10 **Abstract.** While in the southern Hemisphere a single water sample can be sufficient for tritium-based young groundwater dating, several tritium measurements spanning over multiple years are still needed in the northern Hemisphere. Although it is advised to focus tritium-based groundwater age dating on sites where long chronicles of tritium data are available, we tested in this study the potential for short high-accuracy tritium data series (~4 years) to date groundwater from 35 springs draining the Luxembourg Sandstone aquifer (Central Western Europe). We determined groundwater mean transit times by using the

15 lumped parameter model approach in a Monte Carlo uncertainty estimation framework to provide uncertainty ranges inherent to the low number of tritium data at hand and their related analytical errors. Our results show that unambiguous groundwater mean transit time assessments cannot be determined solely based on such recent short tritium time series, given that several ranges of mean transit times appeared theoretically possible. Nonetheless we succeeded in discriminating groundwater mean transit times in the vadose and saturated zones of the aquifer through a stepwise decision process guided with several

20 supplementary data. Our findings are consistent with both the tritium measurements of individual springs and the hydrogeological context of the study area. We have been able to improve our understanding of the water transit times in the Luxembourg Sandstone aquifer. We particularly highlighted a horizontal-vertical water velocity anisotropy in the Luxembourg Sandstone - a key feature that deserves to be explored further.

25 **Keywords.** Tritium, groundwater, mean transit time, Luxembourg Sandstone aquifer.

## 1. Introduction

Determining the timescales at which precipitation is percolating from a recharge area through an aquifer to where it discharges naturally (springs, streams) or is extracted from pumping wells is of key importance for a better understanding of groundwater resources and their sustainable management (Purtschert, 2008; Purtschert et al., 2008). Assessments of groundwater transit

30 times are key to identify, model or forecast anthropogenic impacts of past and present land use practices on groundwater  
quality (e.g., MacDonald et al., 2003; Morgenstern and Daughney, 2012; Morgenstern et al., 2015). This is especially the case  
for young groundwaters – i.e., groundwater recharged during the last hundreds of years, including the time of change from  
low to high intensified land use – which constitute by far the most important component of the active hydrological cycle  
(Gleeson et al., 2015) and are obviously more vulnerable and prone to surface-borne anthropogenic contamination than old  
35 groundwaters (Newman et al., 2010; Beyer et al., 2014; Jasechko, 2019).

The use of tracers – i.e., substances which can be detected in the water and allow following, or tracing, the flow of water – is  
particularly suitable to assess transit times of hydrological systems (Leibundgut et al., 2009; Leibundgut and Seibert, 2011).  
Tracers are divided into two general categories – environmental or artificial – depending on how they enter the system to be  
studied. While artificial tracers are purposefully injected over a limited temporal and spatial scale to infer transit times through  
40 preferential fast flow paths, environmental tracers – which, as their name implies, are present in the environment – make it  
possible to assess the overall and integrated response of hydrological systems (e.g., Einsiedl, 2005; Lauber and Goldscheider,  
2014). The common feature of the environmental tracers used as dating tools is that they are time-dependent, whether because  
of variable input concentrations during recharge, chemical or physical accumulation processes in the subsurface and/or  
radioactive decay (Morgenstern et al., 2010).

45 Among the environmental tracers at hand, tritium (radioactive hydrogen isotope  $^3\text{H}$ ) is particularly interesting for young  
groundwater dating (Newman et al., 2010; Beyer et al., 2014; Jasechko, 2019). Produced naturally in the atmosphere by  
cosmic-ray spallation processes (Lal and Peters, 1967), but also introduced artificially during the atmospheric nuclear weapons  
testing in the 1950's and 1960's (Morishima et al., 1985), tritium enters the water cycle as so-called “tritiated” water ( $^3\text{H}^1\text{HO}$ ).  
Water from precipitation arriving at the ground surface thus contains tritiated water molecules in a given initial concentration,  
50 which then decreases by radioactive decay while in transit through the hydrosystem. Tritium decays with a half-life of  
 $12.32 \pm 0.02$  years (Lucas and Unterweger, 2000) and has the potential for dating groundwater with mean transit times that  
exceed 100 years (Cook and Solomon, 1997; Morgenstern and Daughney, 2012; Beyer et al., 2014).

Alternative gaseous tracers covering a similar dating range to tritium exist (e.g.,  $^3\text{He}$ , CFCs,  $\text{SF}_6$ ,  $^{85}\text{K}$ ) but their use has certain  
disadvantages (Morgenstern and Daughney, 2012; Cartwright et al., 2017; Gerber et al., 2018). Indeed, tritium, as part of the  
55 water molecule itself, allows inferring transit times including travel time through the unsaturated zone, whereas gas tracers  
dissolved in recharge water stay in equilibrium with the atmosphere in the unsaturated zone and derived dating results reflect  
only transit times in the saturated zone. Besides, tritium dating can be applied where an aquifer discharges naturally (springs,  
streams), while the use of dissolved gas tracers at these places is thorny due to the risk of contamination of samples with the  
surrounding air (rapid exchange with the atmosphere after emergence; Busenberg et al., 2006; Han et al., 2006).

60 The use of tritium within the hydrological sciences community for water dating purposes has evolved over time due to the  
varying origin and level of its atmospheric concentration. Even if the potential for natural-borne tritium for dating hydrological  
systems was suggested early on by Libby (1953), most of these pioneering applications capitalized on the considerable  
precipitation tritium increases inherent to the mid-20<sup>th</sup>-century nuclear weapon tests (Jasechko, 2019). These elevated values

65 allowed first to carry out explicit water transit time analyses for several years past the mid-1960's bomb peak, the latter acting  
as a clear time marker. With the bomb tritium pulse decay observed after the 1970's, tritium dating of hydrological systems  
had to increasingly rely on time series with several measurements to deliver unambiguous results – eventually leading to a  
fading interest in tritium as a tracer of choice for water age dating (Stewart and Morgenstern, 2016; Stewart et al., 2021).  
Present-day tritium activities in precipitation have recovered natural cosmogenic levels, i.e., similar to levels noted before the  
nuclear tests (Cauquoin et al., 2015; Terzer-Wassmuth et al., 2022). However, bomb tritium remains present in the hydrological  
70 cycle of the earth (Stewart et al., 2021). The interest in tritium water dating has recently gained new momentum (Morgenstern  
et al., 2010; Stewart et al., 2012). In the southern Hemisphere, the remnant bomb tritium has indeed declined to levels lower  
than those found in modern rainfall (Tadros et al., 2014; Stewart et al., 2021), which allows now unambiguous dating of  
hydrological systems from a single sample relying on the tritium's radioactive decay (Morgenstern et al., 2010; Cartwright et  
al., 2020).

75 However, in the Northern Hemisphere the remnant bomb tritium activities have not yet decayed to below those of current  
rainfall, because precipitation was much more strongly affected by nuclear weapons testing (i.e., the tritium bomb peak was  
two to three orders of magnitude higher than in the Southern Hemisphere; Stewart et al., 2021). Time series with several tritium  
measurements are still needed here for an unequivocal dating of hydrological systems and it is therefore presently advised to  
carry out tritium water dating preferably at sites where past data are available and can be supplemented with analyses of recent  
80 samples, so that a longer time series can be obtained (Stewart and Morgenstern, 2016). Some recent studies have leveraged  
data from such sites (e.g., Stolp et al., 2010; Blavoux et al., 2013; Gallart et al., 2016; Jerbi et al., 2019), but the latter remain  
rare or even absent for most hydrological systems.

As tritium in the environment is at much lower levels at present than in the past, an important aspect that nowadays must also  
be considered much more carefully is the tritium measurement accuracy and its related impact on water dating results (Eastoe  
85 et al., 2012; Stewart et al., 2012; Stewart and Morgenstern, 2016). Recent methodological developments have fortunately  
improved the tritium detection sensitivity and measurement accuracy (Morgenstern and Taylor, 2009). The advantage of using  
these high-precision tritium analyses for obtaining more accurate water dating results have been documented for both the  
Southern Hemisphere (Stewart et al., 2012) and the Northern Hemisphere (Gallart et al., 2016).

Here, we rely on the tritium dating approach to inform on young groundwater transit times in the Northern Hemisphere for  
90 new study sites, i.e., which do not have historical tritium records, but for which we can nevertheless rely on recent high-  
accuracy tritium data. The aim of this study is to evaluate water transit times for several springs draining the Luxembourg  
Sandstone aquifer. Widely used for the country's drinking water supply, but also impacted by anthropogenic pollutants (e.g.,  
Bohn et al., 2011; Gourdol et al., 2013; Farlin et al., 2018, 2019), the Luxembourg Sandstone aquifer is by far the most valuable  
groundwater resource of Luxembourg and, as such, assessing and understanding of water transit times is of national interest.

95 By testing the potential of rather short but high-accuracy recent tritium data time series, our work has pioneering character for  
the dating of young groundwater bodies in Central Europe.

## 2. Study area

Located on the north-eastern boundary of the Paris sedimentary Basin, the Luxembourg Sandstone is a sandy formation interposed in the normal marly-limestone Lias facies. Due to its intrinsic properties, structure, and positioning, it constitutes the main aquifer in Luxembourg hosting the most important groundwater resource of the country and its capital.

### 2.1. The Luxembourg Sandstone: geological and hydrogeological settings

The Luxembourg Sandstone (Fig. 1) is composed of grains of quartz  $\text{SiO}_2$  bonded by a calcareous cement  $\text{CaCO}_3$ . Its average chemical composition is about 65-70%  $\text{SiO}_2$  and 30-35% of  $\text{CaCO}_3$  (Lucius, 1949; Van den Bril, 2008). The Luxembourg Sandstone is in general very homogeneous but may be locally crossed by beds of sandy marls (Lucius, 1948). It is also characterized by a network of mainly NW and NE striking fractures (Berg, 1965). Vertically discontinuous and relatively short, fractures are often limited to one bed with a decametric spacing (fracture density increases with the carbonate content; Colbach, 2005). Some fractured zones exist, sometimes cutting through the whole formation. These zones can consist of intensely weathered, friable and densely fractured sandstone where spacing of several meters exist, but also by one main, up to one-meter-wide fracture (Colbach, 2005). All of these properties confer on the Luxembourg Sandstone reservoir a dual-porosity characteristic, where its capacitive function (storage of water) is mainly supported through the pores of the sandstone and its dynamic function (transfer of water) is provided primarily by the fracture network (Von Hoyer, 1971).

The Luxembourg Sandstone permeability is about  $5 \times 10^{-5}$  m/s (Von Hoyer, 1971). Its matrix porosity ranges from 5 to 40 % depending on the degree of dissolution of the calcareous cement. Its fracture porosity is estimated to be approximately 1% (Gronemeier, 1976; Colbach 2005; Claes et al., 2018; Samir, 2019). More than a hundred artificial tracer tests were done in the Luxembourg Sandstone aquifer and have been compiled in a recent study (Meus and Willems, 2021). The statistical analysis of this dataset confirms the key role of the fissure network on the preferential pathways of groundwater in the saturated zone. Observed transit times to first arrivals and concentration peaks for positive tracer tests led Meus and Willems (2021) to assess average velocities of 52 and 16 m/h respectively (with highest observed velocity of 350 m/h). These figures are fundamental for the understanding of the Luxembourg Sandstone aquifer but nevertheless remain informative only on its fissured fast flow component. Although this fast flow component is of key importance for the protection of the resource (especially for bacteriological contamination from the surface or following localized point source accidental pollution), it is assumed not to dominate water transit times in the aquifer at large scale.

Structurally, the Luxembourg Sandstone, whose average total thickness is about 60-80 m, is characterized by mainly SW-NE striking horsts and grabens, associated to large undulations (Lucius, 1948; Bintz and Muller, 1965). Its slight dip ( $<10^\circ$  towards the southwest) and its resistance to erosion have generated cuestas, which, in Luxembourg alone, have a length of more than 200 km (Lucius, 1948; Berg, 1965; Colbach, 2005; Kausch and Maquil, 2018). Its outcrop area widens to the northeast, beyond the German border, and expands towards a broad plateau in the southern part of Luxembourg reaching out to Belgium ( $\sim 350$  km<sup>2</sup>; Fig. 2). Because of its general dip, it dives below more recent geological strata in France. Overall, the Luxembourg

130 Sandstone aquifer forms consequently a broad trough perched in the East (unconfined aquifer part, Luxembourg Sandstone plateau), covered with a powerful charge of newer and mostly impervious strata to the west (confined aquifer part) and draining groundwater to the SW (Lucius, 1949). The outcrop area of the Luxembourg Sandstone constitutes the aquifer recharge zone. The significantly weathered state of the upper metres of the sandstone bedrock and the sandy nature of the overlying soils have limited the development of the river network and effective precipitation infiltration can be considered as the dominant process (Lucius, 1939; Cammeraat et al., 2018).

