13 (Zongxing Li).

14 **Abstract:** Amid global warming, the timely supplementation of soil water  
15 is crucial for the effective restoration and protection of the ecosystem. It is  
16 therefore of great importance to understand the temporal and spatial  
17 variations of soil water sources. The research collected 2451 samples of  
18 soil water, precipitation, river water, ground ice, supra-permafrost water,  
19 and glacier snow meltwater were collected in June, August, and September  
20 2020. The goal was to quantify the contribution of various water sources to  
21 soil water in the Three-Rivers Headwater Region (China) at different

22 ablation periods. The findings revealed that precipitation, ground ice, and  
23 snow meltwater constituted approximately 72%, 20%, and 8% of soil water  
24 during the early ablation period. The snow is fully liquefied during the  
25 latter part of the ablation period, with precipitation contributing  
26 approximately 90% and 94% of soil water, respectively. These recharges  
27 also varied markedly with altitude and vegetation type. The study  
28 identified several influencing factors on soil water sources, including  
29 temperature, precipitation, vegetation, evapotranspiration, and the freeze-  
30 thaw cycle. However, soil water loss will further exacerbate vegetation  
31 degradation and pose a significant threat to the ecological security of the  
32 “Chinese Water Tower.” It emphasizes the importance of monitoring soil  
33 water, and addressing vegetation degradation related to soil water loss, and  
34 determining reasonable soil and water conservation and vegetation  
35 restoration models.

37 Headwater Region

38

## 39 **1. Introduction**

40 Soil water is an important water resource, forming a link between  
41 precipitation, surface water, and groundwater, and is an essential  
42 component in the formation, transformation, and consumption of water  
43 resources. It substantially impacts regional water resource distribution

44 patterns, the ecosystem, and river runoff as key factors in terrestrial  
45 hydrological cycles and environmental succession (Gao et al., 2017;  
46 Sazibet et al., 2020; Hai, 2020; Liu et al., 2023). Soil water plays a  
47 fundamental role in controlling the exchange of water and heat between the  
48 land surface and atmosphere, which has been widely applied to study  
49 regional microclimates, energy, and material balance, and global climate  
50 change (Spennemann et al., 2017; Sprenger et al., 2017; Lin et al., 2023).  
51 Moreover, soil water is directly involved in physiological activities and  
52 promotes productivity and carbon sequestration capacity. It is sensitive to  
53 the interactions between soil and vegetation that alters soil  
54 physicochemical properties, internal structures, and material composition  
55 (Marchionni et al., 2021). Consequently, soil water sources can be affected  
56 by many factors, such as climate, vegetation, soil type, and topography  
57 (Martinez Garcia et al., 2014; Sun et al., 2023). Understanding the spatial-  
58 temporal changes in soil water sources is essential for better protection of  
59 water and the environment. Thus, studying soil water sources has become  
60 a hot topic in international hydrology and soil science.

61 Research on soil water has progressed in a series of studies related to  
62 hydro-meteorological, hydro-climatological, ecological and  
63 biogeochemical processes. Permafrost can affect inter-annual changes in  
64 soil water, and its degradation, including the increasing active layer  
65 thickness and disappearance, would decrease ecosystem resilience (Liu et

66 al., 2021; Zachary et al., 2013). Soil water has also been extensively studied  
67 in the Three-Rivers Headwater Region (TRHR) (Li et al., 2020; Wang et  
68 al., 2012; Song et al., 2019). Cao and Jin (2021) analyzed the distribution  
69 characteristics of soil water and its relationship with temperature and  
70 precipitation in the TRHR. Precipitation has a more pronounced impact on  
71 soil water in the alpine steppe compared to the alpine meadow, particularly  
72 in lower-altitude areas (Li et al., 2022). Chen et al. (2021) constructed the  
73 spatial-temporal changes in soil water and its influencing factors from 2003  
74 to 2020. Huang et al. (2022) studied the variation of surface soil water in  
75 an alpine meadow with different degradation degrees in the study region.  
76 Xing et al. (2016) analyzed the groundwater storage changes and their  
77 influence on soil water in the TRHR. Guo et al. (2022) concluded that the  
78 main factors influencing soil water changes in the headwater region of the  
79 Yellow River were the normalized vegetation index (NDVI) and  
80 precipitation, followed by air temperature and wind speed. Land  
81 degradation significantly reduced soil water by 4.5-6.1% at a depth of 0-  
82 100 cm and increased the annual mean soil surface temperature by 0.8 °C  
83 under global warming in this region (Xue et al., 2017).

84 The TRHR is undergoing a glacier retreat, permafrost degradation,  
85 precipitation increase, snowfall decrease, water conservation decrease and  
86 soil erosion intensification with global warming (Li et al., 2021a, b). These  
87 changes have caused large fluctuations in soil water, bringing great

88 uncertainty to vegetation growth and causing challenges in vegetation  
89 restoration. Thus, there is an urgent need to quantify soil water sources to  
90 improve the effectiveness of ecological restoration in permafrost regions.  
91 However, field observations are too sparse to satisfy the need for  
92 quantifying soil water sources in the TRHR. As natural tracers, stable  
93 isotopes can be applied in water cycle studies to trace precipitation, soil  
94 water, groundwater, and plant water (Zhang et al., 2017; Wang et al., 2018;  
95 Yang et al., 2019; Li et al., 2022; Wang, 2021). Monitoring the stable  
96 isotope characteristics of soil water could provide information about water  
97 sources, changes in soil water, and moisture cycling (Sprenger et al., 2017).  
98 Using 2451 samples of soil water, precipitation, river water, ground ice,  
99 supra-permafrost water, and glacier snow meltwater collected in June,  
100 August, and September 2020, this study (a) analyzed the spatiotemporal  
101 distribution of  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  in soil water at different ablation stages; (b)  
102 determined the hydrological processes of soil water and its variation; (c)  
103 quantified the major sources and their contributions to soil water; and (d)  
104 confirmed the corresponding implications for ecosystem protection. The  
105 result presents new observational evidence of soil water sources in the  
106 “Chinese Water Tower.” It provides a scientific basis for establishing a  
107 complex interplay between soil, water and vegetation as a theoretical basis  
108 for developing water-soil conservation and vegetation restoration  
109 programs in cold regions, especially in the permafrost region.

