the metrics described above. A general comparison of WAPABA and LSTM
 299 prediction performance is first made over all catchments with a continental-scale analysis of the performance metrics, to
 300 determine:

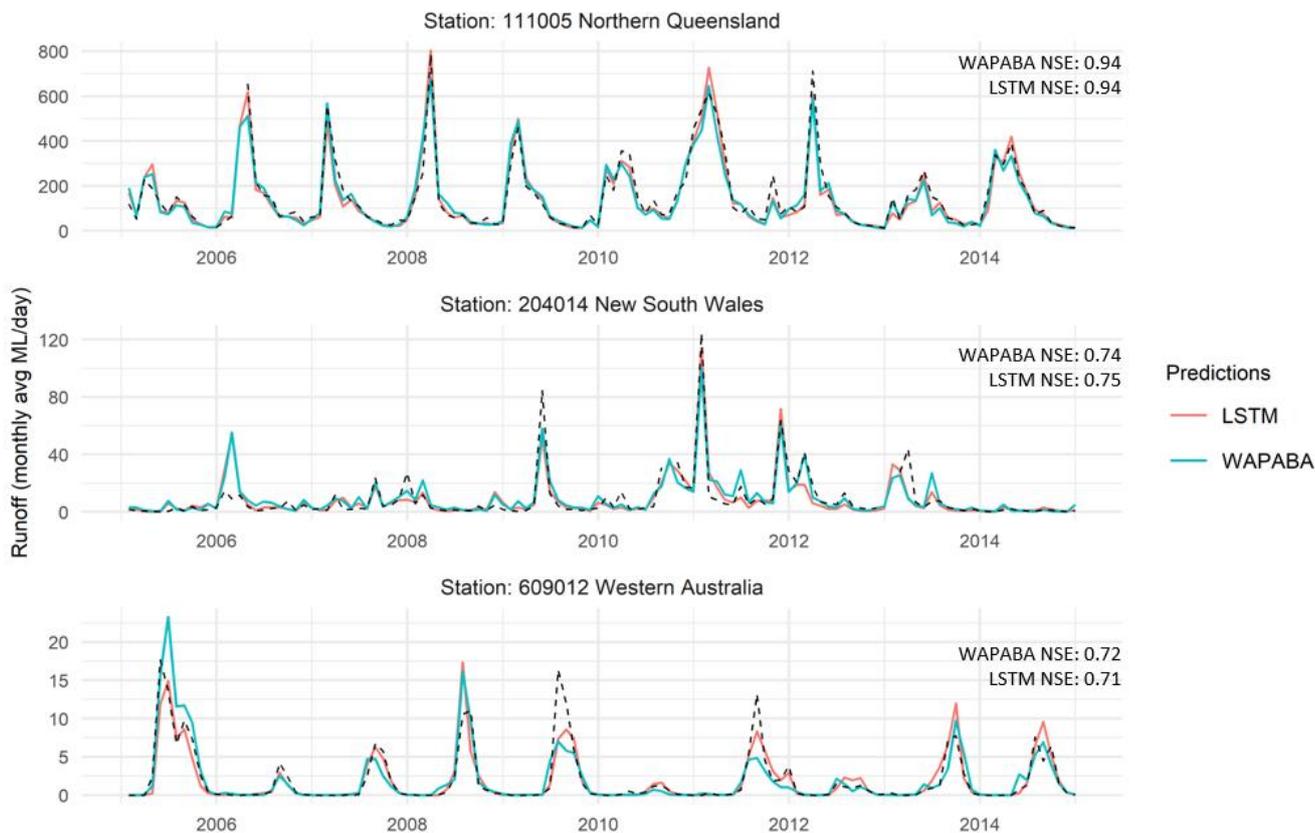

- 301 1) the proportion of overall catchments for which the WAPABAs or the LSTMs produced better predictions,
 302 and
- 303 2) differences at individual catchments in WAPABA versus LSTM prediction performance.

304 A comparison of model performance is then made in relation to various catchment and time series characteristics (eg.
 305 catchment size, flow level, record length), to determine if an association exists between these properties and the relative
 306 performance of the conceptual and machine learning models.

307 Example prediction results

308 As a sample of the modelling output, [Figure 3](#)~~Figure-2~~ shows the WAPABA and LSTM runoff predictions along with the
 309 corresponding observed runoff for the three stations highlighted in [Figure 1](#)~~Figure-4~~ (over the testing period). These
 310 hydrographs are representative of a wet catchment in Northern Queensland (Mulgrave River at the Fisheries, 111005), a

311 temperate catchment in NSW (Mann River at Mitchell, 204014), and a dry, intermittent catchment in Western Australia
 312 (Blackwood River at Winnejup, 609012). NSE values of each of the predictions are noted. The WAPABA and LSTM
 313 predictions both match the observed data reasonably well in the three catchments. The performance of the models, in
 314 particular for the Blackwood River at Winnejup is remarkable because of the difficulty in modelling dry, intermittent
 315 catchments (Wang et al., 2020). The next sections provide a more detailed assessment of the performance over all catchments
 316 using quantitative metrics.

317
 318 **Figure 32:** Observed data (black dashed line) and predicted runoff (by WAPABA and LSTM models) over the testing period for
 319 the Mulgrave River at the Fisheries (111005), Mann River at Mitchell (204014) and the Blackwood River at Winnejup (609012).
 320 Catchment locations are shown on Figure 1.

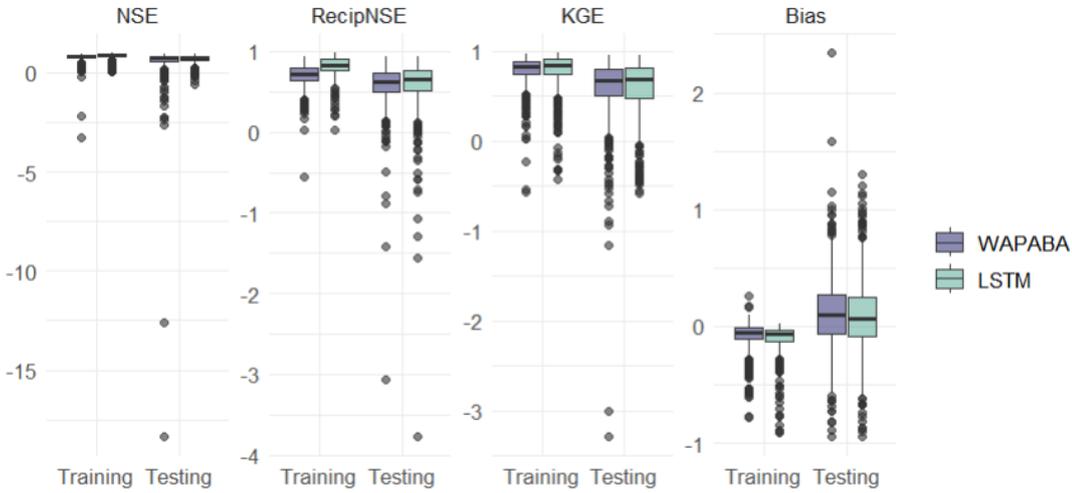

321
 322 **Large-sample performance summary**

323 The general runoff prediction performance of WAPABA and LSTM models on a continent-wide basis is summarized in
 324 [Figure 4](#)[Figure 3](#). From the models run for each catchment, metrics are determined on the training portion (calibration) and
 325 testing portion (validation) separately and gathered here in boxplots. Median and quartiles of NSE, reciprocal NSE, KGE and
 326 Bias over all catchments are shown for each model type, with each data point representing an individual catchment. All data
 327 is shown on the top panel, and due to a few large (negative) outliers the same figure is shown with a restricted y-axis for
 328 visualization purposes on the lower panel. Higher values of the first three metrics (NSE, reciprocal NSE and KGE) indicate
 329 a better match of predicted runoff with observed runoff, whereas lower values of Bias indicate better prediction results.

330 [Figure 4](#)[Figure 3](#) shows that across the set of study catchments the median values of NSE, Reciprocal NSE, and KGE are
 331 slightly higher for LSTM than for WAPABA during both the training and testing phases. Bias has a slightly lower median
 332 for the LSTM. As expected, both model types perform better during the training phase than the testing phase for all metrics.

333 The difference between WAPABA and LSTM performance is relatively large during the training period but similar during
 334 testing, indicating perhaps a higher tendency towards overfitting by the ML models than traditional modellers would be
 335 expecting. The interquartile ranges increase from training to testing (longer boxes during testing), indicating a greater spread
 336 of performance results when the models are run on data not seen during the training phase. Over all catchments, the median
 337 NSE is: 0.74 with the WAPABA models and 0.76 with the LSTM models (on testing data). See Table 3 for median values
 338 of these metrics.