## 135 2.2. The springs of Luxembourg City

In large parts of the country, the Luxembourg Sandstone plateau is notched by deep valleys and consequently is perched on its impervious base. Where the sandstone's impermeable base lies above the valley floors, many natural contact springs (more than 500 in the country) leave the aquifer according to the topography of the impervious base, which mainly controls the groundwater flow together with the Luxembourg Sandstone fracture network (Fig. 3). Most of these springs are tapped, representing the main groundwater resource for the country's drinking water supply (AGE, 2015). Among them, 62 key springs are in the vicinity of Luxembourg City and provide about two-thirds of the drinking water supply of the capital's population. It is this strategic importance that has eventually stimulated research efforts on spring water transit time.

140 Based on the local geomorphology of the geological layer (Fig. 2), the springs of Luxembourg City have been grouped into nine main districts (Lucius, 1939): Birelergrund (B), Glasburen (G), Dommeldange (D), Kopstal rive droite (KRD), Kopstal rive gauche (KRG), Millebach (M), Pulvermuhle (P) and Siwebouren (S). The recharge areas of each of these groups have been redefined very recently (RGD, 2018, 2019, 2021a, 2021b, 2022a, 2022b). Their delineation was based on water balance calculations together with constraints defined by the geological, geomorphological, and hydrogeological contexts (AGE, 2010). An estimation of the average groundwater flow lengths was made for each of the recharge areas. As the borehole density across the Luxembourg Sandstone is insufficient for establishing an accurate water table map, a rough estimate was made by considering the distances between the outer limits of the recharge areas and the emergence lines defined by the springs. The Luxembourg Sandstone thickness was also computed by subtracting the terrain's surface topography from that of the sandstone's impermeable base (interpolated from the elevation of the known geological contact lines). These attributes, together with mean elevation and surface of each recharge area, are listed in Table 1. The mean outflowing discharge used to estimate the extension of the recharge areas (RGD, 2018, 2019, 2021a, 2021b, 2022a, 2022b) are also provided.

150

## 155 3. Material and methods

### 3.1. Tritium water dating

#### 3.1.1. Transit time distribution and mean transit time estimation

Groundwater discharging at a spring is a mixture of water from short and long flow lines, and therefore the water in a sample does not have a single age corresponding to a unique transit time within the aquifer (i.e., related to the time elapsed since the water molecules entered the system at the recharge area, where the age is zero), but has a transit time distribution (TTD; Maloszewski and Zuber, 1982; Stewart et al., 2017). A mean transit time may however be estimated using the Lumped Parameter Model (LPM) approach. Introduced in hydrogeology by Maloszewski and Zuber (1982), LPMs are the most widely used model-based environmental tracer interpretation approach in groundwater studies (Turnadge and Smerdon, 2014). This method relates the concentration of a tracer (in our case tritium) at the outlet of a groundwater system ( $C_{out}$ ) to its input concentration ( $C_{in}$ ) using the well-known convolution integral (Maloszewski and Zuber, 1982):

$$C_{out}(t) = \int_0^{\infty} C_{in}(t - \tau) \exp[-\lambda(\tau)] g(\tau) d\tau \quad (1)$$

where  $t$  is calendar time and the integration is carried out over the transit times  $\tau$ ,  $\lambda$  is the decay rate of the tracer ( $\lambda = 0$  for stable tracers;  $\lambda = \ln 2/T_{1/2}$  for radioactive tracers where  $T_{1/2}$  is the half-life; tritium  $T_{1/2} = 12.32$  years), and  $g(\tau)$  is a transfer function defining the TTD.

The TTD should be described by a conceptual flow or mixing model reflecting the average (steady-state) conditions in the groundwater system (Maloszewski and Zuber, 1982; Leray et al., 2016). Within this work we choose the exponential-piston flow model (EPM; Maloszewski and Zuber, 1982) which mimics a system with two segments of flow in series: one of exponential flow and the other of piston flow. EPM can be used especially when the time lag required for water to flow through the unsaturated zone of an unconfined aquifer cannot be neglected (Jurgens et al., 2012). This is the case for the Luxembourg Sandstone areas that feed the springs of Luxembourg City. In this context, the piston flow component simulates the water flowing through the unsaturated zone, while the exponential model represents the mixing at the outlet of groundwater flowlines coming from the saturated zone. The EPM response function is given by:

$$g(\tau) = 0 \quad \text{for} \quad \tau < \tau_m(1 - F) \quad (2a)$$

$$g(\tau) = \left(\frac{1}{F\tau_m}\right) \exp\left(-\frac{\tau}{F\tau_m} + \frac{1}{F} - 1\right) \quad \text{for} \quad \tau \geq \tau_m(1 - F) \quad (2b)$$

where  $\tau_m$  is the mean transit time, and  $F$  the ratio of the exponential volume to the total volume of the groundwater system. While the model is fully exponential when  $F = 1$ , it completely turns to piston flow when  $F = 0$ . It is also worth noting that  $\tau_m$  can be split into two components, i.e.,  $\tau_{pf}$ , the time lag required for water to flow through the piston flow section, and

$\tau_{exp}$ , the mean transit time for water to flow through the exponential volume.  $\tau_{pf}$  and  $\tau_{exp}$  are obtained by multiplying  $\tau_m$  by  $(1 - F)$  and  $F$ , respectively.

### 3.1.2. Spring water sampling and analytical techniques

190 Spring water samples were collected from 35 of the 62 springs of Luxembourg City (Fig. 2). The spring's selection was balanced to represent the main hydrogeological districts used for the water supply of the country's capital and to reflect a rather wide variability in terms of discharge dynamics and hydrochemical signatures (see 3.2 and 3.3). Note that some "springs", namely S01, S02, S03 and P01, are old natural emergences, but which have since then been excavated and are now being exploited through pumping.

195 To make the assumption of steady-state as acceptable as possible, samples were always taken outside of recharge and rainy periods in order to avoid any potential mixing with young freshwater coming from precipitation, e.g., through preferential pathways. All springs were sampled three times: in June 2011, August 2015 and 2017 for springs K21 and K21A and in September 2013, August 2015 and 2017 for all the others. Samples were collected without filtration or preservation in a 1 L plastic bottle filled to the top.

200 Tritium activities were measured on water samples that had been vacuum distilled and electrolytically enriched 95-fold using liquid scintillation spectrometry (Morgenstern and Taylor, 2009). For all samples, the reproducibility of the enrichment was 1 % and the limit of detection was 0.02 tritium units (TU; 1 TU represents a  $^3\text{H}/^1\text{H}$  ratio of  $10^{-18}$ ). The measurement uncertainty ( $1\sigma$ ), mainly due to the uncertainty of the enrichment and statistical errors of the ultra-low-level decay counting, ranges between 0.07 and 0.12 TU (1.2-1.9 %), depending on the tritium concentration of the samples. These are the measurements referred to  
205 as high-precision measurements in our study.

### 3.1.3. Input time series

Monthly values of tritium in precipitation (including uncertainties) come from the GNIP (Global Network of Isotopes in Precipitation) measurement network, initiated in 1958 by the IAEA (International Atomic Energy Agency) and the WMO (World Meteorological Organization), and were obtained from the WISER database (Water Isotope System for Data Analysis, Visualization, and Electronic Retrieval; IAEA and WMO, 2019; <https://nucleus.iaea.org/wiser>). The data used from 1978 to  
210 present are from the Trier station in Germany (Stumpp et al., 2014; Schmidt et al., 2019), located only 40 km away from Luxembourg City. The history of tritium in precipitation prior to 1978 has been reconstructed through a log-log linear regression ( $r^2 = 0.65$ ;  $p\text{-value} < 10^{-15}$ ) by combining records from Ottawa, Canada, from 1953 with those from Vienna, Austria, from 1961 (Jurgens et al., 2012; Stewart et al., 2017). Before 1953, the pre-bomb background concentration of tritium was  
215 estimated to be 8 TU (Jurgens et al., 2012).

To account for losses due to evapotranspiration (McGuire and McDonnell, 2006), the input of tritium to the ground as recharge was calculated through a weighting procedure like the ones reported by Stewart et al. (2007), Ozyurt et al. (2014) or Duvert et al. (2016). Here, we considered a soil model with a maximum water-holding capacity of 100 mm to assess the amount of

precipitation that infiltrates (i.e., precipitation in excess of that required to supply actual evapotranspiration and the soil water  
220 store: effective precipitation). Through this model, a monthly water balance calculation was done with the precipitation and  
temperature data recorded at the Findel airport WMO weather station, in operation since 1947 (WMO ID 06590; Fig. 2;  
<https://www.meteolux.lu>). Potential evapotranspiration was obtained from the temperature data following Thornthwaite  
(1948). Instead of calculating single annual tritium recharge input values, a one-year sliding window was then used to obtain  
monthly values as follows:

225

$$C_{in\ i} = \frac{\sum_{j=i-11}^i C_j P_{eff\ j}}{\sum_{j=i-11}^i P_{eff\ j}} \quad (3)$$

where  $C_{in\ i}$  is the monthly tritium recharge for the  $i^{\text{th}}$  month, and  $C_j$  and  $P_{eff\ j}$  are the monthly values of tritium in precipitation  
and monthly effective precipitation amounts for the  $j^{\text{th}}$  month, respectively. A Tukey filter (Tukey, 1968) with coefficient 0.4  
230 was applied to the moving window to avoid edge effects (Duvert et al., 2016). To obtain the respective monthly estimates,  
note that the same weighting procedure was applied to both tritium in precipitation and their uncertainties.

### 3.1.4. Modelling strategy

A modelling strategy able to account for the propagation of analytical errors is advocated for transit time determinations using  
LPMs, especially when only a limited number of samples is available (Gallart et al., 2016), as is the case for the springs of  
235 Luxembourg City. To this end, instead of using a best-fit calibration approach, EPM parameters were investigated within this  
work using a Monte Carlo sampling routine in a generalised likelihood uncertainty estimation framework (GLUE; Beven and  
Binley, 1992, 2014).

The approach used follows nearly the same modelling method proposed and applied in Gallart et al. (2016). The EPM  
parameter space ( $\tau_m, F$ ) was randomly explored until enough behavioural solutions were found (5000 within this work). The  
240 goodness of fit of the simulations was evaluated using the Nash–Sutcliffe efficiency coefficient (NSE; Nash and Sutcliffe,  
1970). To propagate tritium analytical errors, input (recharge) and output (spring) normally replicated time series were  
generated beforehand using the means and standard errors of every tritium measurement. These replicated values served for  
the assessment of the goodness of fit of every simulation.

### 3.1.5. Groundwater volumes

245 The volume of groundwater  $V$  stored within an aquifer (also known as the turnover volume, the volume of mobile water or the  
effective aquifer's volume) can be related to the mean transit time  $\tau_m$  of the water leaving it and its average outflowing  
discharge  $Q$  (Maloszewski and Zuber, 1982; McGuire and McDonnell, 2006; Morgenstern et al., 2010; Zhou et al., 2022):

$$V = Q \cdot \tau_m \quad (4)$$

250

Calculating such  $\tau_m$  - derived volumes will be used here to ensure that EPM solutions are to some extent physically valid regarding basic geometries and properties of the studied system.

