## **Abstract**

10 The study of the water cycle in the forest at large scales, such as countries, is challenging due to the difficulty of correctly estimating forest water flows. Hydrological models can be coupled to extensive forest data sources, such as national forest inventories, to estimate the water flow of forests over large extents, but so far the studies conducted have not analysed in detail the role of stand structure variables or the functional traits of the forest on predicted blue/green water flows. In this study, we modelled the water balance of Spanish forests using stand structure and species data from forest inventories to  
15 understand the effects of climate, stand structure, and functional groups on blue water flows. We calculated blue water and green water flows and expressed them relative to received precipitation. Relative blue water flow was mainly concentrated in the wetter regions (Atlantic and Alpine biomes) of Spain (around 25 %) in comparison with the Mediterranean biomes (10-20%) and during the autumn-winter season. Leaf Area Index (LAI) of the forest stand is the most important predictor of relative blue water, exhibiting a negative effect until it reaches a plateau at higher levels (around 2.5-3). Deciduous forests  
20 showed a greater relative blue water flow than evergreen functional groups (25-35 % and 10-25% respectively), primarily due to leaf fall during the autumn-winter season. This study highlights how green water is decoupled from blue water, namely, blue water depends on winter and autumn precipitation, while green water depends on the spring and summer water demand and how the species functional traits (deciduous vs evergreen) can influence the blue water production.

## 25 **1. Introduction**

Forests are one of the most important ecosystems on the planet and constitute a supplier of carbon and water for humanity (MEA, 2005). Even though water is the main determinant of vegetation worldwide (Wang-Erlandsson et al., 2022), the water cycle is particularly challenging to study because of the difficult to measure its components. The water cycle in forests depends on the precipitation that falls in the forest, which can be partitioned into the green water and the blue  
30 water (Caldwell et al., 2016; Schlesinger and Jasechko, 2014). The green water is the evapotranspiration flow from the forest to the atmosphere, formed by the water transpired by plants, together with the evaporation of intercepted precipitation by vegetation and the evaporation from the soil surface (Llorens et al., 2011). Climate, specific traits, stand forest structure, and

their interactions determine the partitioning of precipitation between green water and blue water. Forest evapotranspiration is determined by local climate conditions, such as air temperature, radiation, vapour pressure deficit or soil water availability  
35 (Granier et al., 2000). Moreover, plant transpiration is different among species depending on their specific traits, as leaf area, xylem traits determining the efficiency of water transport or leaf phenology (evergreen and deciduous) (Ford et al., 2011). Stand forest structure is also key in rainfall partitioning through its relationship with stand LAI (total area of leaves of the canopy per unit horizontal ground area) which is a key variable determining transpiration (Granier et al., 2000) and/or the interception of vegetation. On the other hand, blue water can be split into two flows: the surface runoff and the surplus of  
40 groundwater by the system and available downstream.

Green water reduces the amount of blue water produced at local scale but recycles the water through evapotranspiration at global scale (Ellison et al., 2012). Green water flow is usually greater than blue water's in forests and grasslands in comparison with croplands or wetlands due to the greater transpiration of the former (Oki and Kanae, 2006). Green water represents around 40-70 % of water flow in temperate and boreal forests (Schlesinger and Jasechko, 2014), and  
45 even 90-100 % in dryer environments or years, including Mediterranean forests (Ungar et al., 2013; Campos et al., 2016; Qubaja et al., 2020). The combination of different rainfall dynamics, transpiration, stand structure, and specific life traits can modify the partitioning between green and blue water. For instance, water yield can be affected by the temporal distribution of rainfall events (seasonality and torrentiality). Relative water interception by trees decreases when rainfall increases, being greater in arid environments compared to humid forests (Levia and Frost, 2003). In Mediterranean forests the interception is  
50 greater than in temperate forests due to the smaller rainfall amount and intensity and the higher evaporation caused by the higher temperature (Limousin et al., 2008). However, evaporation of intercepted water is lower during late-summer intense convective storms since the rainfall intensity is very high and of short time (torrentiality) (Llorens and Domingo, 2007). Physiological and phenological differences among species also modulate water flows. Evergreen Mediterranean trees can reduce their transpiration in summer (water saver) but deciduous trees increase it due to higher water demand (water  
55 spender) (Baquezano and Castillo, 2006; Klein, 2014; Link et al., 2014; McDowell et al., 2008). Therefore, Mediterranean forests show transpiration seasonality, with a reduction in stomatal conductance during the summer drought, while the transpiration in temperate forests follows leaf phenology more closely (Llorens et al., 2011).