339

340

341 **Figure 43:** Performance metrics summary for the set of 496 catchments (zoomed in on lower panel, excluding outliers <-1). Median
 342 values of LSTM performance metrics are slightly higher than WAPABA for NSE, Reciprocal NSE and KGE (higher indicates
 343 better performance), and slightly lower for Bias (lower Bias is preferable). For all four metrics on both models, the training results
 344 were better than the testing results, with the longer testing boxes indicating more spread in performance results when predicting
 345 on new data.

346 **Table 3:** Median values of metrics over the set of catchments (n=496)

	WAPABA	LSTM
NSE	0.74	0.76
Reciprocal NSE	0.62	0.65
KGE	0.68	0.70
Bias	0.09	0.06

347

348 Aggregated performance metrics may mask performance variability within certain aspects of the time series (Mathevet et
 349 al., 2020). The KGE has the benefit of being easily decomposed into three components for further error analysis: bias of the
 350 mean (ratio of mean of simulations to mean of observations), bias of variability (ratio of standard deviation of simulations
 351 to standard deviation of the observations), and correlation (matching of the timing and shape of the time series to the
 352 observations).

353 Table 3: Median values of metrics over the set of catchments (n=496)

	<u>NSE</u>	<u>Reciprocal NSE</u>	<u>KGE</u>	<u>Bias</u>	<u>Bias of the mean</u>	<u>Bias of variability</u>	<u>Correlation</u>
<u>WAPABA</u>	<u>0.74</u>	<u>0.62</u>	<u>0.68</u>	<u>0.09</u>	<u>1.10</u>	<u>1.05</u>	<u>0.90</u>
<u>LSTM</u>	<u>0.76</u>	<u>0.65</u>	<u>0.70</u>	<u>0.06</u>	<u>1.07</u>	<u>0.97</u>	<u>0.90</u>

354
 355 In ~~Figure 5~~Figure 4 and Table 3, model performance is assessed with respect to each component of the KGE metric.
 356 Boxplots of the decomposed KGE components are shown by model type and training/testing period. During testing, the
 357 medians of bias of the mean and standard deviation are above zero for WAPABA and greater for WAPABA than LSTM.
 358 This indicates that mean streamflow and streamflow variability tend to be overestimated more by the WAPABA models
 359 compared to the LSTMs. ~~With the LSTM median, bias of streamflow~~ variability is below zero, and therefore streamflow
 360 variability is more prone to underestimation. ~~(median below zero)~~. For bias of the mean and standard deviation, the depth
 361 of the boxplots increases from training to testing, indicating the bias values from individual catchments are more diverse
 362 during the testing period.

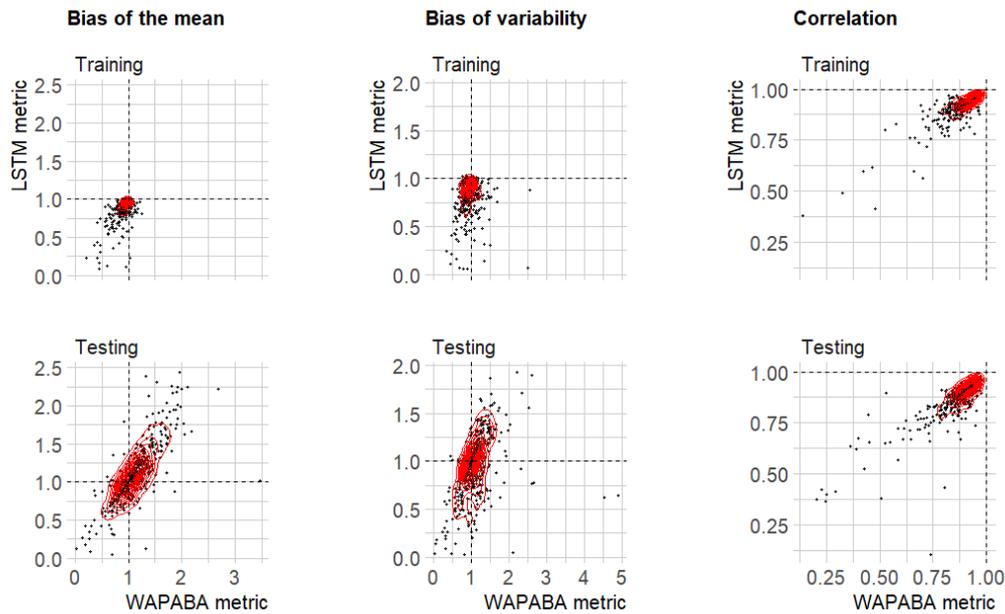

363 The scatterplots in the lower part of ~~Figure 5~~Figure 4 compare the KGE components at individual catchments for the
 364 WAPABA and LSTM models (each dot represents a catchment), separately for training and testing portions of the data.
 365 Most values of bias of the mean (left column) are between 0 and 1 during training (underestimating) yet during testing
 366 values extend beyond 2, indicating the mean flow in many catchments is overestimated by both model types on the testing
 367 data. The observable correlation in testing period bias of the mean between WAPABA and LSTM indicates that this error is

368 not specific to model type. Correlation between simulations and observed data is similar for both model types and remains
 369 relatively constant between training and testing periods (right column).

370

371

372

373 **Figure 54: KGE decomposition into three components: bias of the mean, bias of variability, and correlation.** Each dot represents
 374 an individual catchment (large outliers have been omitted for visualization purposes.) The mean flow and variability (left and
 375 middle columns) tend to be underestimated during training and both under- and overestimated during testing by both model types.
 376 The correlation (right column) remains similar during training and testing.

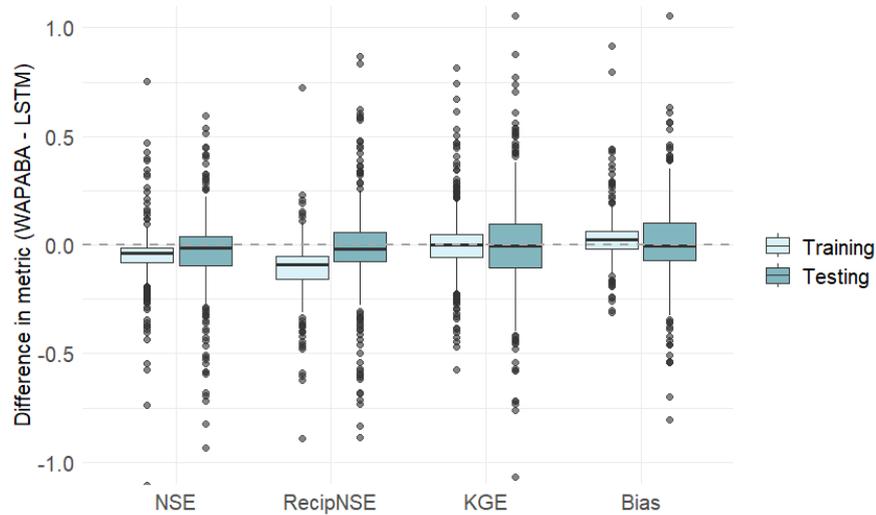

377

378 Performance differences at individual catchments

379 The differences between WAPABA and LSTM performance at each catchment (eg. $NSE_i = NSE_{i,WAPABA} - NSE_{i,LSTM}$ for
 380 catchment i) are summarised in [Figure 6](#)~~Figure 5~~. Values above zero indicate higher metrics obtained by WAPABA, and
 381 values below zero indicate higher metrics obtained by the LSTM model at a specific catchment.

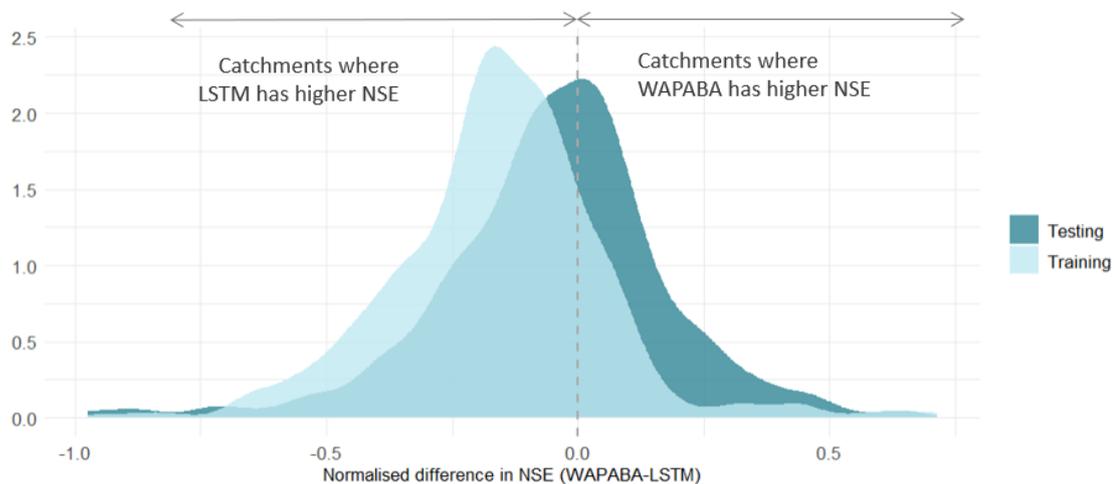

382 The boxplots indicate that median differences in WAPABA and LSTM prediction performance at each catchment (measured
 383 by NSE, Reciprocal NSE, KGE and Bias on the testing data) are very close to zero. However, there are outliers (black dots)

384 representing large performance differences between WAPABA and LSTM models, both positive and negative. These indicate
 385 that each model provides advantages for predicting runoff in certain catchments. In this figure the boxplots are restricted to
 386 the range [-1,1] for visualisation purposes. A version of this figure including the large outliers is provided in Figure A1 of
 387 the Appendix.