### 3.2. Response time of spring discharge to precipitation input

#### 3.2.1. Cross-correlation analysis applied to groundwater time series

255 Introduced in karst hydrology by Mangin (1981a, 1981b, 1984), the use of correlation analysis applied to groundwater time series has since then widely expanded to understand the functioning of groundwater systems with varying characteristics. The cross-correlation analysis, which consists in studying the correlation between two time series (Box and Jenkins, 1970), was used in particular to assess the response of aquifer systems at springs or wells to precipitation input which is responsible for their recharge (e.g. Padilla and Pulido-Bosch, 1995; Angelini, 1997; Larocque et al, 1998; Lee and Lee, 2000; Panagopoulos and Lambrakis, 2006). Calculating the values of the cross-correlation coefficient results in a graph called a cross-correlogram that represents the correlation as a function of the time lag between the two series. A usual precipitation-groundwater time series correlogram reaches a peak of correlation after a certain time lag, the latter characterizing the response time of groundwater to the precipitation input. This response time can then be interpreted in terms of flow mechanisms. For instance, response times of unconfined aquifers derived from cross-correlation analysis have often been related to unsaturated zone characteristics (e.g., Lee and Lee, 2000; Lee et al., 2006; Fiorillo and Doglioni, 2010; Bloomfield and Marchant, 2013; Bloomfield et al., 2015; Al-Jaf et al., 2021).

265 Here, we did not follow the standard cross-correlation method to define the response time of groundwater to precipitation input, but rather used the methodology originally proposed by Fiorillo and Doglioni (2010) and subsequently taken up by Bloomfield and Marchant (2013), Bloomfield et al. (2015) or Van Loon et al. (2017). Starting from the premise that groundwater response at a given time does not result from a single precipitation pulse at a previous moment, but that it depends on a previous period of precipitation, Fiorillo and Doglioni (2010) propose an alternate way to the usual precipitation-groundwater time series cross-correlation analysis. Instead of using one single input time series, they suggest exploring multiple precipitation time series data constructed over varying cumulative time windows as input and retain the one with the maximum correlation peak. The correlation peak time lag of the considered cross-correlogram, added in a second step to the extent of the cumulative precipitation time window, thus allows to estimate a minimum and a maximum response time of the groundwater system, respectively. The average of these two values is defined in this study as the mean response time MRT.

275

#### 3.2.2. Spring discharge time series

Discharge of the springs of Luxembourg City has been measured from the mid-1990s, typically at weekly to quarterly time steps, with the aim to grasp both seasonal and multi-year temporal dynamics. These raw data were aggregated to monthly

280 mean values. If no observations were available for a given month, then a linear interpolation was used to estimate the missing monthly discharge values. Only gaps of maximum 6-month length were filled.

Monthly discharge time series were thus created for each investigated spring, except for P01 whose water collection facility is unsuitable for discharge measurements. Note that the springs S01, S02 and S03 were not processed individually, but jointly, because only records of their cumulative discharge are available. The length of the monthly discharge chronicles is 14 years  
285 or more, except for the M01 spring for which the time series is 7 years long. In 81 % of the springs, observations span over 25 years. Finally, it is worth noting that on average missing, interpolated and measure-derived monthly discharge data relate to 4, 25 and 71 % of the time series, respectively.

### 3.2.3. Input time series

In line with Jemcov and Petric (2009), who have documented the value of using effective infiltration in cross-correlation  
290 analysis to assess the functioning of karst aquifers, we did not select precipitation as input signal, but used instead effective precipitation. The proportion of precipitation eventually percolating to the groundwater is indeed a function of several processes linked to climatic conditions, vegetation, and soil characteristics, and prevailing in the superficial section of the system. By using precipitation as the entry signal, these processes, which usually only affect the first few tenths of centimetres of the subsoil, are not separated from the processes deeper inside the aquifer. Using effective precipitation instead can  
295 overcome this oversimplification and potentially avoid misinterpretation if one is particularly interested in the internal structure of the aquifer.

The effective precipitation was considered homogeneous for the entire study area whose spatial extension is relatively restricted. As with the weighting of the tritium input time series (see 3.1.3), their calculation relied on precipitation and temperature data recorded at the Findel airport weather station, which is less than 10 km away from each spring of Luxembourg  
300 City and whose elevation (368 m) is close to those of the spring recharge areas (see Fig. 2 and Table 1). As a reminder, the water balance leading to the effective precipitation calculation considers a soil model with a maximum water-holding capacity of 100 mm and the Thornthwaite's method (Thornthwaite, 1948) for estimating the potential evapotranspiration. Ultimately, we built a data set of 60 input time series for an effective precipitation accumulation period varying from 1 to 60 months.

### 3.2.4. Assessment of mean response times and uncertainty ranges

305 The cross-correlation analysis applied in groundwater studies typically considers multi-year time series data to characterize input-output relationships over the whole data period. An alternative moving window cross-correlation approach was recently proposed by Delbart et al. (2014) to assess temporal variability in response times. This increasingly used method (e.g., Cai and Offerdinger, 2016; Jeong et al., 2017; Le Duy et al., 2021) was initially set to reveal the seasonal variability of the response time of an aquifer to rainfall by using a relatively short sized moving window (Delbart et al., 2014). Here, we applied the cross-  
310 correlation in the same moving window framework, but used a larger window (i.e., 5-year long window and 3-month moving increment) to attribute to springs not only a unique MRT to precipitation input but also an uncertainty range. To do so, the

cross-correlograms between the multiple effective precipitation inputs and the discharge output for a given spring were first calculated for each moving window and the related MRT was defined as per section 3.2.1. Next, the results of individual moving windows were collected as an ensemble of possible solutions and summarised using standard percentile values (i.e., 5<sup>th</sup>, 25<sup>th</sup>, median, 75<sup>th</sup> and 95<sup>th</sup>).

### 3.3. Spring hydrochemistry

The chemistry of groundwater varies because of a wide range of natural and anthropogenic processes. Some hydrochemical variations are due to time-dependent water-rock interactions inside the aquifer and can be related to groundwater transit time (Purtschert, 2008). For instance, major ion concentrations are sometimes found to increase with increasing groundwater transit time (e.g., Edmunds and Smedley, 2000; Katz et al., 2004; Zuber et al., 2005; Edmunds and Shand, 2009), although these relationships may be of complex nature (Morgenstern et al., 2010).

Since late 2004, the springs of Luxembourg City are regularly sampled for hydrochemical analyses (Bohn et al, 2011; Gourdol et al., 2013;). Among the hydrochemical parameters available, major ion concentrations ( $\text{Ca}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ ,  $\text{HCO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ), as well as dissolved silica ( $\text{SiO}_2$ ), electrical conductivity ( $\text{EC}_{25^\circ\text{C}}$ ), dissolved oxygen ( $\text{O}_2$ ), and pH have previously been related to water-rock interaction processes occurring inside the Luxembourg Sandstone aquifer (Von Hoyer, 1971; Gourdol et al., 2013). In this study, we thus assessed the potential of these parameters for serving as geochemical proxies of groundwater transit times that might be used at sites where no tritium data is available.

Sampling methods and analytical details related to the acquisition of these data are described in Gourdol et al. (2013). As the spatial variability of the hydrochemistry of the springs of Luxembourg City is stable over time, both year-to-year and seasonally (Gourdol et al., 2013), the available data were aggregated into a single average value for each parameter and every of the 35 springs considered in this study.

## 4. Results

### 4.1. Tritium water dating

#### 4.1.1. Tritium in precipitation, recharge, and spring waters

Tritium analytical results for the investigated springs of Luxembourg City are reported in Table 2 and displayed in Fig. 4, together with the monthly and 1-year moving average tritium concentrations observed in precipitation at Trier, as well with the derived recharge input function.

Due to the mid-20th-century nuclear weapon tests, tritium in precipitation and recharge peaked at over 1000 TU in 1963 and then decreased progressively back to pre-bomb background level in recent years (Fig. 4a). We can notice that because precipitation is mostly effective in winter and rainfall tritium content is overall lower during this season, the tritium

concentration in the estimated recharge input function is most of the time significantly below that determined for yearly mean rainfall.

345 Tritium concentrations in spring waters average 5.42 TU and range from 4.31 to 7.13 TU during the observation period. They display a clear general downward trend (average decrease of about 0.25 TU per year), while measured precipitation and derived recharge tritium time series have been relatively stable for a decade disregarding seasonal variation (2010-2019 mean value of 8.39 and 6.75 TU, respectively; Fig. 4b), emphasizing the presence of bomb tritium in the Luxembourg Sandstone aquifer. As shown in Fig. 4c, springs belonging to the same recharge area are generally characterized by similar tritium contents. For instance, the highest tritium concentrations are typically associated with group B springs and the lowest ones to springs from groups KR D and KR G. Note that tritium contents in group G are more heterogeneous from one spring to another.

#### 350 4.1.2. Age simulation of spring waters

##### 4.1.2.1. EPM parameter space exploration

The assessment of spring mean transit times using the tritium recharge input function through the EPM model was done in two stages as illustrated in Fig. 5 for one of the investigated springs.

355 In a first step, a wide parameter space was explored with  $\tau_m$  ranging from 0 to 200 years and  $F$  between 0 and 1 (Fig. 5ab). An NSE threshold value of 0 was retained at this stage to define behavioural solutions. For every spring, one large subpopulation of solutions with  $\tau_m$  values greater than 35 years was easily discriminable. This subpopulation, whose mean  $\tau_m$  value varies between 64 and 98 years depending on the springs, can be confidently rejected as being unreasonably old given the characteristics of the aquifer, the discharge of the springs of Luxembourg City and the extension of their recharge areas. These  $\tau_m$  values would indeed have required groundwater levels to be too close to or even above the land surface (according to Eq. (4); see details in 4.1.3).

360 The parameter space was thus narrowed in a second step with  $\tau_m$  ranging from 0 to 35 years (bounds of 0 and 1 for  $F$  were kept; Fig. 5cd). A more stringent NSE threshold value of 0.5 was also retained for this screening. Modelling results of this second screening are provided for each spring in the Supplement (Fig. S1-S35). Owing to the short record of tritium measurements for every spring and despite the reduced parameter space combined with the more severe NSE threshold, the 365 5000 resulting behavioural solutions were not distributed around an unambiguous peak but spread into several overlapping subpopulations. To obtain a more coherent ensemble of solutions, we decided to keep only the most likely third of the behavioural solutions by relying on a 2D kernel NSE weighted density thresholding filter (Fig. 5c, Fig. S1a-S35a). For most springs, the remaining behavioural solutions were circumscribed in a single area of the parameter space. For cases with more than one population, we ultimately restricted the most likely behavioural solutions to the dominant one, i.e., both the best and 370 largest subpopulation. It is worth noting that in any case an ensemble of more than 1000 behavioural solutions was retained.

#### 4.1.2.2. Dating results

The retained ensembles of the most likely model solutions are summarized for every spring in Table S1 of the Supplement using standard percentile thresholds (i.e., 5<sup>th</sup>, 25<sup>th</sup>, median, 75<sup>th</sup> and 95<sup>th</sup>) and in Fig. 6 as violin and box plots. To facilitate the assessment of inter-spring variability, two additional scatter plots are presented in Fig. 7, i.e., the first relating  $F$  and  $\tau_m$  values and the second one  $\tau_{pf}$  and  $\tau_{exp}$  values.

Ranging from 0.68 to 0.93, NSE median values of the ensembles are on average 0.86 and above 0.8 for 31 of the 35 studied springs. This indicates an overall good agreement between modelled and measured tritium concentrations in spring waters. Predicted EPM parameters of springs are characterized by median values ranging from 0.46 to 0.97 for  $F$  and between 7.4 and 24 years for  $\tau_m$ . Considering the difference between their 95<sup>th</sup> and 5<sup>th</sup> percentiles bounds as a metric, the ensembles of most likely model solutions display a degree of uncertainty varying between 0.07 and 0.53 for  $F$  (mean 5-95<sup>th</sup> percentiles range of 0.29) and from 3.5 to 15.8 years for  $\tau_m$  (mean 5-95<sup>th</sup> percentiles range of 8.6 years).

Considering the quite large overlap between ensembles in the parameter space, the predicted EPM parameters show similar values for springs belonging to the same recharge area on the one hand, while they also highlight significant differences between spring groups on the other hand (Fig. 6-7).