## 110 **2. Materials and methods**

### 111 **3. 2.1 Study region**

112 The Three-Rivers Headwater Region (TRHR) (31°39'-36°12'N, 89°45'-  
113 102°23'E, 2610-6920m a.s.l.) is the source region of the Yangtze (YZR),  
114 Yellow (YLR), and Lancangjiang Rivers (LCR) and is a significant  
115 freshwater resource in China and Asia (Fig. 1). The TRHR is  $36.3 \times 10^4 \text{ km}^2$   
116 and accounts for approximately 50.4% of the total area of Qinghai Province.  
117 The region has a plateau continental climate with an annual average  
118 temperature of -5.38-4.14 °C and annual precipitation of 262.2-772.8 mm  
119 (Cao and Pan, 2014). The radiation is abundant, with total annual sunlight  
120 as high as 2300-2900 h due to the high altitude. The permafrost is  
121 extensively developed and is well distributed in the YZR with a depth  
122 averaging between 50 and 120 m, whereas the permafrost is discontinuous  
123 and sporadic, with a depth below 50 m in the YLR and LCR (Zhang et al.,  
124 2001b). The YLR, YZR, and LCR cover 167,000 km<sup>2</sup>, 159,000 km<sup>2</sup>, and  
125 37,000 km<sup>2</sup>, accounting for 46%, 44%, and 10% of the total area of the  
126 TRHR, respectively. The YLR, YZR, and LCR contribute approximately  
127 49%, 25%, and 15% of the total runoff and supply up to  $600 \times 10^8 \text{ m}^3/\text{a}$  in  
128 freshwater resources. Additionally, more than 180 rivers, 1800 lakes, 2000  
129  $\times 10^8 \text{ m}^3$  of glaciers, and 73,300 km<sup>2</sup> of wetlands are found in the TRHR.  
130 Protecting the ecosystems of the TRHR, maintaining and improving their  
131 water-soil conservation functions, and water containment are of vital

132 importance to the stable supply of water resources, as well as to climate  
133 stability, ecological security, and sustainable economic and social  
134 development throughout Asia. The country's largest national park, the  
135 Three Rivers Headwater National Park, was established as a restorative  
136 practice region for constructing an eco-friendly society and beautifying  
137 China.

138 Grasslands are the main ecosystems in the TRHR and comprise  
139 approximately 70% of the regional vegetation area. The grasses are typical  
140 for alpine meadows and alpine steppes, dominated by *Kobresia capillifolia*,  
141 *Kobresia humilis*, *Stipa purpurea*, *Elymus dahuricus*, etc. Other vegetation  
142 types are temperate steppe and alpine desert with small distributions,  
143 dominated by *Stipa spp.*, *Achnatherum splendens*, *Carex spp.*,  
144 *Thylacospermum caespitosum*, *Androsace tapete*, *Oxytropis sp.*, *Saussurea*  
145 *subulata*, respectively (Fan et al., 2010). The ecosystems in the TRHR are  
146 characterized by diversity, fragility, sensitivity, and weak carrying and  
147 restoration capacities. Most of the soils are thin and coarse in texture. From  
148 high altitude to low altitude, the soil types are alpine desert soil, alpine  
149 meadow soil, alpine steppe soil, mountain meadow soil, grey-cinnamon  
150 soil, castanozems, and mountain forest soil, respectively. The alpine  
151 meadow soil is the primary soil type in the region, and other intrazonal  
152 soils are also commonly developed.

## 153 **2. 2 Data and methods**

### 154 **2.2.1 Samples: collection and preparation**

155 Primary data was collected through fieldwork in June, August, and  
156 September of 2020. It was used to explore seasonal patterns and their  
157 influence on soil and water sources. A scientific understanding of  
158 vegetation restoration in the “Chinese Water Tower” (Fig. 2) was  
159 developed from these soil-water source data. A total collection of 2451  
160 samples included soil water, ground ice, precipitation, river water, supra-  
161 permafrost water, and glacier snow meltwater in the TRHR, with spatial  
162 and temporal frequency sampling (Fig. 3). The sampling details are  
163 described in the following sections:

164 **Soil samples:** The soil profile was excavated, and its thickness was  
165 determined based on the actual thickness of the soil layer. Samples were  
166 collected at 20 cm intervals from 79, 70, and 93 sampling sites in June,  
167 August, and September, respectively (Fig. 3). Meanwhile, soil temperature  
168 was measured in °C, and the test range was from -40 to 100 °C,  $\pm 0.5$  °C.  
169 Soil moisture was measured as a % ( $m^3/m^3$ ), with a test range of 0 to 100%  
170 and a response time of less than 2 s. Three parallel samples were collected  
171 from each layer for soil-water stable isotope analysis. The samples were  
172 collected from 2 cm below the surface to avoid being affected by contact  
173 with the atmosphere. For preservation, a total of 741 soil samples were  
174 collected and stored in HDPE bottles sealed with parafilm.

175       **Precipitation samples:** At Zhimenda (92.26°E, 34.14°N, 3540 m),  
176 Tuotuohe (34.22°N, 92.24°E, 4533 m), Zaduo (32.53°N, 95.17°E, 4066.4  
177 m), Dari (33.45°N, 99.39°E, 3967 m) and Maduo (34.55°N, 98.13°E,  
178 4272.3 m) stations, a total of 375 precipitation event-scale samples were  
179 collected from June 2019 to July (Fig. 3). All precipitation occurring from  
180 20:00 on the first day of the event to 20:00 the next day was collected.  
181 During sample collection, precipitation, air temperature, wind speed, and  
182 relative humidity were recorded at the corresponding national  
183 meteorological stations. To avoid evaporation, the sample was collected  
184 immediately after the event.