388
 389 **Figure 65:** Difference in the metrics (WAPABA – LSTM) for each catchment. A positive value indicates WAPABA has a higher
 390 metric for that catchment, and a negative value indicates LSTM has a higher metric. The median difference in each metric lies
 391 close to zero for the testing portion of the dataset, signifying overall similarity in catchment-specific metrics between model types.
 392 Large negative outliers have been excluded from this figure for visualisation purposes, but are included in the reproduction in the
 393 Appendix.

394
 395 This data set represents a range of catchments across Australia, some being characterised by highly arid conditions. To enable
 396 comparisons between these diverse catchments, the impact of large negative NSE values which can occur at very dry
 397 catchments is minimised by calculating the normalised differences in NSE between the WAPABA and LSTM predictions at
 398 each catchment, as per Equation 9. The normalised differences fall into the range [-1,1], facilitating comparison. This
 399 distribution is shown in [Figure 7](#) ~~Figure 6~~ for the 496 catchments. The portion of the distribution lying to the right of the
 400 vertical dashed line corresponds to catchments with better prediction by WAPABA and catchments to the left have better
 401 prediction by LSTM. The x-axis corresponds to percentage differences between the sum of squared errors of the two model
 402 types (ie. -0.5 indicates a 50% performance gain by LSTM and 0.5 indicates a 50% performance gain by WAPABA).

403

404

405

406

407

408

Figure 76: Distribution of normalized differences between WAPABA and LSTM prediction performance at individual catchments (measured by NSE). The values on the x-axis represent percentage/100 difference in sum of squared errors between WAPABA and LSTM at the same catchment (ie 0.5 -> 50% difference in sum of squared errors). The catchments under the curve on the right of the dashed line have better predictions by the WAPABA model and on the left by the LSTM model.

409

In ~~Figure 7~~ ~~Figure 6~~, it can be seen that during the training period the majority of catchments are to the left of the line indicating better prediction by LSTM, and in the testing period there is a more even split. The median normalised difference in NSE across the 496 catchments over the training period is -0.15 (mean -0.16) and -0.04 (mean -0.05) during the testing period. This equates to a median 15% performance advantage by LSTM versus WAPABA during training and 4% during testing based on sum of squared errors.

414

This figure suggests that in general there is little overall advantage of either the WAPABA or LSTM models when predicting on unseen data across the whole sample of catchments. However, the width of the distribution indicates that both the WAPABA and LSTM models have advantages at certain individual catchments, which will be explored in the next section.

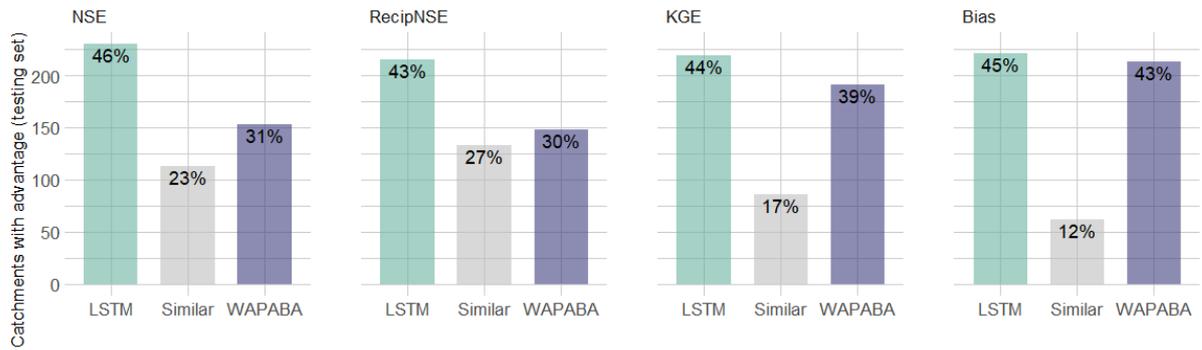

417

~~Figure 8~~ ~~Figure 7~~ quantifies the proportion of catchments with similar or better prediction performance by either WAPABA or LSTM (on the testing data). ‘Similarity’ is defined here as an absolute normalised difference in NSE of less than 0.05 between WAPABA and LSTM predictions, meaning the sum of squared errors of the WAPABA and LSTM models at an individual catchment differ by no more than 5%.

421

The LSTM models produce similar or higher NSE values for 69% of the catchments when tested on data not seen during the training process (and 89% of the catchments during training, not shown). It can also be seen that 70% of catchments have similar or higher reciprocal NSE (focusing on low flow predictions) with ~~the LSTM~~, 61% have similar or higher KGE with ~~the LSTM~~ (higher being preferable), and 57% have similar or lower Bias (lower being preferable) with ~~the LSTM~~ model compared to WAPABA on the same catchment.

425

427

428

429

430

431

Figure 87: Percentage of catchments with similar or better performance metrics on the testing portion of the data (note better Bias is lower, all others is higher). For catchments in the ‘similar’ category, the sum of squared errors of the WAPABA and LSTM predictions differ by less than 5%. The LSTM model produces predictions with similar or higher NSE values compared to the WAPABA predictions for 69% of the catchments.

432

433

434 **Prediction performance comparison by catchment or time series characteristics**

435

In this section, ~~it is we~~ investigated if the abilities of WAPABA and LSTM to accurately predict runoff at individual catchments vary based on attributes such as catchment area, flow level and length of historical record.

436

437 **Catchment size**

438

~~Figure 9~~~~Figure 8~~ shows the association of prediction performance with catchment area. The left panel shows the catchment area compared to the normalised difference in NSE between LSTM and WAPABA prediction performance for each catchment. Data points are coloured according to the model that produced the better prediction for that catchment. This figure indicates the largest performance gains of LSTM versus WAPABA occurred in large catchments (points furthest to the left are found in the upper portion of ~~the plot~~~~figure~~). Splitting the catchments into quintiles by area, ~~we can analyse~~ the results ~~can be analysed~~ for the largest 20% of catchments. Of these catchments, over three-quarters (78%) had similar or better runoff predictions with the LSTM (with similarity defined as less than 5% difference in sum of squared errors compared to WAPABA predictions). In this top quintile of catchments ~~by area~~, those with higher NSE values from the LSTM show a greater average advantage (average 24% lower sum of squared errors, maximum 97% lower), than those with better WAPABA predictions (average 15% lower sum of squared errors, maximum 65% lower).

439

440

441

442

443

444

445

446

447

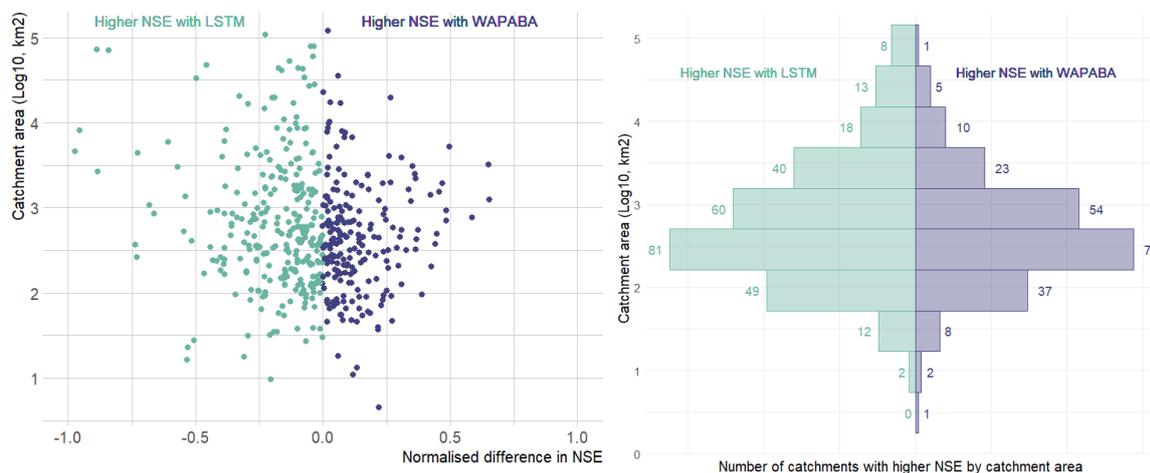

448

The mirrored histogram in the right panel of Figure 8 shows catchments stratified into bins by area (log base 10), coloured and counted by the model type that produced the better runoff prediction at each catchment. The LSTM models produced higher NSEs for a greater number of catchments than the WAPABA models in all of the bins, except the lowest bin (where n=1).