Springs belonging to groups S, M and D are characterized with an exponential to total flow ratio  $F$  close to 0.7 (median values between 0.64 and 0.76) and relatively low  $\tau_m$  values (median values ranging from 7.6 to 10.9 years). Group B and P springs stand out with higher median values, spanning from 0.77 to 0.97 for  $F$  and between 14.1 and 19.3 years for  $\tau_m$ . Results obtained for group G are more heterogeneous, especially with respect to the mean transit time – the group indeed includes the spring with the lowest  $\tau_m$  median value (C05, 7.4 years) and the one with the highest (C01, 24 years) – but also regarding the  $F$  parameter (spring  $F$  median values range from 0.67 to 0.83). Finally, characterized by  $\tau_m$  median values ranging from 10.7 and 15.1 years, springs of the KRD and KRG groups are distinguishable from those located in other areas with particularly low  $F$  values (median values between 0.46 and 0.67), indicating a greater importance of the EPM piston component in this region. Note that it is eventually for the KRD and KRG groups that the highest  $\tau_{pf}$  median values are observed (up to 8.1 years).

Note that  $\tau_m$  median values characterizing the retained ensembles of EPM solutions correlated positively and significantly with spring mean tritium contents ( $r = 0.62$ ;  $p$ -value  $< 10^{-4}$ ). The correlation between spring mean tritium contents and  $\tau_{exp}$  median values is even stronger and more significant ( $r = 0.93$ ;  $p$ -value  $< 10^{-14}$ ).

#### 4.1.3. Groundwater volumes

The volumes of water  $V$  stored in the Luxembourg Sandstone aquifer that contributes to the discharge of spring groups have been estimated from Eq. (4) using the mean discharge values characterizing each recharge areas (Table 1) and the average of  $\tau_m$  median values (Table S1) of springs belonging to each group.

Considering the average of  $F$  median values (Table S1) of each group of springs, the calculated  $V$  volumes were subsequently split in  $V_{pf}$ , the part of the water volume associated to the EPM piston component ( $V_{pf} = (1 - F) * V$ ), and  $V_{exp}$ , the water volume stored in the EPM exponential section ( $V_{exp} = F * V$ ). For each recharge area  $S$  (Table 1) and assuming an overall  
405 porosity of 25 % for the Luxembourg Sandstone (which was set regarding the available porosity figures values available from the literature, cf. 2.1),  $V_{pf}$  and  $V_{exp}$  have been finally converted into mean equivalent sandstone layers required for the water storage in the saturated zone (assumed to match the exponential part of the EPM model;  $H_{exp} = V_{exp}/(S * 0.25)$ ) and the vadose zone (assumed to correspond to the EPM piston segment;  $H_{pf} = V_{pf}/(S * 0.25)$ ).

The obtained results are displayed in Fig. 8 as a bar plot in which  $H_{exp}$  and  $H_{pf}$  calculated values are overlaying the mean  
410 thickness of the Luxembourg Sandstone estimated for each recharge areas (Table 1). Overall, Fig. 8 indicates that the retained EPM solutions are physically valid whatever the recharge area. It should nevertheless be noticed that results obtained for group B appear less optimal compared to those of the other spring groups. Indeed, according to the figures, the void filling rate by water in the vadose zone would reach 65 % in this area, while elsewhere it ranges more realistically between 3 and 17 % (mean value of 10 %).

#### 415 4.2. Response time of spring discharge to effective precipitation input

Results of the spring discharge – effective precipitation cross-correlation analysis are reported for each spring in Table S2 of the Supplement through standard percentile values and displayed in Fig. 9 as violin and boxplots.

As indicated by correlation peak values, spring discharge correlates generally well with accumulated effective precipitation regardless of the considered spring (medians of maximum cross-correlation peak values range from 0.7 to 0.9 and average  
420 0.84; percentiles 5<sup>th</sup> and 95<sup>th</sup> are for most of the ensembles of solutions greater than 0.6 and 0.9, respectively). Whereas the maximum correlations are associated with widely varying extents of the cumulative effective precipitation window (median values of ensembles ranging from 4 to 37 months), observed correlation peak time lags are generally null or less than 4 months. The resulting MRT ensembles are characterized by median values spanning from 2 to 20 months and mean interquartile and 5-95<sup>th</sup> percentiles ranging from 8 to 18 months, respectively. The lowest MRT values are typically associated with group B  
425 springs and the highest ones to groups' KRD and KRG springs.

Finally, Fig. 10 compares the different spring discharge responses to the effective precipitation inputs according to their median MRT value. While springs with a median MRT lower than or equal to 10 months show a discharge dynamic characterized with a strong seasonal pattern, the ones with median MRT comprised between 10 and 15 months are characterized predominantly by interannual dynamics. The overall discharge dynamic of the springs with a median MRT equal to or greater  
430 than 15 months is even more damped and delayed compared to the monthly effective precipitation input function.

### 4.3. Spring hydrochemistry

Spring mean physicochemical characteristics are provided in Table S3 of the Supplement and presented in Fig. 11 as a heat map where dark red and dark blue tones denote the highest and lowest values for each parameter, respectively.

435 Springs belonging to the same recharge area generally have very similar characteristics. For instance, group B springs are typically the most mineralized, while those of group KRD count among the less enriched (Fig. 11). The observed mineralization of spring waters and their hydrochemical facies are in line with previous observations (Von Hoyer, 1971; Gourdol et al., 2013) and reflect the dissolution of the calcareous cement of the Luxembourg Sandstone and its composition, the weathering of the grains of quartz of the sandstone and the oxidation of pyrite disseminated in the rock matrix.

440 Note that  $\text{SiO}_2$ ,  $\text{Ca}^{2+}$ ,  $\text{HCO}_3^-$ ,  $\text{K}^+$ , total dissolved solids (TDS; sum of major ions and dissolved silica contents) concentrations and  $\text{EC}_{25^\circ\text{C}}$  measurements are strongly correlated with each other (minimum correlation  $r$  of 0.77). Due to second-order natural or anthropogenic factors (e.g., road salt inputs),  $\text{Na}^+/\text{Cl}^-$  and  $\text{Mg}^{2+}/\text{SO}_4^{2-}$  ratios are partly disconnected from the global enrichment of spring waters. It is finally worth considering that the observed depletion of  $\text{O}_2$  and pH with increasing mineralization is also linked to the water-rock interaction (i.e., due to the pyrite oxidation).

### 4.4. Comparison of tritium derived transit times with other spring characteristics

445 We tested the correlation of tritium derived transit times with other spring characteristics by applying a simple linear model. Although this analysis would not identify direct causalities and does not account for possible multi-collinearities, it should nevertheless help to shed new light on potential controls of mean transit times.

The parameters involved here are  $\tau_m$ ,  $\tau_{exp}$  and  $\tau_{pf}$  median values of the ensembles of EPM solutions (Table S1), mean groundwater flow lengths and Luxembourg Sandstone thickness of the recharge areas the springs are belonging to (Table 1), 450 the MRT median values characterizing the response time of spring discharge to effective precipitation input (Table S2), and the average values of hydrochemical parameters (Table S3).

Results are shown in Fig. 12 as a correlation matrix which indicates the sign (blue and red tones for positive and negative correlation, respectively), the strength (the darker the tone, the stronger the correlation and vice versa), and the significance of the linear correlation between each pair of parameters (a black square –  $p < 0.05$  – denotes a significant correlation and a white circle –  $p < 0.001$  – highlights a very significant one). 455

It can be observed that  $\tau_m$  and  $\tau_{exp}$  median values are in general correlated positively with the mineralization of the spring water and negatively with  $\text{O}_2$  and pH values. However, these correlations are most of the time weak ( $|r| < 0.3$ ) and not significant ( $p > 0.05$ ). Note that the linear correlation of  $\tau_{exp}$  median values with  $\text{HCO}_3^-$  ( $r = 0.42$ ),  $\text{Cl}^-$  ( $r = 0.38$ ),  $\text{Na}^+$  ( $r = 0.37$ ) and  $\text{SiO}_2$  ( $r = 0.34$ ) is nonetheless significant ( $p < 0.05$ ). The relationship relating the mean groundwater flow lengths of the recharge areas to  $\tau_{exp}$  median values is also statistically significant ( $r = 0.38$ ,  $p < 0.05$ ), while the one with  $\tau_m$  median values is not ( $r = 0.18$ ,  $p > 0.05$ ). As shown in Fig. 13a, we can further notice that the correlation between  $\tau_{exp}$  median values and the mean groundwater flow lengths at the scale of the recharge areas is characterized by an  $r$  value of 0.67. 460

Finally, the strongest positive and more significant correlations of tritium derived transit times with the other spring characteristics is shown in Fig. 12 for the EPM piston component. Indeed, the correlation of  $\tau_{pf}$  median values with the mean Luxembourg Sandstone thickness of the recharge areas and the MRT median values characterizing the response time of spring discharge to effective precipitation input are particularly strong ( $r = 0.57$  and  $0.60$ , respectively) and very significant ( $p < 0.001$ ). At the scale of recharge areas, the correlation of  $\tau_{pf}$  median values with the mean Luxembourg Sandstone's thickness and MRT is characterized by an  $r$  value of  $0.67$  and  $0.86$ , respectively (Fig. 13bc).

## 5. Discussion

The use of LPM for tritium-based water transit time studies of hydrological systems requires several aspects to be considered upfront (e.g., McGuire and McDonnell, 2006; Leray et al., 2016; Stewart and Morgenstern, 2016; Stewart et al., 2017). As described in section 3.1, we have pondered several methodological choices. For instance, the use of a soil water balance model to account for the variation over time of evapotranspiration water losses, combined with the proximity of the Trier Station to our study site, allowed us to assume a suitable characterization of the tritium recharge input signal. The spring samples were also taken at selected times to best consider for the steady-state assumption (although presuming stationarity for groundwater is in general less critical than for stream water), and their analysis was carried out with high-accuracy methods for minimizing the potential impact of tritium analytical errors on modelling results (Stewart et al., 2012; Gallart et al., 2016).

The tritium output data record length is of particularly critical importance to the characterization of hydrological systems in the Northern Hemisphere. While a single tritium sample can be sufficient in the Southern Hemisphere, the use of time series with several measurements remains a prerequisite in the Northern hemisphere for an unequivocal dating of hydrological systems (Stewart and Morgenstern, 2016). This problem may be tackled by valuing sites for which past tritium measurements are available (e.g., Stolp et al., 2010; Blavoux et al., 2013; Jerbi et al., 2019). Here, we have explored the potential for the sole use of recent high-accuracy tritium data to date groundwater. We did eventually rely on time series, but of minimal length (as a reminder, time series of 3 samples taken every  $\sim 2$  years). In this context, we did not use a standard best-fit calibration approach as is most commonly done, but followed the advice of Gallart et al. (2016) to use a modelling framework combining a resampling procedure associated with the GLUE approach (Beven and Binley, 1992, 2014). This approach delivers dating results together with uncertainty ranges reflecting the EPM parameter identifiability issue arising jointly from the low number of spring samples and the tritium analytical errors. Easy to implement and conceptually simple, GLUE is one of the most widely used methods for uncertainty assessment of hydrological models (Moges et al., 2021). However, it is important to note that its subjectivity can be criticized for the choice of the behavioural threshold, the number of sample simulations and their potential impact on the results (Li et al., 2010). Other alternative techniques could have been used, such as a Bayesian inference framework (e.g., Thiros et al., 2023), but the results would probably have been comparable (e.g., Li et al., 2010; Dotto et al., 2012).

First of all, our findings show that the short spring tritium data time series, even though of high-accuracy, did not allow direct unambiguous dating results. Indeed, even after restricting the mean transit time  $\tau_m$  to 35 years maximum to rule out the unlikely oldest solutions considering the hydrogeological context of the study area, the behavioural parameter sets resulting from the random exploration of the focused EPM parameter space still did not define an unambiguous set of solutions, and this for each spring and despite the more stringent NSE threshold of 0.5. This led us to apply an additional 2D kernel NSE weighted density thresholding filter to conserve the *a priori* most likely solutions and tend towards what we assumed to be the more coherent ensembles of parameter sets. Overall, the NSE figures characterizing these ensembles of most likely solutions (i.e., NSE median values ranging from 0.68 to 0.93 and averaging 0.86) indicate a good match between modelled and observed tritium data. As observed in Fig. S1-S35 and summarized in Fig. 14, the simulated spring tritium concentrations are consistent with the tritium measurements of spring samples, their downward trends, as well as with their analytical errors. Finally, it is worth noting that a few older tritium data are available for the investigated springs of group KRD (Farlin et al., 2013a, 2013b, 2017). Covering the 2008-2012 period, these data are out of the specific scope of this work because of their lower accuracy ( $1\sigma$  average analytical error of 0.52 TU), hence they were not directly used for the modelling. Included in Fig. S16-S24, we can nonetheless observe that they fit well with the simulation ensembles and therefore represent to some extent an additional consolidating argument for the consistency of the obtained tritium dating results.