Water balance in forests has been studied mainly at local and landscape scales, like in watersheds (Caldwell et al., 2016; Guzha et al., 2018; Schwärzel et al., 2020) or forest stands (Benyon et al., 2017; Simonin et al., 2007). Analyses at  
60 regional scales have also been carried out (Hoek van Dijke et al., 2022; Mastrotheodoros et al., 2020; Sun et al., 2005), analysing the water flow variation by topoclimate or landscape vegetation cover with hydrological models. The study of water fluxes in forest ecosystems is an important challenge to forest management. Ecohydrological simulations have been shown as a valuable tool to understand water fluxes at different spatial scales, complementing the limited field data available (Hoek van Dijke et al., 2022; Mastrotheodoros et al., 2020). The effect of stand structure variables on water flow have been  
65 studied at local scale with field data (Benyon et al., 2017; Simonin et al., 2007). Nevertheless, landscape-level

ecohydrological simulations have been most often carried out without incorporating the role of the stand structure variables or the differences in species and functional composition (Hoek van Dijke et al., 2022; Mastrotheodoros et al., 2020).

In our study, we analysed the spatial pattern and partitioning of blue and green water in Spain using ecohydrological simulations with the MEDFATE water balance model (De Cáceres et al., 2023, 2015) using detailed field stand structure and species composition derived from forest inventory data. We simulated water flows and their green and blue water components at daily resolution, and we studied the spatial distribution of relative blue water and its seasonality. Spain is an adequate region to study the partitioning between blue and green water, because it shows contrasting climate gradients, in terms of temperature, rainfall amount and seasonal distribution. Importantly, it includes a contrasted climate between the Mediterranean area —with hot temperature, low precipitation and seasonal drought— and the temperate area —with warm temperature, higher rainfall amount and without seasonal drought (Rivas-Martínez et al., 2011). In addition, peninsular Spain harbours both temperate and Mediterranean forests that span a broad gradient of forest types and stand structures that can modify the partitioning between blue and green water. The questions addressed by the study are: 1) Which are the spatio-temporal patterns of blue and green water along the Spanish Peninsula and among climate subregions? 2) How this partitioning between blue and green water varies among contrasting forest functional groups? 3) Which are the main climatic and forest structural drivers of this partitioning between blue and green water?

## 2. Material and Methods

### 2.1 Study area

The studied area spans the forested areas of Spain, including the Iberian Peninsula and the Balearic Islands, but excluding the Canary Islands. This encompasses two climatic domains: the temperate climate with Atlantic Sea influence, in the north and west parts of the Iberian Peninsula, and the Mediterranean climate, in the rest of the territory. The temperate climate is wetter and colder, while the Mediterranean climate is hotter and drier. We have classified the Iberian territory into six biomes (see map in Figure S1) according to the Iberian climate classification of (Allué Andrade et al., 1990): (i) Arid (9.0 % of the Spanish surface), with warm winters and summers and very low precipitation (< 400 mm); (ii) Temperate Mediterranean (34.8 %), hot in winter and summer with low precipitation (400-600 mm); (iii) Continental Mediterranean (30.9 %), cold in winter and hot in summer with low precipitation (400-600 mm); (iv) Submediterranean (11.0 %); cold in winter and hot in summer with wetter precipitation (about 800 mm); (v) Atlantic (10.5 %), characterized by a mild winter and summer and high precipitation (> 1000 mm); and (vi) Alpine (3.8 %), very cold in winter and cool in summer and high precipitation (> 1000 mm).

95

### 2.2. Forest inventory data

We used the permanent fields plots from the Spanish national forest inventories to characterize the predominant species and stand structure variables across the study area. The Spanish national forest inventories (SFI) are distributed with

a systematic survey along the forested areas with a density of ~1 plot/sq km. Specifically, we used the third inventory (SFI3) 100 carried out in 1997-2008, which is the most recent and complete survey available to date. Spanish permanent field plots have four concentric circular sub-plots with radii of 5, 10, 15 and 25 m. Trees were identified and measured within variable circular size plots (5 m radius for trees with dbh  $\geq$  7.5 cm, and trees with  $2.5 \leq \text{dbh} \leq 7.5$  cm are counted; 10 m radius for trees with dbh  $\geq$  12.5 cm; 15 m radius for trees with dbh  $\geq$  22.5 cm; and 25 m radius for trees with dbh  $\geq$  42.5 cm). Moreover, the shrub species or genus within the 10-m-radius subplot were measured with their corresponding percent cover 105 values and average height.