185       **Ground ice:** To collect ground ice samples, a 1 m deep soil profile of  
186 the active permafrost layer was dug at each of the sampling sites to locate  
187 permafrost ground ice (Fig. 3). In June, August, and September, 66, 40,  
188 and 37 ground ice samples were respectively obtained. These samples were  
189 preserved in pre-cleaned HDPE bottles sealed with parafilm and kept  
190 frozen. The outer layer of each ice sample was chipped off to avoid  
191 contamination from the soil.

192       **River water:** River water (259, 231, and 186 samples in June, August,  
193 and September, respectively) was collected to analyze the spatial and  
194 temporal relationship between soil and river water. River water samples  
195 were collected 20 cm below the river surface and stored in HDPE bottles  
196 sealed with parafilm.

197       **Supra-permafrost water:** Supra-permafrost water is mainly stored  
198 in the active permafrost layer (Li et al., 2020). To study the hydraulic  
199 connection between supra-permafrost water and soil water, 125, 161, and  
200 130 samples were collected at different altitudes during June, August, and  
201 September, respectively. First, a 1 m-deep profile of the active permafrost  
202 layer was manually dug at each sampling site. Second, the collected water  
203 samples were immediately filtered with a 0.45- $\mu$ m millipore filtration  
204 membrane at the bottom of each profile, then stored in HDPE bottles sealed  
205 with parafilm.

206       **Glacier snow meltwater:** At Jianggudiru (91°E,33.45°N, 5281 m),  
207 Dongkemadi (92°E, 33°N, 5423 m), and Yuzhufeng Glaciers (94.22°E,  
208 35.63°N, 5180 m) in the headwaters of the Yangtze River (Fig. 1), Halong  
209 glacier (99.78°E, 34.62°N, 5050 m) in the headwaters of the Yellow River,  
210 and Yangzigou glacier (94.85°E, 33.46°N, 5260 m) in the headwaters of  
211 the Lancangjiang River, 27, 32 and 41 samples were collected from streams  
212 flowing out of the glacier front during June, August and September,  
213 respectively, and stored in HDPE bottles sealed with parafilm.

214       Before analysis, all samples were stored at 4 °C in a refrigerator,  
215 without evaporation. Soil water had to be extracted from the soil. We used  
216 a cryogenic freezing vacuum extraction system (LI-2000, Liga United  
217 Technology Co., Ltd., Beijing, China) to extract soil water, as it can

218 achieve complete extraction and has high precision (Li et al., 2016). The  
219 test tubes containing soil samples were installed on the extraction line and  
220 frozen with liquid nitrogen. After 10 min, the line was checked to ensure  
221 no leaks. After it was completely sealed, the larger test tube was heated  
222 using a heating sleeve at 95 °C, and the smaller test tube was frozen with  
223 liquid nitrogen (-196 °C). Due to the temperature gradient, water vapor  
224 moved from the larger test tube to the smaller one and condensed into ice.  
225 The extraction process took 2 h and had an efficiency above 98%. Water  
226 samples were analyzed for  $\delta^{18}\text{O}$  and  $^2\text{H}$  through laser absorption  
227 spectroscopy (DLT-100 liquid water isotope analyzer, Los Gatos Research,  
228 Mountain View, CA, USA) at the Key Laboratory of Ecohydrology of  
229 Inland River Basin, Northwest Institute of Eco-Environment and  
230 Resources, CAS. The results are reported relative to the Vienna Standard  
231 Mean Ocean Water (VSMOW). Measurement precisions for  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$   
232 were better than 0.5‰ and 0.2 ‰, respectively.

233 In addition, air temperature, precipitation, evaporation, and ground  
234 temperature in the TRHR were mainly obtained from the China  
235 Meteorological Data Network (<http://data.cma.cn/>). The normalized  
236 vegetation index (NDVI) is derived from MODIS data, downloaded from  
237 the NASA website (<https://search.earthdata.nasa.gov/>), with a spatial  
238 resolution of 0.05° and a temporal resolution of 16 d, and the data are given  
239 in HDF format.

## 240 **2.2.2 Tracer methods**

241 The end-member mixing analysis (EMMA) tracer approach has been  
242 widely used for analyzing potential soil water sources (Hooper et al., 1990;  
243 Hooper, 2003; Gibson et al., 2005; Peng et al., 2012; Li et al., 2014; 2020).  
244 The EMMA tracer method assumes that i) the tracer concentration in a  
245 potential water source varies significantly in time and space, ii) the  
246 chemical properties of the selected tracer are stable, and iii) changes occur  
247 as a result of water mixing. Tracer techniques involve graphical analyses  
248 in which chemical and isotopic parameters represent the designated end  
249 members. Essentially, the changing composition of the studied water likely  
250 results from intersections during its passage through each landscape.  
251 Tracers can be used to determine the sources and flow paths. Both the two-  
252 and three-component methods can be described by a uniform equation:

$$253 \quad Q_t = \sum_{m=1}^n Q_m, \quad Q_t C_t^j = \sum_{m=1}^n Q_m C_m^j, j = l, \dots, k \quad (1)$$

254 where  $Q_t$  is the total runoff discharge,  $Q_m$  is the discharge of component  $m$ ,  
255 and  $C_m^j$  is the tracer  $j$  incorporated in the component  $m$ . In addition, the  
256 global meteoric water line (GMWL), local meteoric water line (LMWL),  
257 and evaporation line (LEL) have been used to analyze the relationship  
258 between soil water and other waters in the TRHR.