Although necessary, the consistency of the results with the tritium measurements is however not sufficient as it does not guarantee their correctness, particularly if the selected model does not adequately characterize the water flow field (Leray et al., 2016; Stewart et al., 2017). Here, we opted for the EPM because of its potential to simulate for unconfined aquifers both the water flowing through the vadose zone (i.e., with the EPM piston segment), as well as the mixing of groundwater flowlines coming from the saturated zone at the outlet of the system (i.e., mimicked by the EPM exponential section; Jurgens et al., 2012). Even if assessing the validity of the LPM selection is not straightforward (Leray et al., 2016), two key aspects of the findings nevertheless support the EPM choice here. First, the dating results retained *in fine* appear overall physically plausible when translated into equivalent sandstone heights (Fig. 8) using the rational average characteristics of the Luxembourg City spring recharge areas (i.e., outflowing discharge, impluvium, sandstone thickness, porosity). Secondly, the significant and consistent correlations found between  $\tau_{pf}$  and  $\tau_{exp}$  with several other characteristics describing the vadose and saturated zone of the Luxembourg Sandstone aquifer (Fig. 12) are also strongly supporting the choice of the EPM model. Indeed, while no straightforward significant correlation of  $\tau_m$  values with the other characteristics could be observed, several did appear when  $\tau_{pf}$  and  $\tau_{exp}$  were regarded separately.

Considering the full thickness of the Luxembourg Sandstone as a proxy for the thickness of its unsaturated zone, the very significant correlation highlighted in Fig. 12 between  $\tau_{pf}$  values and the Luxembourg Sandstone thickness means estimates of each group of springs is a first element that supports the ability of the EPM piston segment to deliver plausible transit times characterizing the percolation of water through the vadose zone of the aquifer. The Luxembourg Sandstone thickness –  $\tau_{pf}$  relationship presented at the scale of the recharge area in Fig. 13b indicates, however, that group KRD springs deviate overall

from the general behaviour with particularly high  $\tau_{pf}$  values. A possible explanation for this specific behaviour is the known presence of a marly layer intercalated in the Luxembourg Sandstone formation in the KRD area (thanks to an observational borehole drilled there; Farlin et al., 2013a). A second argument that supports the EPM piston component's potential for adequately reproducing the transit times required for infiltrating water to cross the vadose zone is the highly significant correlation of  $\tau_{pf}$  values with response times of spring discharge deduced from the cross-correlation analysis (i.e., MRT values; Fig. 12 and Fig. 13c). Such cross-correlation time series analysis of response times to effective precipitation inputs have indeed been related to the characteristics of the unsaturated zone for several other unconfined aquifers (e.g. Lee and Lee, 2000; Lee et al., 2006; Fiorillo and Doglioni, 2010; Bloomfield and Marchant, 2013; Bloomfield et al., 2015; Al-Jaf et al., 2021). As shown in Fig. 15, it is worth noting that the MRT -  $\tau_{pf}$  relationship seems linear, but not one-to-one. MRT values are in general almost four times lower than  $\tau_{pf}$  ones. A potential explanation for this difference is that MRT would reflect water celerity, i.e., the speed at which the water infiltration signal is transmitted through the vadose zone to the springs, while  $\tau_{pf}$  relate to water velocity, i.e., the movement of water molecules (McDonnell and Beven, 2014; Scaini et al., 2017; van Verseveld et al., 2017; Shao et al., 2018; Worthington and Foley, 2021).

Although none of the studied physicochemical parameters were highlighted as a direct reliable proxy of water transit times in the Luxembourg Sandstone aquifer, the global correlation pattern of  $\tau_{exp}$  with the hydrochemistry of the spring waters (Fig. 12) suggests an overall progressive mineralization of groundwater with increasing flow path length in the saturated zone. The significant correlation between  $\tau_{exp}$  values and the average groundwater flow lengths estimated for each of the recharge areas also allows the exponential component of the EPM model to be related to the saturated zone of the aquifer (Fig. 12). It should nevertheless be noticed that the average groundwater flow length characterizing the recharge area of group B seems overall relatively short compared to the relatively large  $\tau_{exp}$  values that have been calculated for the springs that drain it (Fig. 13a). This inconsistency, which has already been raised indirectly when translating the tritium dating results into equivalent sandstone heights (see 4.1.3 and Fig. 8), could however be due to an incorrect estimate of the impluvium of this group of springs and would therefore not reflect a problem with the tritium-EPM derived dating results. It is moreover worth noting that a previous study (Luxconsult, 1992) estimated the recharge area of Group B springs (shown in Gourdol et al., 2013) to be twice as large as the one newly defined (RGD, 2021b) – a discrepancy that we have not yet been able to explore further.

To conclude on the reliability of the tritium dating results obtained in this study, a rough assessment of water velocities in the vadose and saturated zones of the aquifer can be undertaken. First, we can assume that the EPM piston and exponential components reflect well the water flowing through the vadose zone and the mixing of groundwater flowlines coming from the saturated zone at the outlet. Second, by dividing  $\tau_{pf}$  and  $\tau_{exp}$  values by the mean values of the vadose zone thickness and the groundwater flow length in the saturated zone respectively, we can approach water velocities in these two specific compartments of the Luxembourg Sandstone aquifer. Conducted at the scale of the recharge area (using the average of  $\tau_m$  and  $F$  median values (Table S1) of each group of springs, mean groundwater flow lengths and Luxembourg Sandstone thicknesses reported in Table 1, and  $H_{exp}$  values as defined in section 4.1.3), this assessment leads to very close figures from one area to

560 another (excluding group B results, whose impluvium was previously questioned). Ranging from  $1.9 \times 10^{-7}$  to  $5.5 \times 10^{-7}$  m/s,  
the water velocity determined for the vadose zone is on average  $3.7 \times 10^{-7}$  m/s. About an order of magnitude higher in all cases,  
the water velocity assessed for the saturated zone ranges from  $4.0 \times 10^{-6}$  to  $8.7 \times 10^{-6}$  m/s and reaches  $5.4 \times 10^{-6}$  m/s on average.  
While one might have expected an inverse relationship between vadose and saturated zone velocities for an isotropic aquifer,  
this tritium derived ratio is also consistent with the anisotropy of hydraulic properties characterizing sandstones. Several studies  
565 focusing on the characterization of the permeability anisotropy have indeed shown that horizontal permeability of sandstones  
is greater than their vertical permeability, and this up to several orders of magnitude (e.g., Hitchmough et al., 2007; Clavaud  
et al., 2008; Goupil et al., 2022). The characterization of the horizontal-vertical anisotropy of the hydraulic properties of the  
Luxembourg Sandstone may require further attention in future studies. This kind of data, associated with other existing datasets  
(e.g., Meus and Willems, 2021), could then be used to feed a physically-based 3D model (e.g., Paradis et al., 2018) that would  
570 more accurately represent the multi-scale complexity of the Luxembourg Sandstone bedrock aquifer (Worthington, 2015). The  
comparison of the output from such a model with that resulting from this study would allow to assess the predictive capacities  
– for instance for pollutant contamination mitigation purposes – of the tritium based LPM approach used here (Eberts et al.,  
2012; Yager et al., 2013; Marçais et al., 2015; Balvin et al., 2021).

## 6. Conclusion

575 We have presented a new set of 105 high-accuracy tritium analyses, carried out on water samples collected three times at  
intervals of  $\sim 2$  years for 35 springs, each of them fed by the Luxembourg Sandstone aquifer. We leveraged these short but  
high-accuracy tritium content time series to investigate the potential of the tritium dating technique to inform on young  
groundwater transit times in the Northern Hemisphere at new study sites where no historical tritium data is available.  
Groundwater mean transit times have been assessed using the LPM approach in a modelling framework, delivering uncertainty  
580 ranges inherent to the low number of tritium data at hand and their analytical errors.

Our results show first that unambiguous groundwater mean transit time estimations solely based on recent short tritium content  
time series are not possible, as several ranges of mean transit times appeared as plausible. Nonetheless, we succeeded through  
a stepwise decision process to discriminate for every spring an ensemble of most likely solutions, consistent with both the  
tritium measurements and the overall hydrogeological context of our area of interest. This assessment was possible thanks to  
585 several independent supplementary data, as well as the large number of investigated springs and their varying characteristics.  
Our work has demonstrated the suitability of the EPM model to assess groundwater mean transit times (through the vadose  
and saturated zones of the Luxembourg Sandstone aquifer) from high-accuracy tritium analyses of spring water samples. Our  
understanding of the water transit times in the Luxembourg Sandstone aquifer has ultimately been improved. Furthermore, our  
results suggest a key role of the horizontal-vertical permeability of the sandstone that deserves further investigations in the  
590 near future.

### **Code and data availability**

The R (R Core Team, 2022) scripts and data used to achieve this study will be archived in an online repository and the DOI will be included in the final published version of the paper.

### **Author contributions**

595 LG conceptualized the study with guidance from MKS, UM and LP. LG implemented the field and modelling work, conducted the data analysis and wrote the first draft of the paper. All the co-authors (LG, MKS, UM, and LP) contributed to and edited the manuscript.

### **Competing interests**

600 A co-author is a member of the editorial board of Hydrology and Earth System Sciences journal. The peer-review process was guided by an independent editor, and the authors have also no other competing interests to declare.

### **Acknowledgements**

This research work spined of a long-term public–public collaboration between the LIST and the City of Luxembourg. We especially thank the Water Service of Luxembourg City for their continuous and highly valuable support. We thank the LIST colleagues Cyrille Tailliez and Jérôme Juilleret for their help during the field work, François Barnich for the hydrochemical analyses, Renaud Hostache and Davide Zoccatelli for fruitful discussions about the modelling aspect of this work, and the technical staff of the GNS Tritium & Water Dating Laboratory for the tritium analyses. The authors are also deeply grateful to Francesc Gallart for providing access to the code of the modelling framework implemented in Gallart et al. (2016).

### **Financial support**

610 The spring discharge and hydrochemical data used in this study was jointly funded by the LIST and the City of Luxembourg, the spring tritium data was funded by the LIST.

**Figure 1.** Pictures of the Luxembourg Sandstone (modified from the proceedings of the 2nd international conference on sandstone landscapes, Vianden, Luxembourg, 25-28/05/2005; Ries and Krippel, 2005) with (a) sandstone outcrop in the Mullerthal area (photo taken by Jiri Adamovic during the pre-conference excursion), (b) sandstone outcrop in the Pétrusse valley in Luxembourg City (Faber and Weis, 2005), (c) optical microscope image of a well cemented sandstone sample under natural light (Colbach, 2005), (d) outcrop showing an alternation of carbonate rich, whitish, sandy limestone and carbonate poor, yellowish sandstone (Colbach, 2005), (e) fresh roadcut showing a closely fractured carbonate-rich bed (Colbach, 2005), (f) roadcut showing a wide open fracture (Colbach, 2005).