449

450

451

452

453 **Figure 98: Model performance by catchment size. Left panel: Each data point represents the normalized difference in prediction**
 454 **performance at an individual catchment, arranged by catchment size. The spread of data points in the top left quadrant indicates**
 455 **that in large catchments the performance gain of LSTM overversus WAPABA can exceed 90% in terms of sum of squared errors.**
 456 **Right panel: count of catchments in each size bin that have better performance with each model.**

457

458

459 **Flow level**

460 Model performance is compared for high, medium and low flow portions of the time series. For each station, each observation
 461 is categorised based on its flow level. High flows are defined here as the top 5% of flow values and low flows as the lower
 462 10% of flows at each station (calculated excluding zeros) over all observed data during the study period. The training and
 463 testing portions of the time series over all the catchments have different distributions of flow levels, as listed in [Table 4](#)
 464 [Table 4](#). During the testing portion of the study period, conditions are dryer with more no-flow and low-flow observations, and
 465 fewer medium- and high-flow observations than during training.

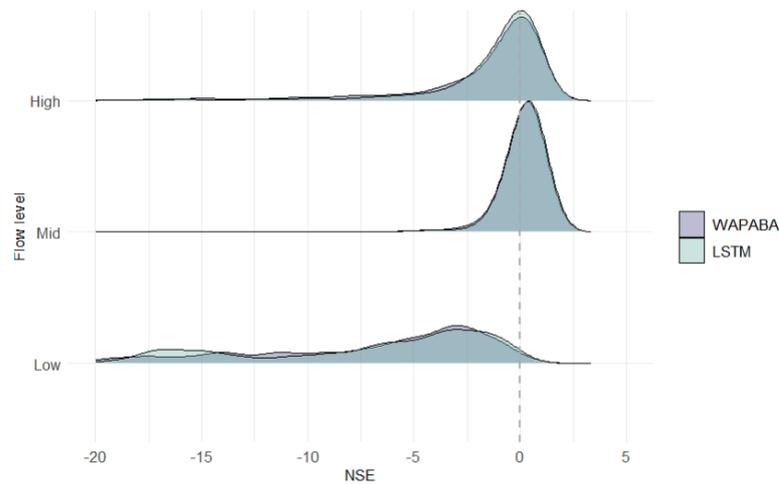

466 Table 44: Distribution of flow levels during training and testing

Flow level	Training observations (n)	Testing observations (n)
No flow	18,728	21,690
Low	11,967	14,668
Medium	127,584	96,089
High	9,192	4,203

467

468 For comparison purposes [in this section](#), [the raw](#)both observed and modelled flow [datas](#) are [standardized](#)standardised by
 469 station based on the mean and standard deviation of all observations at that station during the study period. The observed
 470 mean is subtracted from each value before dividing by the standard deviation of the observations, [allowing for basins with a](#)
 471 [range of flow volumes to be compared](#).

472 [Figure 10](#)[Figure 9](#) shows that when NSE is calculated separately for the low, medium and high flow measurements at each
 473 catchment, both model types have similar NSE distributions. Medium flows are better predicted (NSE peak closer to 1) than
 474 high flows, and low flows appear to be poorly represented by both WAPABA and the LSTM.

475

476

477

Figure 109: NSE distributions calculated separately by flow level over all catchments. Both model types have similar distributions of NSE by flow. Medium flows are best represented, followed by high and then low flows.