## 259 **3. Results**

### 260 **3.1 $\delta^{18}\text{O}$ and $\delta^2\text{H}$ of soil water in different ablation periods**

261 Soil water stable isotopes showed significant changes in the early ablation  
262 period (June), the substantial ablation period (August), and the end of  
263 ablation (September). The average value of  $\delta^{18}\text{O}$  and  $\delta\text{D}$  was relatively  
264 higher in June and lower in August. It again became higher in September,  
265 while exhibiting an opposite trend for d-excess (Table 1). There were two  
266 reasons for this variation: (1) precipitation gradually increased in June,  
267 reaching a maximum in August, and then decreased; (2) the effect of  
268 evapotranspiration on soil water also showed seasonal variations. Soil  
269 water stable isotopes in different ablation periods showed apparent  
270 regional differences, reflecting that precipitation was the main source of  
271 soil water and that differences in precipitation stable isotopes were  
272 reflected in the soil water. The temporal variation of stable isotopes in the  
273 20–80 cm layer was progressively negative in the surface soil (0–20 cm).  
274 This was due to its high susceptibility to perturbation and environmental  
275 changes (Table 1). Soil water stable isotopes on the eastern slope were  
276 increasingly negative from June to September, while the other slope  
277 directions were consistent with the TRHR (Table 1). Moreover, the soil  
278 water isotopes in meadow and grassland areas were increasingly negative  
279 from the beginning to the end of ablation, while it was continuously  
280 negative in forest areas. These facts show the stochastic nature of soil and  
281 water changes as indicators of environmental changes.

282 As Fig. 4 shows, the slope and intercept for LEL were the lowest in

283 the strong ablation period and then higher in the early ablation and end  
284 ablation periods, which reflects the seasonal variation of the influence from  
285 evaporation or non-equilibrium dynamic fractionation. The slope and  
286 intercept of LEL for the 0–40 cm layer was the lowest during the heavy  
287 ablation period. It was relatively high at the beginning and end of ablation,  
288 whereas the slope and intercept of the 40–80 cm layer increased (Fig. 4).  
289 This reflected that the soil layer above 40 cm was greatly affected by the  
290 environment. Its variation was more sensitive to environmental changes,  
291 while the deeper soil layer was relatively stable. For different altitudes, the  
292 slope and intercept of LEL increased continuously from the beginning to  
293 the end of ablation at 3000–3500 m and 4500–5100 m, while at 3500–4500  
294 m the slope and intercept were the lowest during the heavy ablation period  
295 and relatively high at the beginning and end of ablation (Table 2). In the  
296 grassland, forest, and scrub areas, the slope and intercept of LEL were  
297 higher during the heavy ablation period and lower at the beginning and end  
298 of ablation, while the opposite was evident in the meadow areas (Table 2).  
299 More interestingly, the slope and intercept of LEL on the northern and  
300 eastern slopes were lower during the heavy ablation period and higher at  
301 the beginning and end of the ablation period, while on the southern and  
302 western slopes, they gradually increased and reached the maximum at the  
303 end of ablation (Table 2). These changes again reflected the multiplicity  
304 and complexity of factors influencing soil water and suggested that

305 conducting soil water source research should be predicated on continuous  
306 systematic sampling on a regional scale.

### 307 **3.2 Relationship between soil water and surface waters in different** 308 **ablation periods**

309 In the study region, the LMWL was  $\delta^2\text{H} = 7.90\delta^{18}\text{O} + 12.43$  ( $R^2 = 0.97$ ;  $N$   
310  $= 375$ ) based on event-level precipitation. As Fig. 5 shows, soil water was  
311 primarily located on the LMWL, suggesting that precipitation was the  
312 major soil water source, and some soil water was plotted below the LMWL  
313 owing to high evaporation. The  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values varied among  
314 precipitation, ground ice, and snow meltwater in the early ablation period.  
315 This suggested that in June, as the supra-permafrost water, ground ice  
316 meltwater, glacier and snow meltwater, and precipitation combined to  
317 recharge soil water, snow meltwater recharge was mainly in the area above  
318 4000 m. In the heavy ablation period, soil water was located on the LMWL  
319 in August, with some sampling sites below it because of stronger  
320 evaporation (Fig. 5). At this time of year, the snowpack had melted away,  
321 and the ground ice in the active layer was melting rapidly, with  
322 precipitation and ground ice meltwater recharging the soil water. Soil water  
323 lay below the LMWL, and the lower slope reflected the influence of  
324 evaporation at the end of ablation, while the absence of snow meltwater,  
325 and melted ground ice in areas below 4000 m meant that precipitation was  
326 the dominant soil water source (Fig. 5). These variations reflected seasonal

327 variability in soil water sources and suggested that freeze-thaw cycles were  
328 a key influence on soil water variability.

329         Interestingly, soil water, supra-permafrost, and river water showed a  
330 clustered distribution at all ablation stages in the TRHR, reflecting a close  
331 hydraulic connection (Fig. 5). Precipitation first recharged soil water due  
332 to permafrost distribution, while some soil water transformed into supra-  
333 permafrost water. Then some soil and supra-permafrost water recharged  
334 the runoff, reflecting the uniqueness of the hydrological process in cold  
335 regions. These observations showed that various recharge sources with  
336 significant seasonal variations influence soil water sources. The  
337 relationship between soil water and the LMWL varied significantly at  
338 different altitudes. The higher the altitude, the lower LMWL tends to be  
339 above 4000 m, while the lower the LMWL below 4000 m tends to occur at  
340 the end of ablation (Fig. 5). Reflecting the variation of soil water sources  
341 at different altitudes in the end ablation period, soil water was mainly  
342 recharged by precipitation in areas below 4000 m, while it was also  
343 recharged by ground ice meltwater strongly influenced by evaporation,  
344 resulting in a relatively positive soil water stable isotope. In the early  
345 ablation period, the order of altitude was close to the LMWL: from 3500–  
346 4000 m, 4000–4500 m, above 4500 m, and below 3500 m, confirming the  
347 variability of soil water sources at different altitudes (Fig. 5). On the one  
348 hand, precipitation in the area below 4500 m was primarily liquid, while