### Outcrop area of the Luxembourg Sandstone

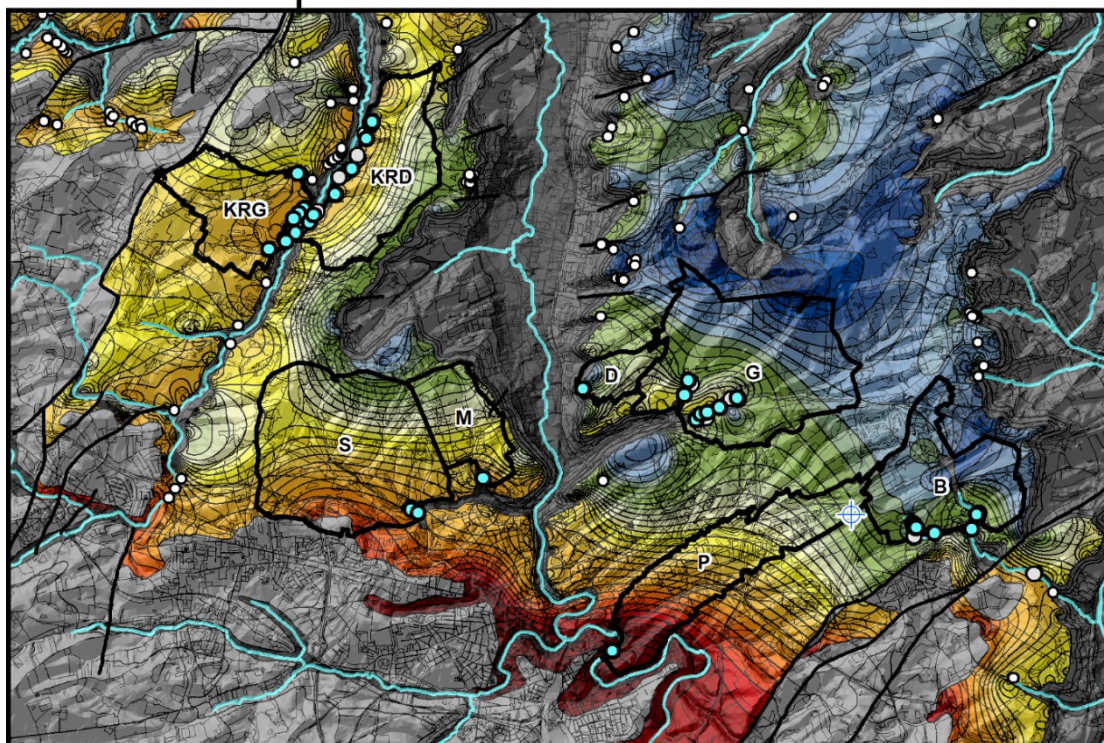

- Meteorological station
- Major rivers

### Hydrogeological context

- Luxembourg Sandstone springs
- Springs of Luxembourg City
- Investigated springs
- Approximative recharge areas

- Faults
- Alluvial material
- Marls and limestones
- Luxembourg Sandstone
- Marls, clay and sandy marls

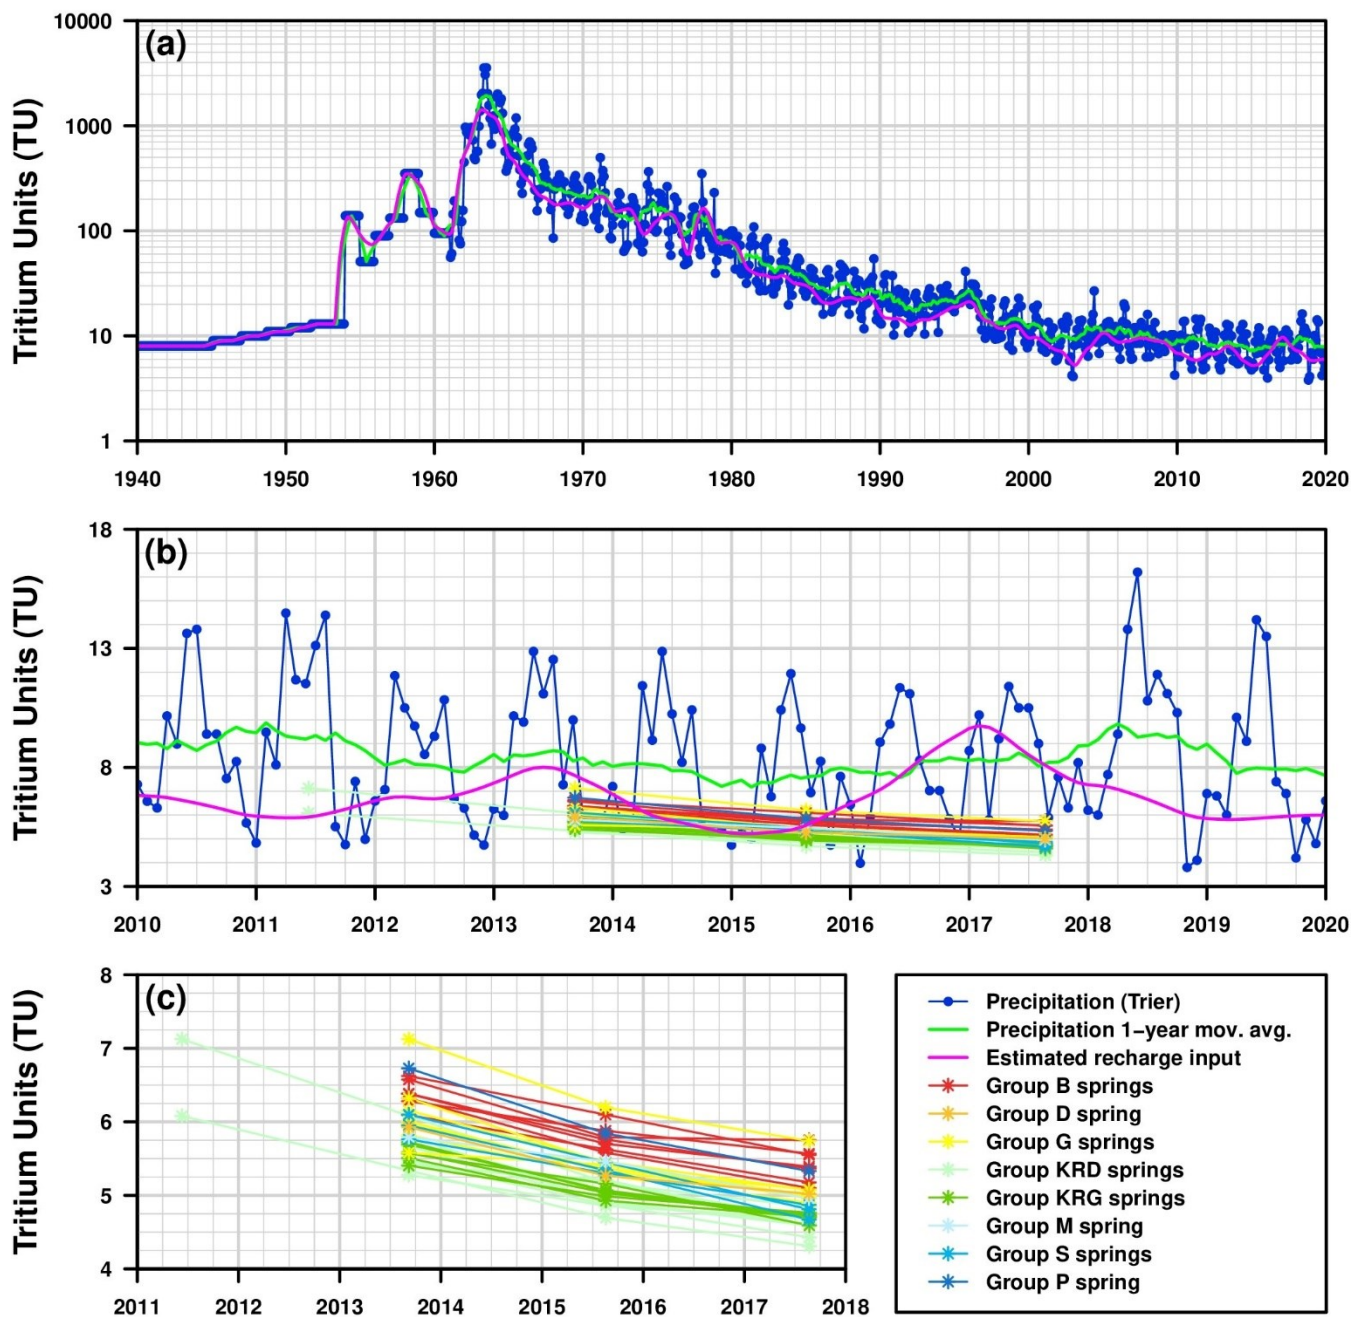

Elevation of the base of the Luxembourg Sandstone aquifer (m)

990 **Figure 2.** Geological and hydrogeological settings of the study area.

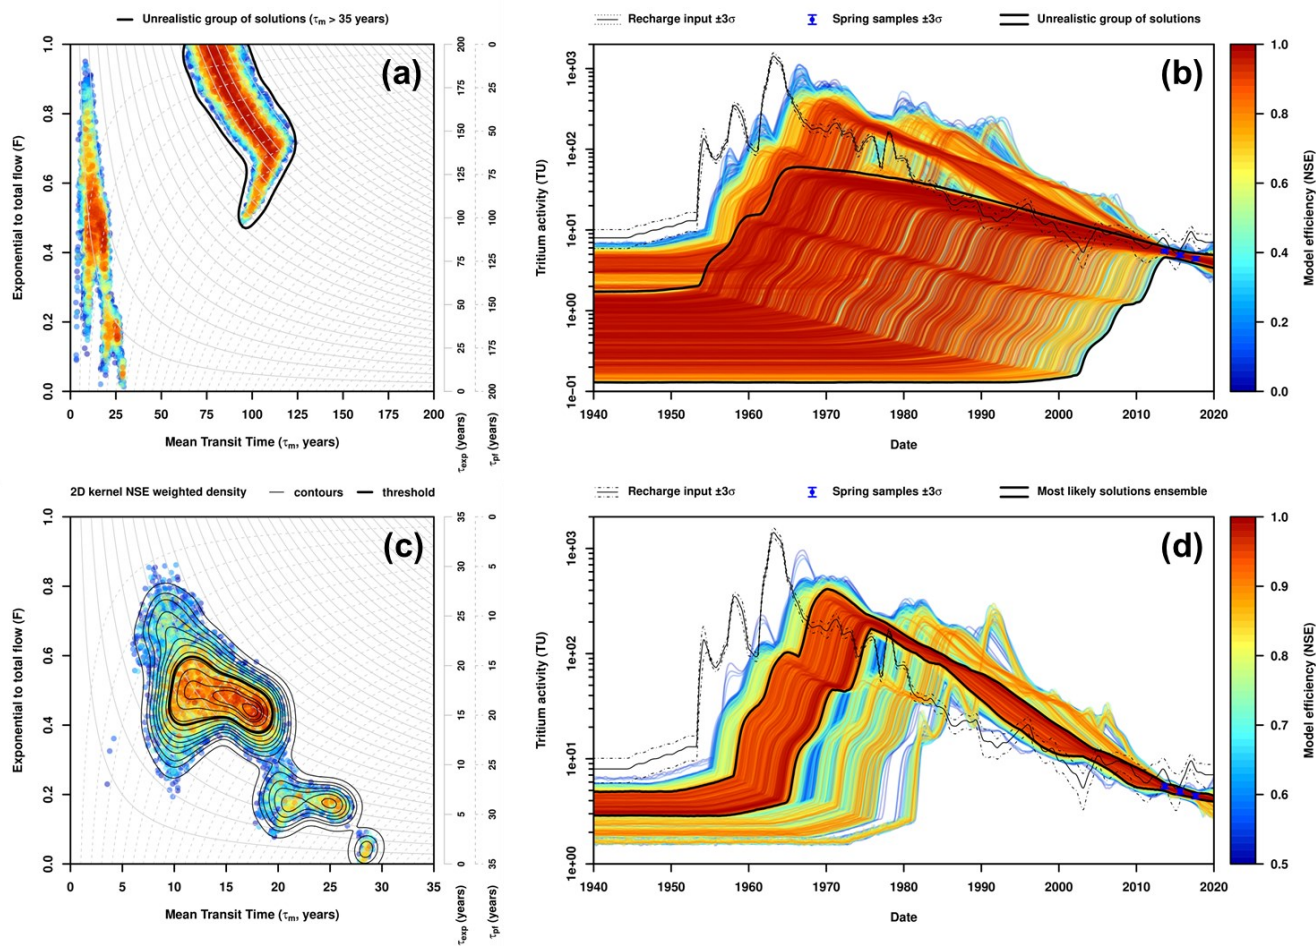

995 **Figure 3.** Conceptual diagram of the functioning of the Luxembourg Sandstone unconfined aquifer summarizing bibliography-derived information (adapted from a sketch of Raymond Rouch representing a karstic aquifer published in Mangin, 1975).