478

479

480

481

482

483

484

485

486

487

488

489

490

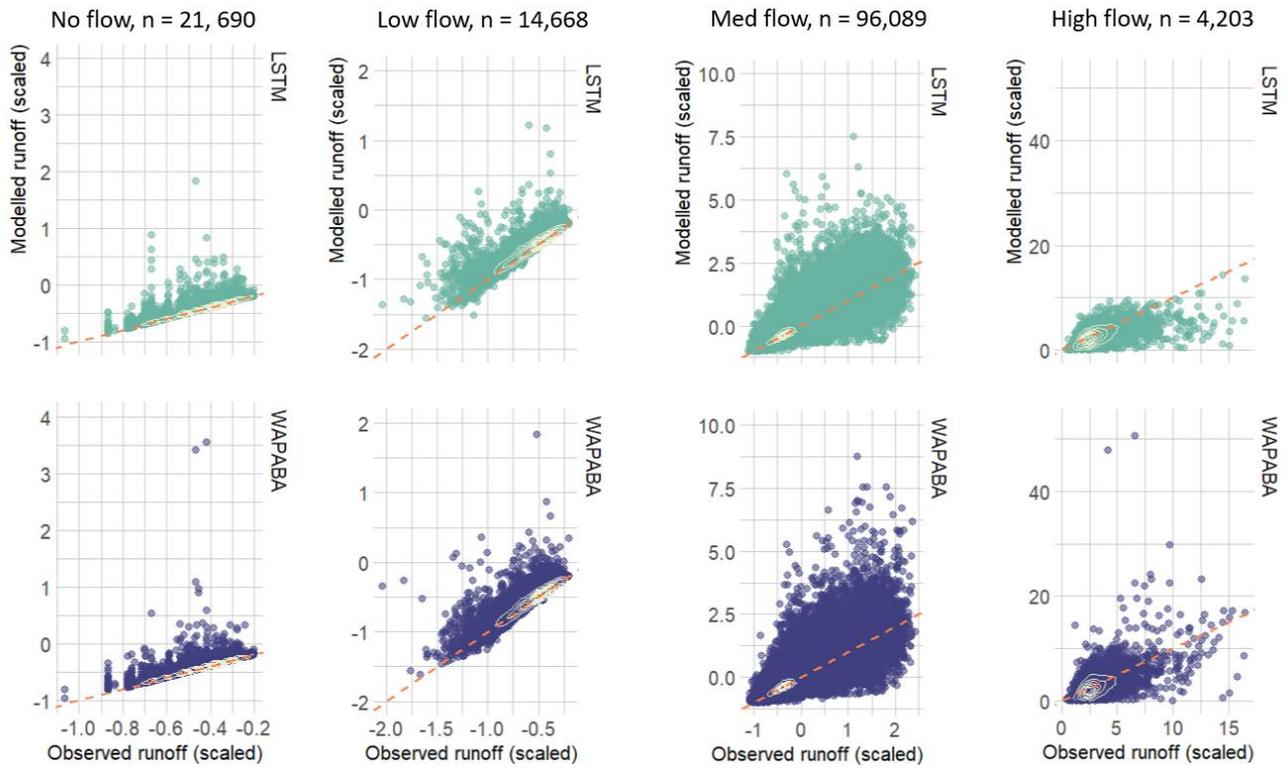

491

492

493

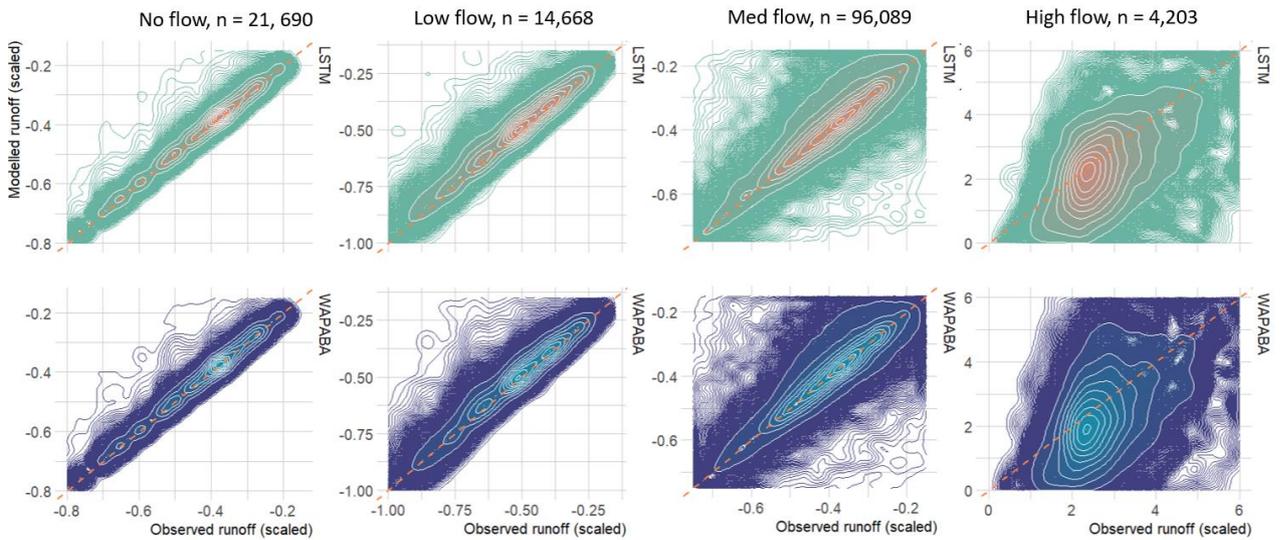

494

Figure 11~~Figure 10~~ compares the ~~standardized~~ modelled flow to the ~~standardized~~ observations for all testing observations at all stations. Kernel density contours split the data into 10 density regions on each plot and a 1:1 line is added to aid interpretation. The lower panel focuses on the regions of highest density for each subset of flows. Note that the standardization procedure used in this section leads to standardized ‘no-flow’ data points that do not fall exactly on zero in the plot even though the raw flow values at these points are zero. For no-flows and low flows (left two panels), the densest portions of the observation/prediction clouds are closely aligned along the 1:1 line ~~for both WAPABA and LSTM~~ indicating similar predictions obtained with both models. The magnitude of the outliers (beyond the outermost contour) is greatest above the 1:1 line indicating that prediction errors for no-flows and low flows are dominated by overestimations. For medium flow levels, the contours again follow the 1:1 line. The contours tend to expand upwards as flow size increases, indicating a tendency towards more overestimation with higher flows. The shape of the contours is similar for both models. On the upper panel it can be seen that the edges of the data cloud ~~also~~ expand upwards and outwards as the flows increase. The medium flow prediction errors with largest magnitude tend to be overestimations, with the WAPABAs producing greater overestimations than the LSTMs on the higher flows (still in this medium-flow subset). For high flows (on the far right panel), the majority tend to be underestimated by both LSTM and WAPABA (central density located below the 1:1 line), though there is a difference in the outliers – most of the larger errors in LSTM high flow predictions are underestimations, whereas the high-magnitude WAPABA errors are both over- and underestimations of high flows.

495

496

497

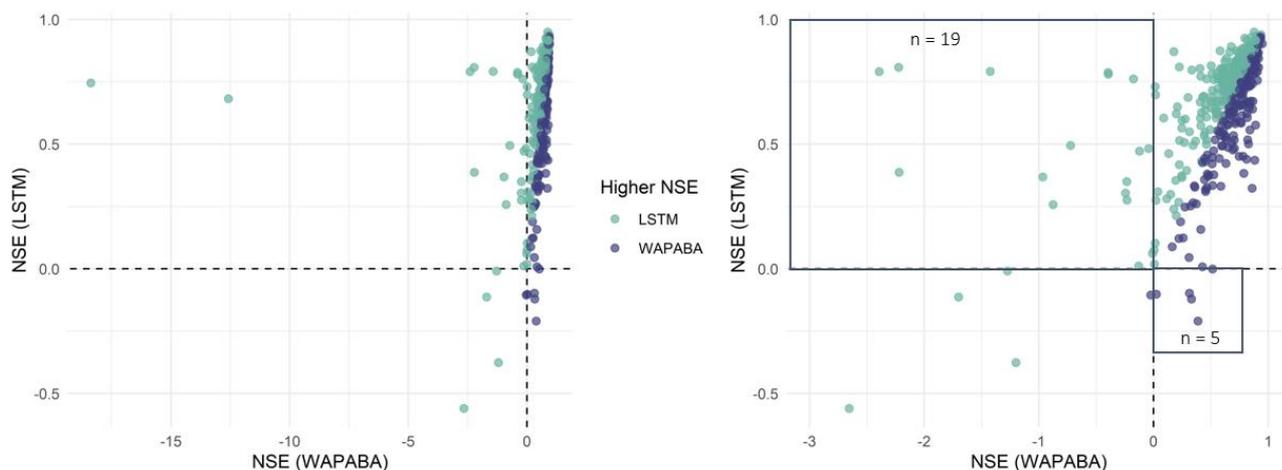

498 **Figure 1140: Prediction performance related to flow level. Upper panel: Observed vs. modelled flow pairs (normalized data) at all**
 499 **stations, separated into no-flow, low, medium and high flows (testing data only). The densest portion of the data cloud is**
 500 **identified with density contours. Note that the data are standardized based on observed mean and**
 501 **standard deviation leading to non-zero values in the 'no-flow' category. Lower panel: Comparison of density distributions of the**
 502 **data, zoomed in on the kernel density contours. In general, the largest errors on medium flows tend to be overestimations (by both**
 503 **models) and on high flows tend to be underestimations (by both models WAPABA and LSTM) or overestimations (by WAPABA).**

504

505

506 *Poorly predicted catchments*

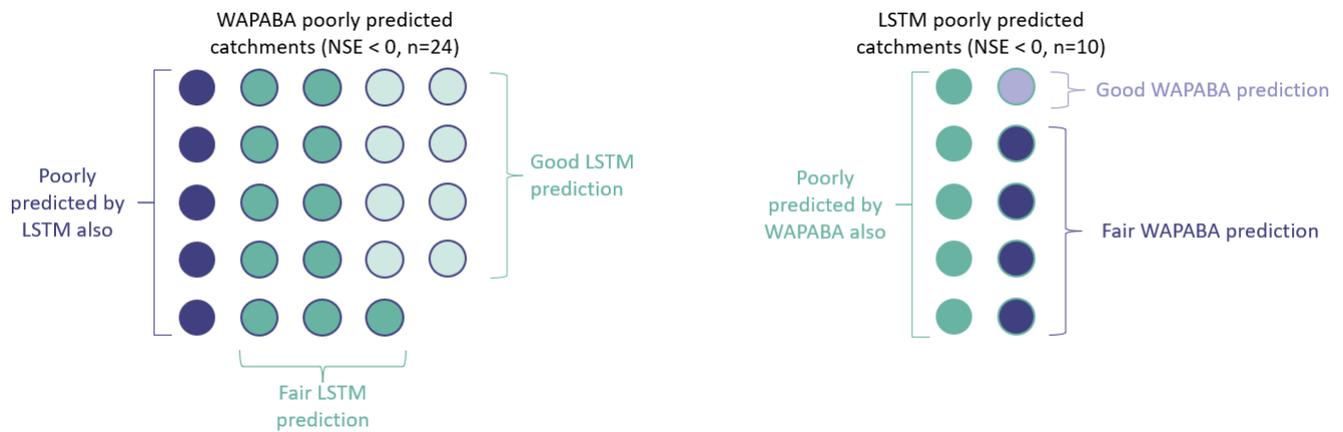

507 **Figure 12** compares the NSEs for WAPABA and LSTM runoff predictions by catchment. Each dot represents an
 508 individual catchment, coloured according to the model with higher NSE at that catchment. The top left quadrant contains
 509 catchments where $NSE_{WAPABA} < 0$ and $NSE_{LSTM} > 0$ (n=19), and the lower right quadrant contains catchments where NSE_{LSTM}
 510 < 0 and $NSE_{WAPABA} > 0$ (n=5).

511 **Figure 12**: Comparison of NSEs on testing data - each data point represents the WAPABA and LSTM values of NSE for a single
 512 catchment, coloured by the model which provides the best prediction at that catchment. On the right panel, two far-left outliers
 513 have been removed to enable better viewing of the other datapoints. Catchments in the upper left quadrant are those in which
 514 runoff is poorly predicted by WAPABA ($NSE < 0$) and better predictions ($NSE > 0$) are obtained with LSTM. The lower right
 515 quadrant correspondingly shows catchments in which the NSE values from LSTM are below 0 and WAPABA has better
 516 predictions ($NSE > 0$).
 517

518
 519 WAPABA and LSTM predictions at each catchment are classified into poor ($NSE < 0$), fair ($0 \leq NSE \leq 0.5$) or good (NSE
 520 > 0.5) categories. In this set of catchments, the runoff at 5 catchments is poorly predicted ($NSE < 0$) by both model types
 521 (lower left quadrant of **Figure 12**). All other catchments are better represented by one model or the other, with either
 522 WAPABA or LSTM producing predictions with NSEs above 0.

523 For the 5% (n=24) of overall catchments that are poorly represented by WAPABA ($NSE < 0$), runoff predictions at 23 of
 524 these catchments (96%) are improved with use of the LSTM. In fact, one-third (n=8) of these have 'good' predictions by the
 525 LSTM ($NSE > 0.5$). Conversely, for the 2% of catchments (n=10) that are poorly represented by the LSTM, 60% are improved
 526 with use of WAPABA, and one-tenth (n=1) have 'good' predictions by WAPABA (in this catchment the LSTM prediction
 527 is on the border of poor and fair ($NSE=0.001$)). **Figure 13** depicts the number of catchments poorly represented by
 528 each model and how these specific catchments are represented by the alternate model. For half of the catchments with poor
 529 LSTM predictions, WAPABA does poorly as well; whereas in 79% of the catchments with poor WAPABA predictions, fair
 530 or good predictions were obtained with the LSTM.