349 above it was mostly snow, which is strongly affected by evaporation when  
350 it melts, resulting in a relatively positive soil water stable isotope and lower  
351 recharge to soil water. Conversely, precipitation in June was relatively low,  
352 while the temperature in the lower altitude area rose faster and evaporation  
353 was strong, which led to a positive soil water stable isotope. In the heavy  
354 ablation period, the distance between the LEL of soil water and the LMWL  
355 was comparable at different altitudes, being slightly closer below 3500 m  
356 and slightly further apart at 4000–4500 m, reflecting less altitudinal  
357 variability in soil water sources at this time of year, with abundant  
358 precipitation dominating the soil water sources and intense evaporation  
359 becoming an important factor influencing soil water dynamics (Fig. 5).

360 The relationship between soil water isotope and the LMWL also varied  
361 significantly by vegetation, with grassland isotope being farthest from the  
362 LMWL, followed by meadows and forests at the early and end ablation  
363 periods. In contrast, it was farthest for meadows, followed by grassland  
364 and forests in a heavy ablation period (Fig. 5). These variations indicated  
365 that: (1) forests had relatively little effect on shallow soil water content due  
366 to the predominant use of groundwater and the lower effect of  
367 evapotranspiration under the shade of the trees; (2) under relatively low  
368 precipitation, the low soil water in grassland, combined with the effect of  
369 evapotranspiration, resulted in relatively positive soil water stable isotopes;  
370 (3) soil water stable isotopes were positive when the meadow was growing,

371 and evapotranspiration was intense in the wet season. Evapotranspiration  
372 mainly dominated the influence of vegetation on soil water sources. These  
373 changes indicated the stochastic nature of the soil water sources and the  
374 multiplicity of influencing factors.

### 375 **3.3 Soil water sources in different ablation periods**

376 Based on the EMMA model, there were significant differences in the d-  
377 excess and  $\delta^{18}\text{O}$  concentrations of ground ice, precipitation, snow  
378 meltwater, and soil water during different ablation periods (Fig. 6).  
379 Accordingly, these  $\delta^{18}\text{O}$  and d-excess data were selected for analysis  
380 because they could effectively characterize the sources. There were large  
381 spatiotemporal variations in the  $\delta^{18}\text{O}$  and d-excess concentrations. Soil  
382 water was plotted on a triangle spanning the three end members, suggesting  
383 that soil water was a mixture of them in the early ablation period (Fig. 6).  
384 Therefore, precipitation was considered the first end member. Whereas soil  
385 water was plotted on a straight line spanning the two end members,  
386 suggesting that soil water was a mixture of precipitation and ground ice in  
387 the heavy and end ablation periods (Fig. 6). The intersection between the  
388 LMWL and the LEL is considered to be the isotopic value of the initial  
389 water body that recharges the soil water, and the corresponding  $\delta^{18}\text{O}$  and  
390  $\delta^2\text{H}$  were -17.63‰ and -127.61‰, -18.81‰ and -136.94‰, -23.04‰  
391 and -170.36‰ during the early, heavy, and end ablation periods in the

392 TRHR, respectively. These values were extremely close to the  
393 corresponding mean monthly precipitation values, reflecting that  
394 precipitation was the main source of soil water.

395       Based on this calculation, precipitation, ground ice water, and glacier  
396 snow meltwater accounted for approximately 72%, 20%, and 8% of soil  
397 water during the early ablation period, respectively (Fig. 7). Moreover, the  
398 recharge pattern showed a significant variation in different altitudes, with  
399 no snow meltwater recharge below 4000 m due to snow melting depletion  
400 and a higher snow meltwater recharge at higher elevations. The maximum  
401 ground ice meltwater recharge occurred at 3500–4000 m and decreased  
402 with increasing altitude. This showed that the change in altitude of snow  
403 and ground ice meltwater was a key factor affecting the source of soil water  
404 during the early ablation period. Regarding different vegetation types, the  
405 contribution of ground ice meltwater was higher in meadow areas. In  
406 contrast, snow meltwater recharge was relatively high in grassland areas  
407 and mainly in precipitation recharge in forest areas. Ground ice and snow  
408 meltwater recharge were significantly higher on shaded slopes than on  
409 sunny slopes (Fig. 7).

410       In the heavy ablation period, precipitation and ground ice accounted  
411 for approximately 90% and 10% of soil water in the TRHR, respectively.  
412 Snow was completely melted at this time of year, and the recharge of soil  
413 water by precipitation decreased with increasing altitude, while ground ice

414 meltwater gradually increased, with all soil water recharged by  
415 precipitation in the regions lower than 3500 m. The forested soil water was  
416 fully recharged by precipitation, while the meadow area was recharged by  
417 ground ice meltwater at a higher rate than the grassland area, with the rate  
418 on the shaded slope being greater than that on the sunny slope (Fig. 7).

419 According to the EMMA model, precipitation and ground ice  
420 accounted for approximately 94% and 6% of soil water in the TRHR,  
421 respectively, during the end-ablation period. All ground ice in soils below  
422 4000 m at this time of year was lost, and all soil water was recharged by  
423 precipitation, with a small amount of ground ice water recharge occurring  
424 in the higher altitude areas. There was only a small amount of recharge  
425 from ground ice meltwater on shady slopes, which was still higher in  
426 meadow areas than in grassland areas (Fig. 7).