We focused on the field plots with > 70 % of plot basal area of the most predominant tree native species (Table S1) and an overall basal area of > 3 sq m/ha (to ensure that very sparse woodlands, which can hardly be considered a forest, were excluded), resulting in a total number of plots of 32,514. Plots were classified according to the dominant species in terms of basal area, into five functional groups: temperate (e.g., *Fagus sylvatica*) and Mediterranean deciduous (e.g., *Quercus pyrenaica*), 110 temperate (e.g., *Pinus sylvestris*) and Mediterranean coniferous (e.g., *Pinus pinea*) and sclerophylls (e.g., *Quercus ilex*) (see Figure S3 for SFI3 map of the plots selected and Table S1 for the classification of the tree species in these five groups).

### 2.3. Environmental variables

115 We downloaded the daily data of total precipitation and maximum, mean and minimum temperature for the 5 years before and after the date of survey for every plot (that is, 10 years per plot) from E-OBS data at 1 km horizontal resolution (Moreno and Hasenauer, 2016); <ftp://palantir.boku.ac.at/Public/ClimateData>). Topographic variables of slope, aspect and altitude were derived from a digital elevation model (DEM) at 25 sq m of the PNOA Spanish project through the IGN website (downloaded on 14/02/2022; <https://centrodedescargas.cnig.es/CentroDescargas/index.jsp#>). We used these 120 topographic variables to obtain daily values of the relative humidity, solar radiation and potential evapotranspiration (PET) per plot through the *meteoland* R package (De Cáceres et al., 2018). We characterized plot-level climatic conditions using three climatic indexes; climatic moisture (mean annual precipitation/mean annual PET), continentality (mean temperature of the hottest month - mean temperature of the coldest month) and precipitation seasonality ((standard deviation of monthly precipitation/mean of monthly precipitation) \* 100).

125 A summary of the main stand structure and climate characteristic of the different functional groups and biomes is shown in Table S2.

### 2.4. MEDFATE model

MEDFATE model (version 2.9.3) has been designed to simulate plant water balances and soil in structurally- and compositionally-heterogeneous forest stands (De Cáceres et al. 2015; De Cáceres et al., 2023). MEDFATE uses daily 130 weather as input and most processes are simulated at daily time steps. Aboveground stand structure is represented in terms of

total crown ratio (CR), height (H) and leaf area index (LAI) of a set of woody plant cohorts. The soil is represented by vertical layers having different hydraulic properties and each cohort may have a different root distribution, specified using the depth corresponding to cumulative 50 % and 95 % of fine roots (Z50 and Z95, respectively).

Each day, the model updates the leaf area for (semi-) deciduous vegetation based on a simple phenological model that  
135 dictates leaf budburst and leaf drop. This model relies on the SGDD parameter, representing the degree days needed for  
budburst (assuming evergreen plants maintain a consistent leaf area throughout the simulation). Subsequently, the model  
revises the light attenuation within the canopy, adhering to the Beer-Lambert model, as well as the canopy's water storage  
capacity, which signifies the minimum water quantity required to saturate the canopy. Following the canopy status update,  
140 the model addresses the input of water from precipitation. Prior to augmenting the soil layers' water content, the model  
initially deducts the water loss from rainfall due to interception and surface runoff. Rainfall interception loss is estimated  
using the simplified version of the Gash model (Gash et al., 1995), while runoff is calculated according to USDA SCS curve  
number method (Boughton, 1989). Processes related to lateral water transfer are omitted from consideration. Soil water  
storage capacity and water potential are derived from soil texture through pedotransfer functions (Saxton et al., 1986). When  
145 replenishing a specific soil layer, a portion of the water is assumed to directly infiltrate the layer below, as determined by  
microporosity (Granier et al., 1999). The water percolating from the deepest layer is presumed to be lost through deep  
drainage.