531

532

533

534

535

Figure 13.12: Number of catchments with poor runoff predictions by each model type. Colouring indicates the prediction results from the alternate model type. One-third of WAPABA poorly predicted catchments have good predictions with the LSTM. One-tenth of LSTM poorly predicted catchments have good predictions with the WAPABA. Results are denoted as poor (NSE < 0), fair (0 <= NSE <= 0.5), or good (NSE > 0.5).

536

537

538 *Generalising to changing conditions*

539

540

541

542

543

The ability of a model to generalise outside of the conditions encountered during training is important, especially in the context of a changing climate. A model that is able to make predictions on unseen (testing) data to a comparable performance level as on the training data will provide confidence in making predictions into the future when external conditions are not expected to remain constant. In this data set it is well known that conditions differ between the training and testing data, with wetter climate conditions during the training period and a dryer testing period.

544

545

546

547

548

549

It was found that 2% (n=11) of WAPABA models struggled with generalising outside of the training period, with ‘good’ (NSE > 0.5) runoff predictions during training but ‘very poor’ predictions (NSE < -0.5) during the testing period. The testing predictions for all of these catchments were improved by use of the LSTM, and at 4 of these catchments ‘good’ predictions (NSE > 0.5) were obtained with the LSTMs. Conversely, one LSTM model produced ‘good’ training runoff predictions and ‘very poor’ testing predictions. This catchment was one of the 11 that also had poor generalisation (and ‘very poor’ predictions) with the WAPABA.

550

551 *Historical record length and data set size*

552

553

The performance of each model type is compared to the length of historical records available at each station. Training data length has been categorized here as 14-25 years (38% of stations), 25-35 years (40%), and 35-47 years (23%).

554

555

556

557

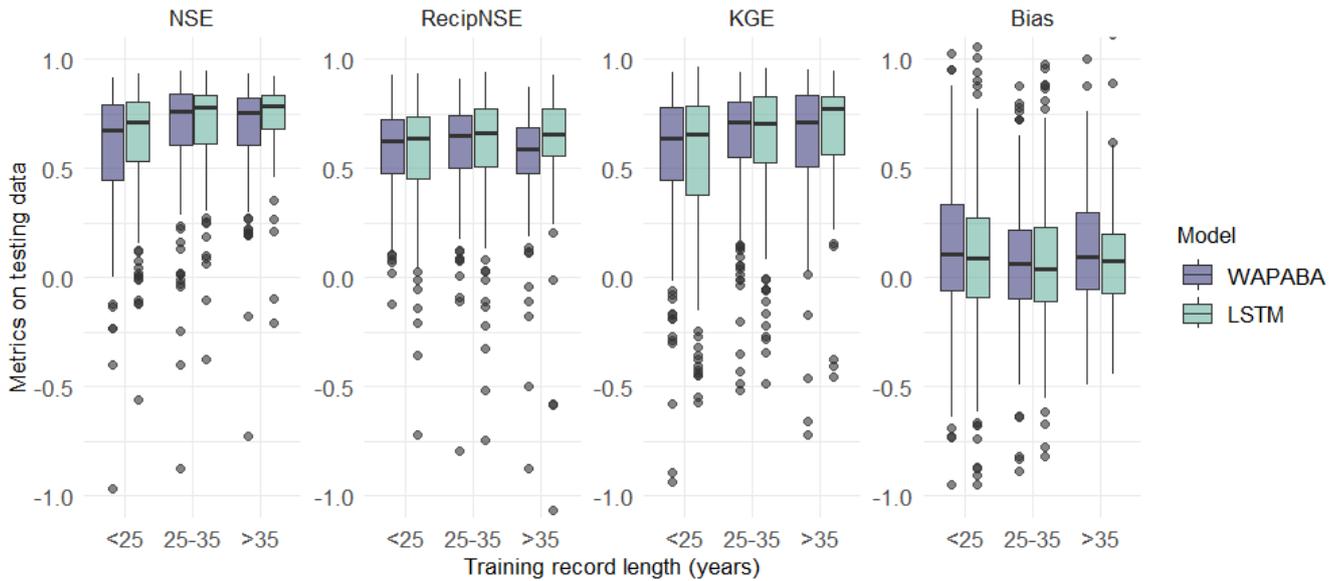

558

Figure 14 ~~Figure 13~~ (top panel) shows prediction performance varying slightly with record length (for visualisation purposes, this figure is shown without large negative outliers – the figure including outliers is provided in Figure A2 of the Appendix). Stations with medium record length tend to have slightly better predictions according to the four metrics than those with shorter records. The performance levels tend to even out as record lengths increase beyond 35 years, and there is even a slight decline in the WAPABA reciprocal NSE.

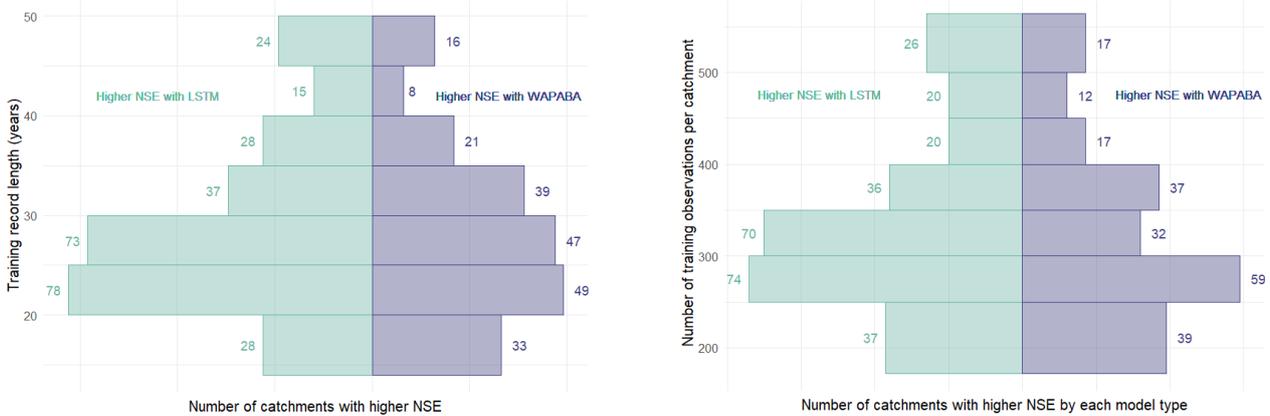

559 Considering catchments individually, the median normalised difference in NSE between WAPABA and LSTM predictions
 560 (on testing data) is just slightly below zero for all record lengths: -0.03 (<25 years of record), -0.04 (25-35 years), -0.04 (>35
 561 years). This indicates that, in each of the short, medium and long record length categories, at least half of the individual
 562 catchments have higher NSEs with the LSTMs.

563 The mirrored histogram in the lower left panel of Figure 14 quantifies the number of catchments within 5-year bins of record
 564 length in which runoff is better predicted by the LSTM or by the WAPABA. In six of the eight bins, the majority of
 565 catchments are better represented by the LSTM.

566

567

568

569 **Figure 1413:** Effect of record length and training data size on prediction performance for each model type. Upper panel: Medians
 570 of the NSE and KGE on testing data increase with record length for both WAPABA and LSTM predictions (large negative outliers
 571 have been excluded for visualization purposes, but are included in the corresponding figure in the Appendix). Lower left panel:
 572 Advantage of each model in 5-year increments of record length based on NSE values. Lower right panel: Advantage of each model
 573 based on number of training observations.

574

575 The mirrored histogram in the lower left panel of Figure 13 quantifies the number of catchments within 5-year bins of record
 576 length in which runoff is better predicted by the LSTMs or by the WAPABAs. In six of the eight bins, the majority of
 577 catchments are better represented by the LSTMs.

578 Comparing performance based on the number of years of record does not take into account the actual size of the data sets,
579 since measurement frequency differs at each station. Catchments in this study have between 172 and 564 training data
580 observations (425-846 including testing data). The lower right panel of ~~Error! Reference source not found.~~ [Figure 14](#) shows
581 the number of catchments best modelled by the WAPABA or LSTM model (determined by higher NSE on the testing data)
582 in relation to the number of training observations. Median NSE values of both the WAPABA and LSTM predictions increased
583 with increasing number of training data points (not shown). Of particular note is that runoff at catchments with the smallest
584 data sets (less than 250 training data points) were similarly well predicted by both LSTM (median NSE = 0.67) and WAPABA
585 (median NSE = 0.66).

586

587 4. Discussion

588 ~~When considered over the entire study set of catchments,~~ The machine learning models were found to match the conceptual
589 model performance for the majority of catchments ~~in this study.~~ ~~When considered over the entire catchment set,~~ the median
590 NSE of runoff predictions was 0.74 with the WAPABA models and 0.76 with the LSTMs ~~(on the testing data), and .~~ The
591 medians of other metrics were similarly aligned.