## 427 **4. Discussion**

### 428 **4.1 Influencing factors on soil water sources in different ablation** 429 **periods**

430 The above analysis shows that there are multiple sources of soil water. For  
431 the same reason, various factors influence soil water sources, including  
432 temperature, precipitation, vegetation, evapotranspiration, and the freeze-  
433 thaw cycle. As mentioned above, soil water is mainly recharged by  
434 precipitation and ground-ice meltwater. The amount of ground ice is  
435 challenging to measure, but it can be estimated by high or low ground

436 temperatures. As supplemental Fig. 1 shows, spatial correlations of soil  
437 moisture with air and ground temperatures were analyzed during the  
438 sampling period. Interestingly, there was a positive correlation in the early  
439 ablation period because the active layer of permafrost was in the process  
440 of melting. The higher the ground temperature, the faster the ground ice  
441 melts, causing an increase in soil water, especially at lower altitudes. The  
442 liquid water produced by ground ice melting and the snow meltwater on  
443 the surface would move down to the upper limit of permafrost, and the  
444 precipitation will also move downward when the active layer completely  
445 melts, which increases the soil water in the active layer (Jiao et al., 2014).  
446 Liquid soil water increased in the cold months under increasing soil  
447 temperature and ground ice melting, while changes in the warm months  
448 were the results of competition between positive precipitation and adverse  
449 soil temperature effects in permafrost regions (Lan et al., 2015). The active  
450 permafrost layer melted slowly at higher altitudes, and evaporation  
451 increased with higher ground temperatures. Wen et al. (2020) also reported  
452 that temperature increases reduced the shallow soil water in cold regions.  
453 In the heavy ablation period, soil water exhibited a clear negative  
454 correlation with ground temperatures, with the end of thawing the active  
455 permafrost layer and the weakening effect of permafrost ground ice on soil  
456 water, and the higher the temperature, the stronger the evaporation and  
457 lower the soil water. Most regions displayed a clear positive correlation in

458 September, with only a few lower-altitude areas showing a negative  
459 correlation. Two phenomena can account for this: (1) the top layer of soil  
460 at higher altitudes starts to freeze at night and thaws during the day, thus  
461 increasing soil water; (2) soil water at lower altitudes is affected by  
462 evaporation and decreases again. These facts also indicate that changes in  
463 freeze-thaw processes have an important influence on the evolution of soil  
464 water. During the thawing phase of the active permafrost layer, the increase  
465 in precipitation or soil water led to an increase in the thawing rate of frozen  
466 soil, accompanied by an increase in water infiltration as the frozen soil  
467 continued to thaw, leading to an increase in deep soil water and a decrease  
468 in surface soil water (Ma et al., 2021). Under freeze-thaw cycles, the  
469 adequate soil water in the root layers of different alpine meadows was  
470 ranked as follows: non-degraded meadow > moderately-degraded meadow >  
471 seriously degraded meadow (Lv et al., 2022). Xue et al. (2017) found that  
472 permafrost degradation significantly reduced soil water by 4.5–6.1% at a  
473 depth of 0–100 cm and increased the annual mean surface soil temperature  
474 by 0.8 °C in the headwater region of the Yangtze River.

475       Precipitation infiltration is considered the primary source of soil water  
476 in the active permafrost layer during the freeze-thaw process, which is  
477 considered a major factor and imposes limitations (Cao et al., 2018). In  
478 June, the spatial variation of soil water and precipitation in most regions,  
479 especially at high altitudes, showed a negative correlation, while only a

480 few low-altitude regions showed a positive correlation (supplemental Fig.  
481 2). On the one hand, this indicated that precipitation in high-altitude  
482 regions was mainly in the form of snowfall, which does not easily recharge  
483 soil water directly, and that the active permafrost layer melts slowly. There  
484 is also the phenomenon of alternating between freezing and thawing, such  
485 that the more precipitation there is, the less the soil water changes. On the  
486 other hand, all the permafrost in low-altitude regions melted by June, and  
487 soil water was mainly recharged by precipitation, such that the more  
488 precipitation there was, the higher the soil water. The correlation between  
489 soil water and precipitation was low during the warm season in permafrost  
490 areas and high in seasonal frozen areas because permafrost may help  
491 maintain soil water stability. In contrast, permafrost degradation would  
492 reduce the regulating capacity of soil water, affecting the Tibetan Plateau  
493 ecosystem and hydrological cycle (Wu et al., 2021).

494         Soil water changes in August exhibited a negative correlation with  
495 precipitation. During this period, the active layer of permafrost melted.  
496 However, the source of soil water was mainly precipitation. More  
497 precipitation resulted in a higher quantity of soil water (supplemental Fig.  
498 2). Most areas showed a positive correlation in September. Only a few  
499 high-altitude areas displayed a negative correlation; due to the lower  
500 temperature, precipitation in high-altitude areas was mainly snowfall,  
501 which had less effect on soil water recharge, while the lower-altitude areas

502 still showed a positive correlation with rainfall, which directly recharged  
503 soil water. Deng et al. (2020) also indicated that soil water increased with  
504 precipitation in most regions of the TRHR. Based on observations in the  
505 TRHR, the soil water at 10 cm, 20 cm, and 30 cm increased by 0.47%,  
506 0.46%, and 0.41%, respectively, when the precipitation increased by 1 mm,  
507 while the soil water at 10 cm, 20 cm, and 30 cm decreased by 3.8%/d,  
508 3.3%/d, and 2.3%/d, respectively, when the number of days without  
509 precipitation increased by 1 d (Li et al., 2022). The average soil water  
510 during 2003–2020 was 20%, increasing at a rate of 0.5%/10a, and its  
511 changes were influenced by precipitation and temperature in the TRHR  
512 (Chen et al., 2021). In addition, the effect of snow cover on soil water  
513 thawing was greater than that on freezing, and the effect on shallow swamp  
514 soils was greater than that on shallow meadow soils (Chang et al., 2012).