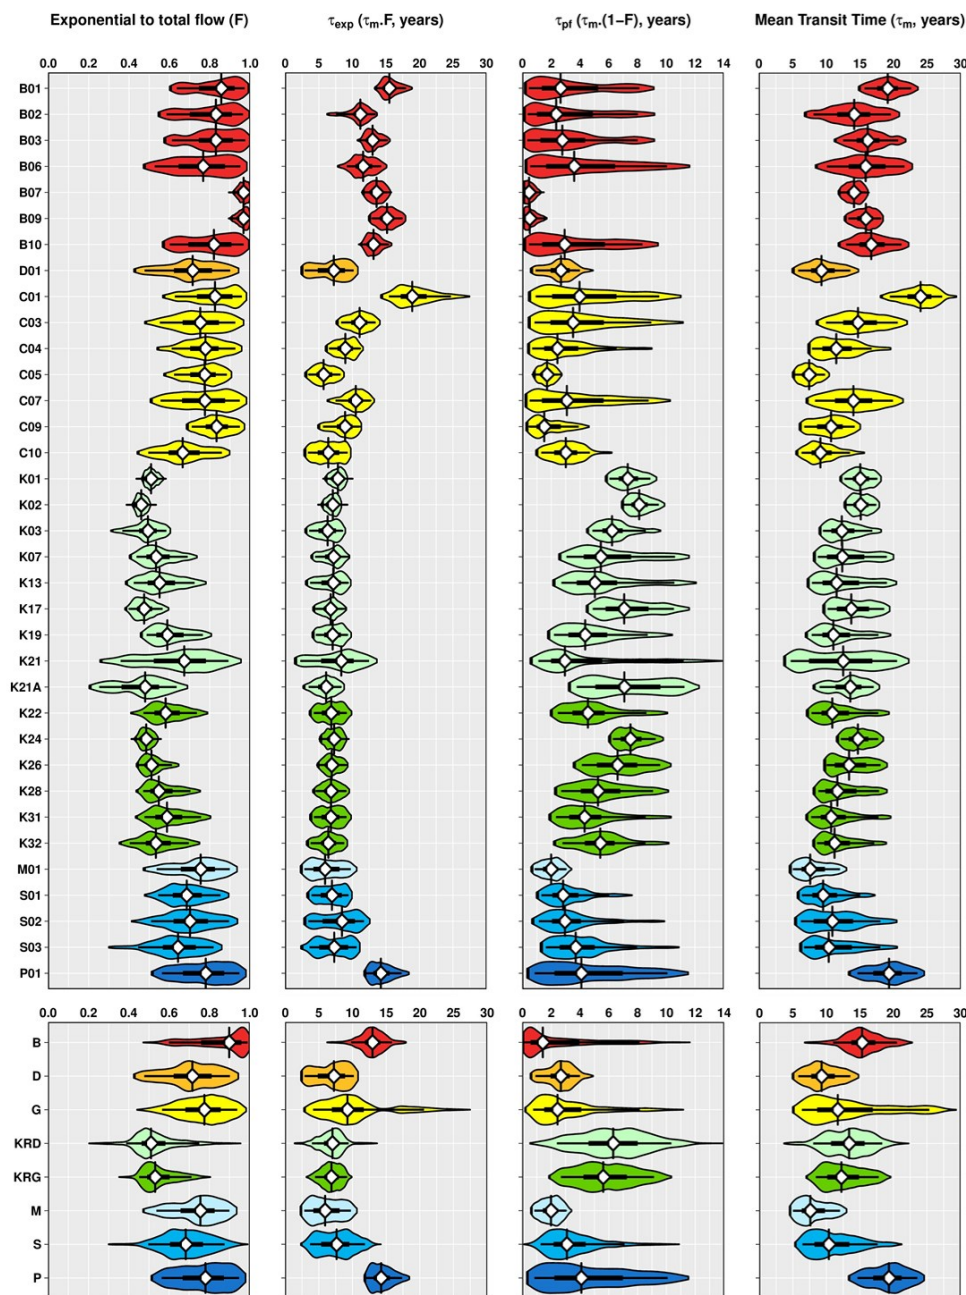

1000 **Figure 4.** Tritium concentration in (a, b) precipitation, recharge, and (b, c) investigated springs of Luxembourg City (a) from 1940 to 2020 with a log scale, and (b) from 2010 to 2020 and (c) 2011 to 2018 with a linear scale.

Figure 5

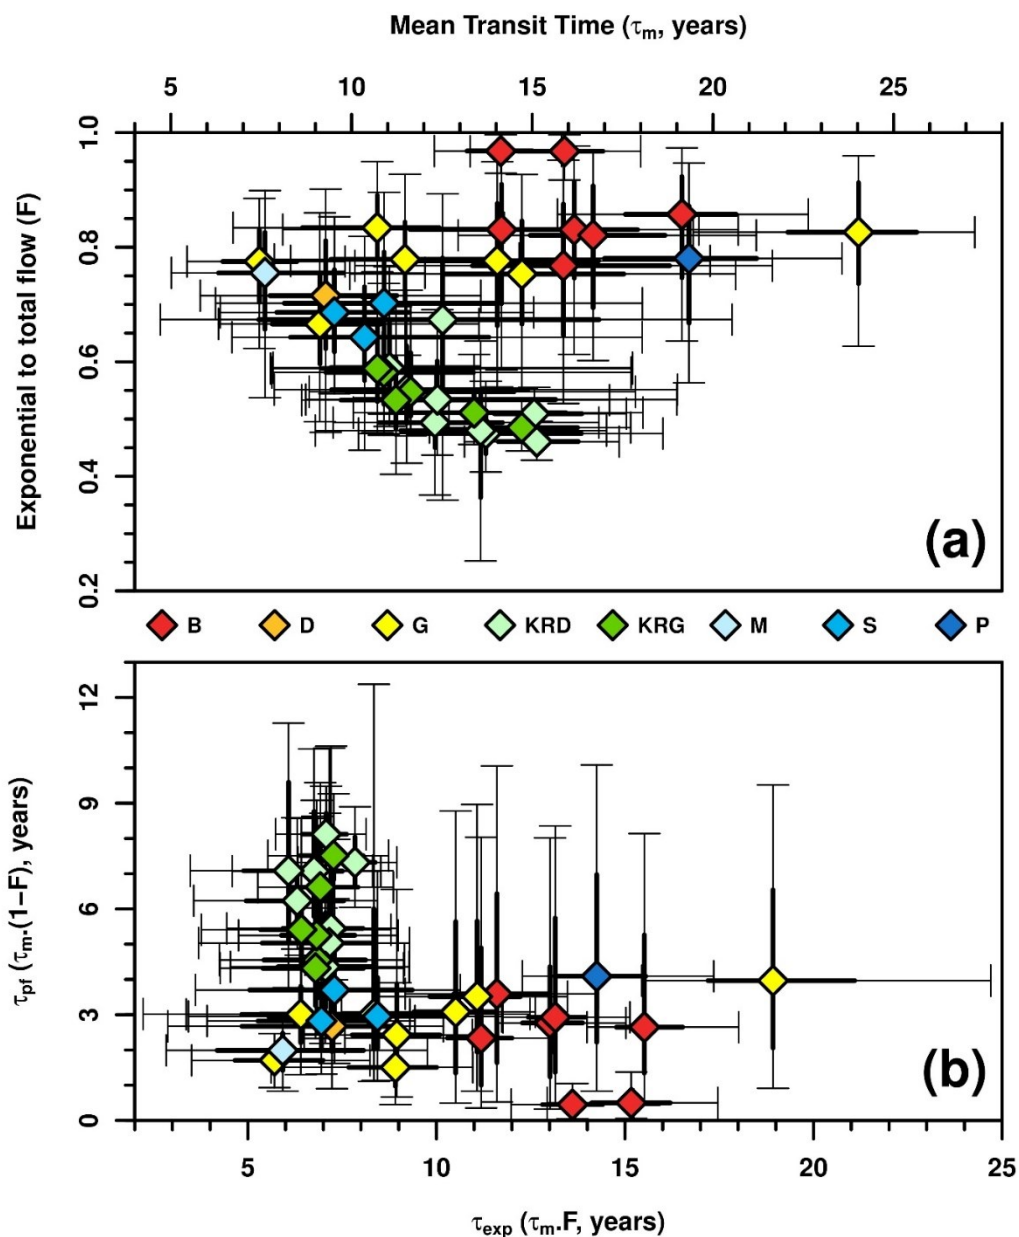

1005 **Figure 5.** Modelling results of spring K17 in the EPM parameter space (a, c) and associated modelled tritium time series (b, d) for the first (a, b) and the second (c, d) screening stages.

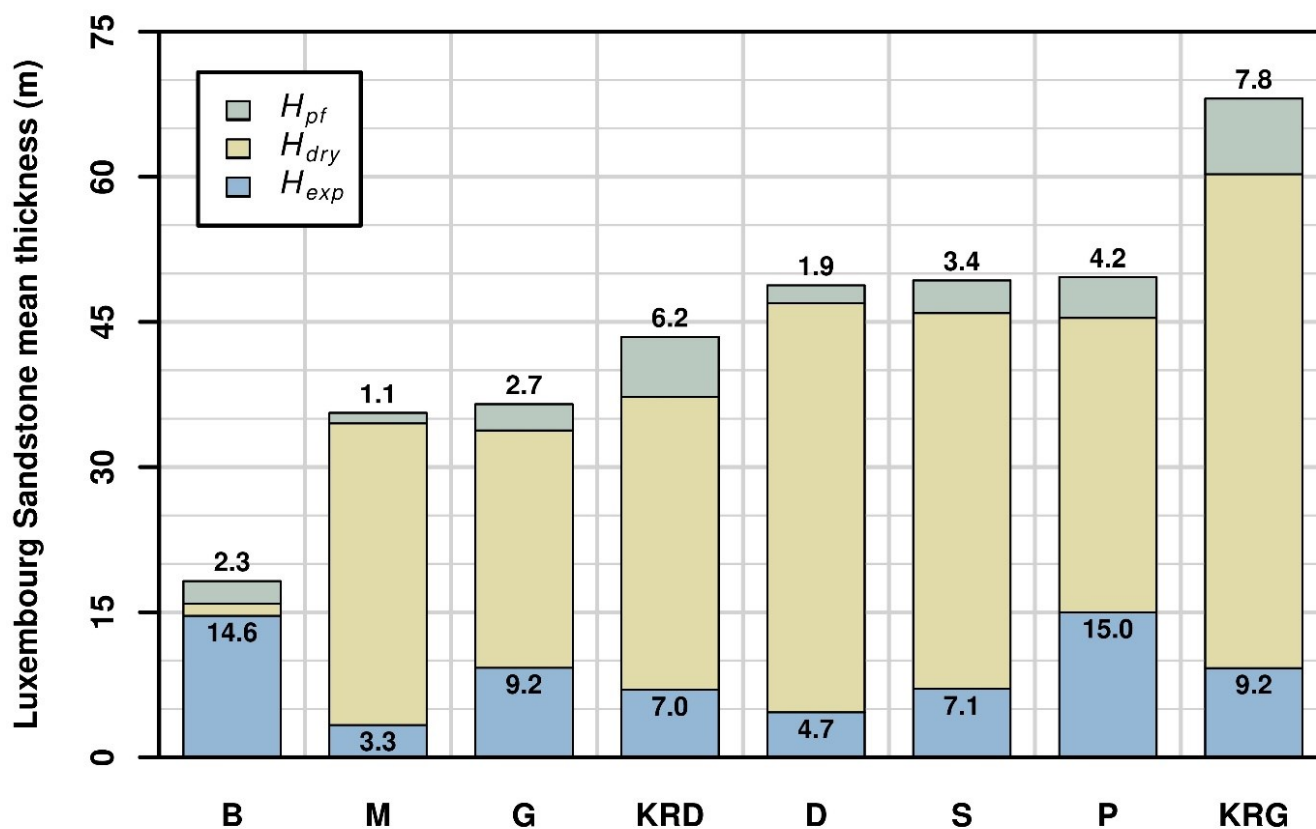

1010 **Figure 6.** Violin plot with boxplot overlay representation of the ensembles of most likely EPM model solutions retained for each spring (upper panels) and by group of springs from the same recharge area (lower panels). The violin plot lines correspond to a kernel density of the distribution (i.e., a smoothed histogram). The violin plot fill colors allow to discriminate the different groups of springs. The white diamond shape with the vertical line indicates the median of the distribution. The horizontal thick and thin lines represent the interquartile and 5-95<sup>th</sup> percentile ranges of the distribution, respectively.