592 ~~When considering the differences between models in predicting runoff at~~ individual catchments, LSTM ~~runoff prediction~~
593 performance was similar to or exceeded WAPABA performance in 69% of the catchments in this study (based on the NSE
594 metric). The median differences in metrics (NSE, Reciprocal NSE, KGE and Bias) between the model types at individual
595 catchments were close to zero, though the range of differences was wide in both directions suggesting many catchments had
596 noticeable prediction advantages with either the WAPABA or LSTM models.

597 Medium flows were similarly well ~~represented~~ by both model types, with less accurate predictions for high flows and worse
598 again for low flows. Both WAPABA and LSTM ~~models~~ tend to overestimate low flows, ~~while;~~ high flows are noticeably
599 underestimated by LSTM and both over- and underestimated by WAPABA. Across all flow levels, the mean flow is
600 prevalently overestimated during testing for both model types, though slightly more so by WAPABA (higher bias of the
601 mean). This overestimation is expected as the testing period in this study is drier than the training period and it is common
602 to have an overestimation of mean during dry periods ([Vaze et al., 2010](#)). ~~V~~Streamflow variability ~~of streamflow~~ tends
603 towards overestimation by WAPABA and underestimation by LSTM.

604 Larger catchments were found to have the potential for greater prediction improvements with the LSTM. This finding
605 supports the work of ([Fluet-Chouinard et al., 2022](#)), who found that deep learning methods compete especially well with
606 traditional models in larger non-regulated rivers where the influence of time lags is significant.

607 Though it is known that, ~~in general,~~ machine learning models ~~generally~~ benefit from large amounts of training data, it is often
608 not possible to provide large hydrological data sets. In this comparison, shorter training record lengths ~~were not found to~~
609 ~~not~~ affect one model type more than the other; the catchments with the smallest training data sets (less than 250 observations)
610 did not show a distinct prediction advantage with either WAPABA or LSTM (median NSEs of 0.66 and 0.67 respectively).

611 In past studies, traditional models have been found to struggle to make accurate runoff predictions under shifting meteorologic
612 data ([Saft et al., 2016](#)). This is an issue that researchers have noted deep learning models may have the potential to overcome
613 ([Li et al., 2021](#), [Wi and Steinschneider, 2022](#)). In this study, the variation in differences in prediction performance at
614 individual catchments is more evident during the testing portion than the training portion of the time series, implying that the
615 WAPABA and LSTM models may each have advantages or drawbacks for generalising to unseen data on various catchments.

616 It was found that in catchments where the WAPABA models provide good runoff predictions during training but struggle to
617 make accurate predictions on new data, the LSTM provides improved predictions in all cases (ie., for those with testing NSE
618 < 0 with WAPABA, all but one had $NSE > 0$ with the LSTM). In the opposite case, where the LSTM produced substantially
619 poorer predictions on testing data than training data, these predictions were not outdone by WAPABA. This improvement by
620 the LSTM in predicting beyond conditions experienced during training will become progressively important as climate
621 change continues.

622 Aside from scientific considerations, another important advantage of developing rainfall-runoff models using a machine
623 learning software framework is to easily share them among users and to benefit from software optimisation provided by well-
624 established frameworks such as Tensorflow, Keras, or Pytorch. Better benchmark datasets and centralised repositories will
625 be the key to advancement of machine learning in hydrology (Nearing et al., 2021, Shen et al., 2021). Initiatives are being
626 made to grow reusable software for applying machine learning in hydrology and to benchmark these against other approaches
627 (Abbas et al., 2022) and (Kratzert et al., 2022).

628 Metrics and models

629 Certain caveats are acknowledged regarding the metrics and models used here. It is possible that the use of individual metrics
630 to compare predictions along the entire length of the time series may mask any variability in model performance that occurs
631 in subperiods of the time series (Clark et al., 2021, Mathevet et al., 2020). These limitations were partially addressed by
632 comparing high, medium and low flow periods separately, though there are many other subdivisions of the time series that
633 we have not been included in the scope of this study.

634 WAPABA is only one example of a conceptual rainfall-runoff model. Tand there are others that could have been chosen for
635 this analysis, though fewer are suitable for comparisons at a monthly time step than would be the case at the daily time step.
636 Model comparisons in Wang et al. (2011), Bennett et al. (2017) and the subsequent body of work with WAPABA in Australia
637 have established WAPABA as a reasonable benchmark against which to assess the machine learning model performance.

638 Though this study has focused on comparing the LSTM model to the WAPABA, readers may wonder if the more traditional
639 feed-forward neural network (FFNN) may suffice in producing as good results. The FFNN has been used in hydrology for
640 many years to model the relationship between climatic predictors and hydrological responses and many researchers are
641 familiar with this basic neural network structure. However, the FFNN is a static network and does not consider the sequential
642 nature of the input data. Though the six months of lagged predictor variables could be input as separate variables, this requires
643 an increase in the complexity of the training space and is not likely to be the optimal choice for time series data as the
644 cumulative impact of the predictor sequences may not be captured. Many studies have already considered the comparison of
645 FFNNs to LSTMs for rainfall-runoff modelling and have determined the LSTM to provide superior runoff predictions (eg.
646 Rahimzad et al., 2021). As an experiment, the FFNN has been run on this set of 496 catchments and added to the comparison
647 of overall model performance, shown in Figure A3 of the Appendix. It can be seen that the FFNN leads to lower NSE, KGE,
648 Reciprocal NSE, bias of the mean, bias of variability and correlation values, and therefore provides less accurate estimations
649 of runoff than both the WAPABA and the LSTM. For this reason, the FFNN has not been included in the bulk of this study.

650

651 Future research directions

652

653 Future work may entail an expansion of the architecture and complexity of the LSTMs ~~for models used here~~ ing this set of
654 catchments, to determine what advantages could be gained from the use of more sophisticated model setups ~~LSTMs~~. This
655 may involve the development of hybrid models blending existing conceptual models with LSTMs, the production of a global
656 LSTM incorporating all of the time series, or a type of transfer learning where a model is trained on data from all catchments
657 is and then fine-tuned on a catchment-by-catchment basis, as in Kratzert et al. (2019).

658 A simple LSTM has been used in this study, with a single layer and no catchment-specific hyperparameter tuning. Through
659 appropriate tuning of the models' architecture and hyperparameters for each catchment, more accurate results could be
660 expected. For example, it is known that the performance of data-driven runoff models is heavily dependent on the amount
661 of lagged data that is used as input ([Jin et al., 2022](#)). In this study, a lag of 6 months has been used for all of the catchments,
662 ~~based on a trial of up to 24 months lag on 10 random stations. A~~ and as such, only temporal patterns of up to 6 months are
663 captured by the LSTMs used in this paper. Varying the length of lag on a catchment-specific basis may lead to better
664 performance.

665 Opportunities also exist for multiple time series analyses on this set of basins to capture patterns in hydrologic behaviour that
666 surpass the catchment scale. With multiple time series analysis one ~~we~~ might expect to see greater benefits in the use of
667 machine learning over traditional hydrologic models, since these large-scale studies present obstacles to traditional modelling
668 due to their greater input data and parameter requirements to accurately describe the ~~ing~~ physical properties of the catchments
669 ([Nearing et al., 2021](#)). ~~This may involve the development of hybrid models blending existing conceptual models with LSTMs,~~
670 ~~the production of a global LSTM incorporating all time series, or transfer learning where a model is trained on data from all~~
671 ~~catchments and then fine-tuned on a catchment-by-catchment basis, as in Kratzert et al. (2019).~~ Deep learning models have
672 been found to produce better predictions when trained on multiple rather than individual basins ([Nearing et al., 2021](#)), and it
673 has been noted that the training of LSTMs on large diverse sets of watersheds may help improve the realism of hydrologic
674 projections under climate change ([Wi and Steinschneider, 2022](#)).

675 Another consideration may be hybrid modelling frameworks, which combine aspects of conceptual models with machine
676 learning models. These have the potential to draw benefits from both types of models to produce more interpretable and
677 possibly more physically realistic predictions. By leveraging the particular strengths of each model type, the limitations
678 inherent in each may be reduced. For example, Okkan et al., (2021) embedded machine learning models into the internal
679 structure of a conceptual model, calibrating both the host and source models simultaneously, and found the product
680 outperformed each model individually. Li et al., (2023) replaced a set of internal modules of a physical model with embedded
681 neural networks, leading to improved interpretability as well as predictions that are comparable to pure deep learning (LSTM)
682 predictions. The authors found that replacing any of the internal modules improved performance of the process-based model.
683 In the Australian context, Kapoor et al., (2023) studied the use of deep learning components in the form of LSTMs and
684 convolutional neural networks to represent subprocesses in the GR4J rainfall-runoff conceptual model for a set of over 200
685 basins. It was found the hybrid models outperformed the conceptual model as well as the deep learning models when used
686 separately, and provided improved interpretability, better generalisation and an improvement in prediction performance in
687 arid catchments. In this case of this study, the soil moisture and groundwater recharge outputs derived from the WAPABA
688 model would likely be useful as additional predictors for the LSTM model.