515 Evapotranspiration is the reverse process of soil water recharge. Soil  
516 water, in general, showed a significant negative correlation with  
517 evapotranspiration in June, August, and September in the TRHR,  
518 indicating that stronger evapotranspiration results in less soil water  
519 (supplemental Fig. 3). Based on observations under simulated warming  
520 conditions at the Chengduo station in the TRHR, the soil temperature  
521 increased by 2.50 °C and 1.36 °C at the soil depth of 0–15 cm and 15–30  
522 cm, respectively, while the soil water decreased by 0.07% and 0.09% at the  
523 soil depth of 0–15 cm and 15–30 cm, respectively (Yao et al., 2019). Cao

524 and Jin (2021) also concluded that soil water is negatively correlated with  
525 air temperature and positively correlated with precipitation.

#### 526 **4.2 Soil water sources and implications for vegetation restoration**

527 As the limiting factor determining ecosystem stability in cold regions, there  
528 may be complex feedback relationships between vegetation and soil water.  
529 This is of great significance for improving understanding of the  
530 hydrological process, soil and water conservation, and water resource  
531 utilization. As supplemental Fig. 4 shows, the correlation between soil  
532 water and vegetation index in June was positive, and the correlations were  
533 more significant in higher-altitude regions. On the one hand, the vegetation  
534 had just resumed growth during this period, and the growth was slow with  
535 the relatively weak evapotranspiration. The soil was dry after a freezing  
536 period, the vegetation had a higher capacity to hold water. The active  
537 permafrost layer was still melting, and ground ice melting increased the  
538 soil water, accompanied by continuous vegetation growth. In the early  
539 stage of vegetation growth, the upper soil layer had a high water-holding  
540 capacity, the infiltration rate of precipitation was slow through the surface  
541 layer to the soil depths, and there was a more uniform spatial distribution  
542 of soil water with an evident water-holding function (Wang et al., 2003).  
543 Liu et al. (2021) also thought that the thawing of frozen soil increased the  
544 soil water in the root zone, regulated root respiration, and brought the  
545 vegetation into the growing season. Wei et al. (2022) also indicated that

546 NDVI and surface soil water were positively correlated in the Loess  
547 Plateau, with a more significant mutual feedback relationship.

548 Soil water displayed a negative correlation with vegetation index in  
549 most areas in August, reflecting better vegetation growth, stronger  
550 evapotranspiration, and lower soil water content, as the active permafrost  
551 layer had all melted by that time of year. Vegetation was in an active  
552 growth phase. Soil water showed a negative correlation with the vegetation  
553 index at most lower elevation areas in September, reflecting better  
554 vegetation growth, stronger evapotranspiration, and lower soil water. Some  
555 higher elevations showed a positive correlation, reflecting the effects of the  
556 freeze-thaw cycle.

557 The vegetation indices were closely associated with soil water, which  
558 played a key role in the active layer thickness-vegetation relationship,  
559 especially at depths of 30–40 cm in the northeastern Qinghai-Tibet Plateau  
560 (Jin et al., 2020). Thus, precipitation and vegetation were the main factors  
561 that caused soil moisture variation in summer and autumn, while the soil  
562 freeze-thaw cycle was the main contributing factor in spring (Ma et al.,  
563 2021). Based on observations in the permafrost region, the mean surface  
564 soil water in the alpine meadow was higher than that in the alpine steppe,  
565 while soil water variability in the cold alpine steppe was larger than that in  
566 the alpine meadow, which decreased with depth (Yang et al., 2011). The  
567 soil water reduced rapidly after vegetation degeneration, especially at soil

568 depths of 0~30 cm, and so global warming and permafrost degradation tend  
569 to decrease topsoil water in the Tibetan Plateau (Wang et al., 2012).

570 The soil water in the alpine steppe and temperate steppe was mainly  
571 affected by air temperature, and the influencing factors for alpine meadows  
572 and shrubs were precipitation and NDVI (Zhang et al., 2022). The effect  
573 of different vegetation types on the surface soil water varied widely, and  
574 the higher the vegetation cover, the greater the increase in soil water (Ma,  
575 2016). The surface soil water appeared to be significantly reduced by  
576 vegetation degradation. The more vegetation was degraded, the faster  
577 water was lost (Wang et al., 2010; Erik et al., 2020). The soil water  
578 continued to decrease, and permafrost degradation increased the  
579 evaporation of soil water, resulting in further soil water loss. It is necessary  
580 to vigorously implement ecological protection and construction projects,  
581 natural forest protection projects, and projects to convert cropland to forest  
582 and grassland to counter these effects. Such strategies could effectively  
583 deal with ecological problems such as decreased water conservation  
584 capacity, increased soil erosion, and vegetation degradation caused by  
585 future permafrost degradation. In the Qilian Mountains, water loss has a  
586 clear positive relationship with soil water and a negative relationship with  
587 soil temperature for shrubland, grassland, and spruce forests (Hu et al.,  
588 2019). Lu et al. (2020) also concluded that community cover was sensitive  
589 to surface soil water and increased as a function of soil water from 1.1%–

590 10.0% and gradually tended to saturate. There was a significant positive  
591 correlation between summer NPP and soil water in the watershed, but their  
592 interactions manifested spatial heterogeneity (Yue et al., 2021). Thus, the  
593 high soil water could support more plants with varied vegetation types  
594 (Jiao et al., 2020).

595 As mentioned above, the variability of soil water has further increased  
596 under warming, becoming the most critical factor affecting vegetation  
597 growth, especially as soil water loss will further exacerbate vegetation  
598 degradation and pose a great threat to ecological security in the “Chinese  
599 Water Tower.” Yue et al. (2022) also found that, under future climate  
600 change, only timely supplementation of soil water could promote net  
601 primary productivity growth, improve vegetation productivity, and  
602 effectively restore and protect the ecosystem. Therefore, active measures  
603 should be taken in the following five areas (Fig. 8).