1015

1020 **Figure 7.** Scatter plots relating (a)  $F$  to  $\tau_m$  and (b)  $\tau_{pf}$  to  $\tau_{exp}$  values of the ensembles of most likely EPM model solutions retained for each spring. The diamond shape indicates the median of the distribution. The diamond shape fill colors allow to discriminate the different groups of springs. The thick lines and bounded thin lines represent the interquartile and 5-95<sup>th</sup> percentile ranges of the distribution, respectively.

1025 **Figure 8.** Transit time derived mean sandstone layers required for the water storage in the saturated zone (assumed to match the exponential part of the EPM model;  $H_{exp}$ ) and the vadose zone (assumed to correspond to the EPM piston segment;  $H_{pf}$ ) overlaid to the mean thickness of the Luxembourg Sandstone estimated for each recharge areas.

1030

**Figure 9.** Violin plot with boxplot overlay representation of the ensembles of solutions resulting from the spring discharge – effective precipitation cross-correlation analysis for each spring (upper panels) and by group of springs from the same recharge area (lower panels). The violin plot lines correspond to a kernel density of the distribution (i.e., a smoothed histogram). The violin plot fill colors allow to discriminate the different groups of springs. The white diamond shape with the vertical line indicates the median of the distribution. The horizontal thick and thin lines represent the interquartile and 5-95<sup>th</sup> percentile ranges of the distribution, respectively.

1035

1040 **Figure 10.** Effective precipitation and spring discharge dynamics with (a) monthly effective precipitation, and (b) standardized discharge time series for springs with a median MRT less than or equal to 10 months, (c) in between 10 and 15 months and (d) greater than or equal to 15 months. In (b-d) the colored thick solid line correspond to the median value of the ensemble of spring discharge time series, while darker and lighter colored shaded area correspond to their interquartile and 5-95<sup>th</sup> percentile envelopes, respectively.

1045

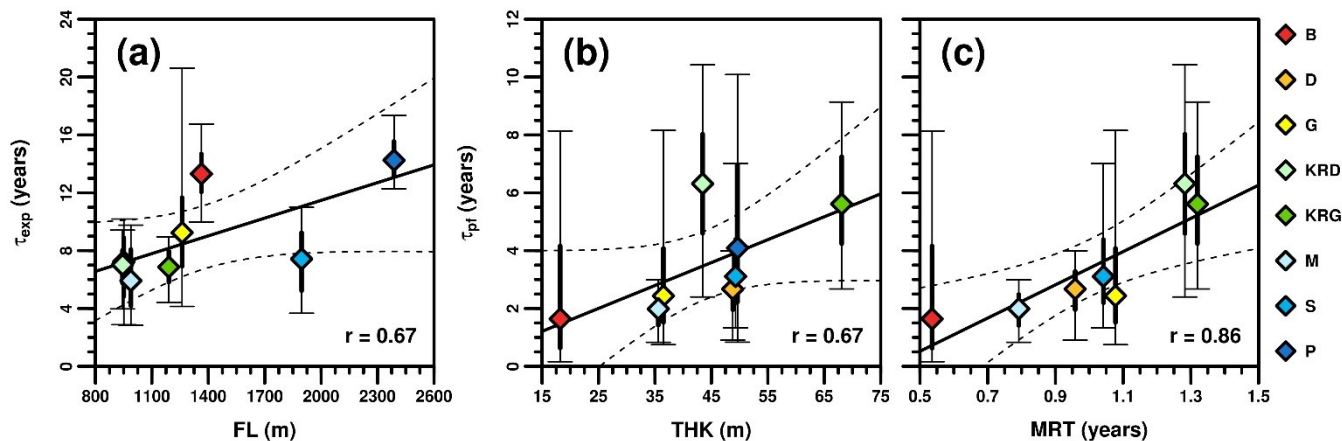

**Figure 11.** Heat map of the average physicochemical characteristics for the investigated springs. Springs and parameters were classified and grouped using a hierarchical cluster analysis (distance measure: Euclidean distance, linkage rule: Ward's method). Prior to the analysis, data were first log-transformed and then each parameter was standardized. According to the dendrograms and the visual inspection of the heat map, 4 clusters of springs and 4 clusters of parameters were emphasized in the figure.

1050

1055

**Figure 12.** Linear correlation (Pearson's  $r$ ) of tritium derived transit times ( $\tau_m$ ,  $\tau_{exp}$  and  $\tau_{pf}$  median values of the ensembles of EPM solutions; black labels) with the other springs characteristics, i.e. the hydrochemical parameters average values (red labels), the estimated mean groundwater flow lengths (FL) and the mean Luxembourg Sandstone thickness (THK) of the recharge areas (green labels), and the MRT median values characterizing the response time of spring discharge to effective precipitation input (blue label). A black square denotes a significant correlation ( $p$ -value  $< 0.05$ ), while a white circle highlights a very significant one ( $p$ -value  $< 0.001$ ).

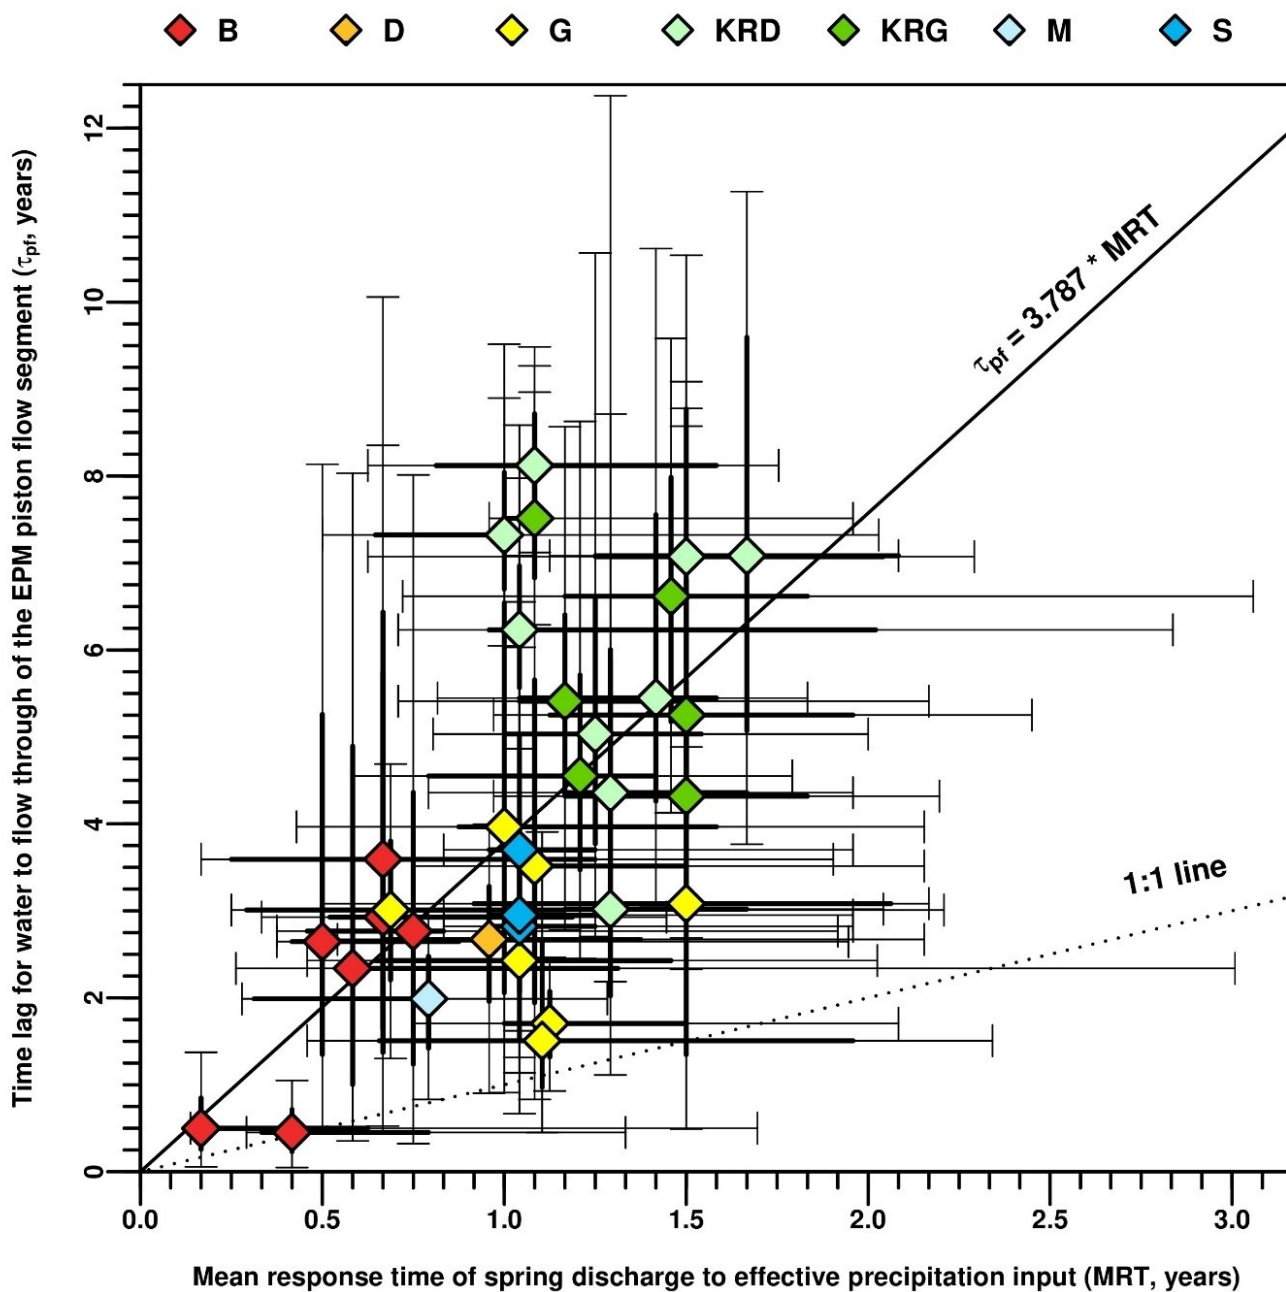

1060

**Figure 13.** Scatter plots relating at the recharge area scale (a)  $\tau_{exp}$  median values of the EPM ensembles to the groundwater flow length (FL),  $\tau_{pf}$  median values of the EPM ensembles to (b) the mean Luxembourg Sandstone thickness (THK) and (c) the average of the MRT median values characterizing the response time of spring discharge to effective precipitation input. The dashed lines represent the 95% confidence intervals of the regression thick lines. The vertical thick and bounded thin lines represent the interquartile and 5-95<sup>th</sup> percentile ranges of  $\tau_{exp}$  or  $\tau_{pf}$  values distributions, respectively.

1065

1070 **Figure 14.** Comparison between observed and EPM simulated concentrations in tritium for the 35 investigated springs of Luxembourg City (N samples = 105). The root-mean-square error between the observed and average simulated concentrations (colored circles) is 0.11 TU. The min-max range of the simulated concentrations (vertical bounded thin lines) and the  $\pm 3\sigma$  range of the measured concentrations (horizontal bounded thin lines) average 0.69 and 0.54 TU, respectively.

1075

**Figure 15.** Scatter plot relating for each spring  $\tau_{pf}$  values of the ensembles of most likely EPM model solutions to MRT values of the ensembles resulting from the effective precipitation – spring discharge cross-correlation analyses. The diamond shapes indicate the medians of the distributions, and their fill colors allow to discriminate the different groups of springs. The thick lines and bounded thin lines represent the interquartile and 5-95<sup>th</sup> percentile ranges of the distributions, respectively.