689
690 The question of catchment-specific circumstances under which the LSTM may provide an advantage to monthly rainfall-
691 runoff modelling has been broached in an elementary fashion here, and a more sophisticated investigation would be warranted
692 in further studies. Investigation of multi-dimensional patterns of catchment or climate characteristics that may be associated

693 with differences in predictive performance between the model types could lead to a greater understanding of the value that
694 LSTMs could add to hydrologic modelling.

695 ~~Aside from scientific considerations, another important advantage of developing rainfall-runoff models~~
696 ~~using a machine learning software framework is to easily share them among users and to benefit from~~
697 ~~software optimisation provided by well-established frameworks such as Tensorflow, Keras, or Pytorch.~~
698 ~~Better benchmark datasets and centralised repositories will be the key to advancement of machine~~
699 ~~learning in hydrology (Nearing et al., 2021, Shen et al., 2021). Initiatives are being made to grow~~
700 ~~reusable software for applying machine learning in hydrology and to benchmark these against other~~
701 ~~approaches (Abbas et al., 2022) and (Kratzert et al., 2022).~~

702

703 5. Conclusion

704 A continental-scale comparison of conceptual (WAPABA) and machine learning (LSTM) model predictions has been made
705 for monthly rainfall-runoff modelling on almost 500496 diverse catchments across Australia. This large-sample analysis of
706 monthly-timescale models aggregates performance results over a variety of catchment types, flow conditions, and
707 hydrological record lengths.

708 The following conclusions have been found:

- 709 ~~•1. The LSTM models matches or exceeds ~~the~~ WAPABA prediction performance at a monthly scale for the majority~~
710 ~~of catchments (69%) in this study.~~
- 711 ~~•2. Both the WAPABA and LSTM models have advantages at certain individual catchments; whilst ~~At individual~~~~
712 ~~catchments, the median difference in ~~WAPABA and LSTM~~ prediction performance is near ~~close to~~ zero, ~~but~~ the~~
713 ~~distribution spreads in both directions, ~~showing both model types have advantages at certain catchments.~~~~
- 714 ~~3. Larger catchments were found to have the potential for greater prediction improvements with the LSTM ~~At larger~~~~
715 ~~catchments, potential for a greater magnitude advantage of LSTM predictions over WAPABA predictions was seen~~
716 ~~than at smaller catchment_s (though some large catchments were better modelled by WAPABA).~~
- 717 ~~4. Mean streamflow and streamflow variability tend to be overestimated more by the WAPABA models than the~~
718 ~~LSTMs.~~
- 719 ~~•~~
- 720 ~~•5. Both model types predict medium flows better than high or low flows. ~~In general,~~ the majority of high flows were~~
721 ~~underestimated by both ~~models LSTM and WAPABA,~~ ~~h~~. However, ~~whilst the largest errors in high flow estimations~~~~
722 ~~by LSTM were underestimates, WAPABA also had some tendency towards large over-estimations of high flows~~
723 ~~that wasn't seen with the LSTMs. Therefore streamflow variability was found to tend towards overestimation by~~
724 ~~WAPABA and underestimation by LSTM.~~
- 725 ~~•~~
- 726 ~~• More catchments are poorly predicted ($NSE < 0$) by WAPABA than by LSTM (5% vs. 2%). For those poorly~~
727 ~~predicted by WAPABA, predictions at 96% were improved by use of LSTM. For those poorly predicted by LSTM,~~
728 ~~60% were improved by use of WAPABA.~~
- 729 ~~•6. Generalisation to new conditions is found to improve with use of the LSTM. In this data set the testing period was~~
~~significantly drier than the training period. This has with implications for making predictions in the context of~~

730 climate change. At catchments in which WAPABA produced good predictions on the training data but very poor
731 predictions on the testing data, the testing predictions were universally improved with use of the LSTM; the opposite
732 case (~~poor generalisation by LSTM improved by WAPABA~~) was not observed (ie., in the one catchment with poor
733 generalisation by the LSTM, this was not improved upon by the WAPABA). ~~In this data set, the testing period was~~
734 ~~significantly drier than the training period. This has implications for making predictions in the context of climate~~
735 ~~change.~~

736 ~~7. Training data set size has little affect on the models.~~ Catchments with the smallest training data sets (< 250
737 observations) were similarly well predicted by both model types.

738 ~~• It has been shown that similar performance to traditional models is able to be reached despite the LSTM being fit~~
739 ~~using limited data on single catchments and a basic model setup.~~

740 With refinement of the LSTM model architecture and hyperparameter tuning specific to each catchment, it may be possible
741 to increase the proportion of catchments for which the LSTM provides good prediction performance. Other benefits may be
742 realised by combining multiple catchments within a global models to capture patterns that transcend catchment boundaries,
743 incorporating hybrid modelling techniques or ~~by~~ transferring knowledge from data-rich catchments to data-poor catchments;
744 within Australia or from international source catchments.

746 Author contributions

747 PF and JMP designed the experiment with conceptual inputs from JL and SC. PF and JMP developed the LSTM model code
748 and performed the simulations, as JL performed the WAPABA simulations. SC conducted the comparison and prepared the
749 manuscript with contributions from all co-authors.

751 Competing interests

752 The authors declare that they have no conflict of interest.

754 Acknowledgments

755 The authors would like to thank the CSIRO Digital Water and Landscapes initiative for their support and for the funding of
756 this project.

758 Data and code availability

759 All data used in this paper are accessible through the website of the Australian Bureau of Meteorology. Rainfall and potential
760 evapotranspiration can be downloaded from the Australian Water Outlook portal at the following address:
761 <https://awo.bom.gov.au/>. Streamflow can be downloaded from the Water Data Online portal at the following address:
762 <http://www.bom.gov.au/waterdata/>. Catchment characteristics (e.g. area) can be obtained from the Geofabric dataset

763 available at the following address: <http://www.bom.gov.au/water/geofabric/>. [The deep learning source code used in this paper](https://csiro-hydroinformatics.github.io/monthly-lstm-runoff/)

901

902 **Appendix**

903 Figures A1 and A2 This appendix includes reproductions of ~~some of the report~~ figures in the report in which large outliers
 904 detract from a decent visualisation of the bulk of the data points. Here the entire data set is included, whereas the
 905 corresponding figures in the report are shown without the large outliers.

906
 907 **Figure A1: Difference in the metrics (WAPABA – LSTM) for each catchment. A reproduction of Figure 1514 that includes**
 908 **outliers.**

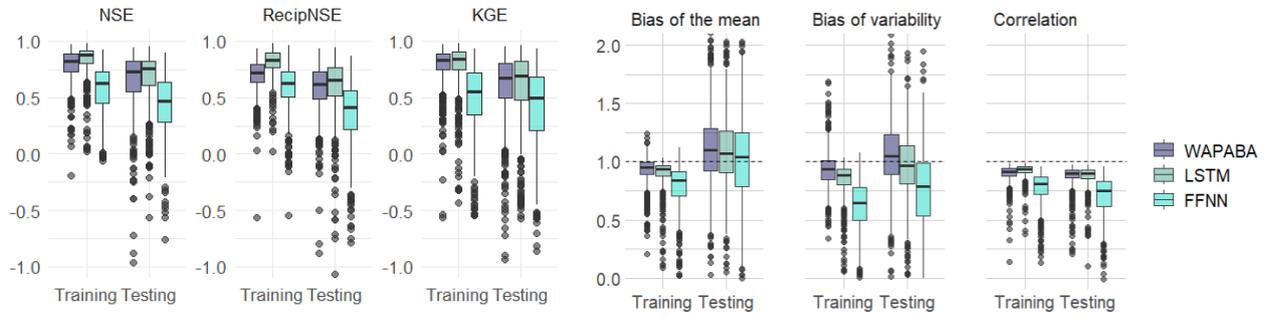

909
 910 **Figure A2: Effect of record length and training data size on prediction performance for each model type. A reproduction of Figure**
 911 **13 that includes outliers.**

912
 913 **Feed-forward Neural Network**

914 To investigate the use of a very simple neural network, the FFNN was run for the 496 catchments. Input variables were the
915 same as for the LSTM and WAPABA, however 6 months of historical values were included with each training observation.
916 A grid search on 5 random catchments was conducted to select learning rate and batch size. Out of a search space of [8, 16,
917 32] for batchsize and [0.1, 0.01, 0.001, 0.0001] for learning rate, a batch size of 16 and learning rate of 0.01 were chosen.

918 Figure A3 includes the FFNN model results in the comparison with LSTM and WAPABA results. The FFNN values are
919 lower than WABAPA and LSTM indicating poorer runoff predictions over this set of catchments.

920
921 **Figure A3: FFNN metrics compared with WAPABA and LSTM metrics, corresponding to Figures 4 and 5.**