604 (1) Build a real-time observation network for soil water variation  
605 relying on ground-based meteorological observation stations, hydrological  
606 stations, and field observation stations, combined with remote sensing  
607 monitoring, to provide data support for the formulation of scientific and  
608 reasonable water-soil conservation and vegetation restoration measures.

609 (2) Conduct an in-depth investigation into the influence mechanism  
610 of soil water on vegetation growth. Develop the construction of vegetation  
611 growth models that integrate soil water dynamics and vegetation carrying

612 capacity. Establish an early warning platform for soil water-vegetation  
613 changes,-vegetation restoration early warning platform, enabling real-time  
614 alerts for vegetation degradation. Provide a scientific foundation for the  
615 restoration of degraded vegetation.

616 (3) Determine scientifically the most suitable time for vegetation  
617 restoration. The melting of the active permafrost layer and the change in  
618 soil water show seasonality. In lower altitude regions, vegetation enters the  
619 growing season in June, and so restoration work should be implemented  
620 bythe end of May to promote seed germination. In higher-altitude regions,  
621 vegetation enters the growing season around the end of June, and to  
622 improve the survival rate of vegetation, rapid seed germination and  
623 breeding techniques should be developed. Mature seedlings should be  
624 directly transplanted to make full use of the short growing season and  
625 improve the effectiveness of vegetation restoration.

626 (4) Take restoration measures according to different degrees of  
627 degradation. There are significant differences in soil water and its  
628 environmental effects in grasslands. The integrated pattern of winter rodent  
629 eradication + growing season grazing ban + fertilizer application  
630 technology is for lightly degraded grasslands, which can significantly  
631 improve the vegetation cover and height of grasses and maintain a stable  
632 increase in soil water. The integrated pattern of winter rodent control +  
633 growing season grazing ban, fertilizer application,and no-till replanting is

634 for moderately degraded grassland, which not only significantly increases  
635 the cover, height, amount of good forage, and above-ground vegetation of  
636 grassland but also promotes water-holding capacity. The integrated pattern  
637 of winter rodent eradication, growing season grazing ban , fertilizer  
638 application, and re-vegetation technology is used in heavily degraded  
639 grasslands to restore vegetation and to ensure that soil water is stable  
640 enough to support vegetation growth.

641 (5) For areas of severe vegetation degradation, focus on the adequate  
642 compensation of precipitation in time and space. Changing the micro-  
643 topography to collect rainwater in the form of runoff or artificially  
644 produced flow, including fish-scale pit and horizontal ditch technologies,  
645 to achieve the objectives of water storage and moisture conservation,  
646 increasing the survival rate of vegetation, and improving ecological water  
647 use.

## 648 **5. Conclusions**

649 Based on 2451 samples of soil and surface water collected in the Three  
650 Rivers Headwater Region, China, the sources of soil water in different  
651 ablation periods were calculated. The results indicated that precipitation,  
652 ground ice, and snow meltwater accounted for approximately 72%, 20%,  
653 and 8% of soil water during the early ablation period, respectively, and that  
654 there is no snow meltwater recharge below 4000 m due to snow melting  
655 depletion. In the heavy ablation period, precipitation and ground ice

656 contributed to 90% and 10% of soil water, respectively. The precipitation  
657 recharge decreased with increasing altitude, while ground ice gradually  
658 increased, accounting for about 94% and 6% of soil water from  
659 precipitation and ground ice, respectively, during the ablation end period,  
660 and the small amount of recharge from ground ice mainly occurred above  
661 4000 m.

662       Soil water loss will further exacerbate vegetation degradation with  
663 global warming and pose a significant threat to the ecological security of  
664 the “Chinese Water Tower.” So, it is urgent to build a real-time soil water  
665 observation network, construct a soil water-vegetation change-vegetation  
666 restoration early warning platform, determine the most suitable time for  
667 vegetation restoration, and apply appropriate soil water conservation and  
668 vegetation recovery programs.

## 956 Figures

957 Fig.1 The location of Three -River Headwater Region in ecological barriers  
 958 of China(a); distribution map of permafrost and seasonal frozen soil (b),  
 959 soil types (c) and vegetation types (d) in the study region

960 Fig.2 the work photo for sampling glacier snow meltwater(a), soil in  
 961 grassland(b), soil in meadow (c), supre-permafrost water (d), river water  
 962 (e), tributary water (f), vegetation (g) and soil in forests (h)

963 Fig.3 Distribution of sampling sites for soils and waters in June (a), August  
 964 (b) and September (c)

965 Fig.4 Plot of  $\delta\text{D}$  versus  $\delta^{18}\text{O}$  and LEL for soil water at different soil layers  
 966 on June (a), August (b) and September (c)

967 Fig.5 Hydraulic connections between soil water and other waters for all  
 968 samples (a), different altitudes (b) and vegetation (c) in June, all  
 969 samples (d), different altitudes (e) and vegetation (f) in August, all  
 970 samples (g), different altitudes (h) and vegetation (i) in September

971 Fig.6 Three end element diagram in June (a) and Two end element diagram  
972 in August (b) and September (c) using the mean values of  $\delta^{18}\text{O}$  and d-  
973 excess for soil water

974 Fig.7 Concept map for contribution from precipitation, snow meltwater  
975 and ground ice to soil water in the whole study region, different  
976 altitudes and different vegetation in June (a), August (b) and  
977 September (c)

978 Fig.8 Concept diagram for real-time monitoring network for soil water, soil  
979 water-vegetation change-vegetation restoration early warning platform and  
980 the different soil water conservation and vegetation restoration patterns in  
981 Three-River Headwater Region