To assess plant transpiration, the model initially calculates a distinct estimation of the maximum transpiration for the  
entire plant community (including trees and shrubs) —that is, without considering the soil water deficiency. This calculation  
is done for each taxon and takes into account the atmospheric evaporative demand. It involves two taxon-specific  
150 parameters: aTmax and bTmax. parameters. The estimation of maximum transpiration for the entire stand ( $E_{max,stand}$ ),  
excluding considerations for soil water deficit, relies on the daily Penman's potential evapotranspiration (PET) and an  
empirical relationship established by Granier et al. (1999). But MEDFATE modified the Granier equation with aTmax and  
bTmax:

$$\frac{E_{max,stand(i)}}{PET} = a_{Tmax} \cdot LAI + b_{Tmax} \cdot LAI^2,$$

155 where aTmax and bTmax represent species-specific parameters (De Cáceres et al., 2023). Assuming reliable species-specific  
estimates are accessible for aTmax and bTmax, the equation can be applied to calculate  $E_{max,stand(i)}$ . Once  $E_{max,stand(i)}$  is determined for each species in the stand, the portion of shortwave radiation absorbed is employed to estimate its maximum  
transpiration ( $E_{max}(i)$ ) from  $E_{max,stand(i)}$  (Korol et al., 1995).

Moreover, the cohort's transpiration is influenced by the vertical distribution of fine roots, the soil moisture profile,

160 and two parameters specific to the taxon:  $\Psi$  extract and c extract. These parameters represent the soil water potential at which 50 % of the maximum transpiration occurs, and the slope of a Weibull function that regulates the rate of transpiration decline, respectively. The plant's water status is expressed as a plant water potential, denoted as  $\Psi$  plant, which is defined as an "average" of the soil water potential in the rhizosphere. The model monitors the effects of drought by assessing the proportion of hydraulic conductance lost due to stem cavitation, referred to as PLC. Increases in PLC occur whenever  $\Psi$  plant decreases, following a xylem vulnerability curve characterized by the parameters VC\_stemc and VC\_stemd. PLC sets limits on actual transpiration rates and does not decrease even when  $\Psi$  plant increases. It is worth noting that the effects of cavitation can only be reversed, i.e., PLC can be reduced, through the formation of new sapwood, as outlined by Choat et al., 165 2018.

## 2.5. Parameter estimation

170 Data from forest inventory plots included tree height ( $H$ ) and tree diameter at breast height, which was used to obtain estimates of foliar biomass (hence leaf area after multiplying by *SLA*) and crown ratio (*CR*) via species-specific allometries (see Table S1-3 of De Cáceres et al., 2023 for more details). In shrubs, foliar biomass is calculated from shrub height via species-specific allometries. In the model, *SLA* (Specific Leaf Area (sq mm/mg)), *the ratio of leaf area to leaf dry mass*, is constant for every specie (De Cáceres et al., 2023). Leaf area index (LAI in  $m^2 \cdot m^{-2}$ ) was calculated from the foliar biomass 175 (in  $kg \cdot m^{-2}$ ) by using a *specific leaf area* coefficient (SLA, in  $m^2 \cdot kg^{-1}$ ) that is species-specific (LAI = foliar biomass \* SLA). Taxon-specific parameter details are shown in supplemental material of De Cáceres et al., 2023. Soil data of each forest inventory plot was extracted from the SoilGrids database (Hengl et al., 2017). For all plots four soil layers down to a total depth of 4 m were initially considered, but the deepest layers were merged into a rocky layer (95 % of rocks) following the depth of the R horizon. A monotonous increase in rock fragment content across soil layers from the surface to the rocky 180 layer was defined based on surface stoniness classes determined in SFI3 plot surveys.

## 2.6. MEDFATE simulations

MEDFATE was run on each selected SFI3 plot using daily weather data (temperature and precipitation, PET, radiation and relative humidity) corresponding to a 10-yr period centered on the year of the SFI3 sampling (1997-2008). We 185 calculated the blue water as the sum of the runoff and deep water and the green water as the evapotranspiration (that included the sum of the transpiration, interception and soil evaporation).

## 2.7 Model evaluation

MEDFATE predictions have already been evaluated at the forest stand scale in terms of soil moisture dynamics, plant 190 transpiration and water status in Mediterranean forest (De Cáceres et al., 2021, 2015). Given the focus of the present work,

we evaluated regional-scale patterns of green and blue water predicted by MEDFATE against those produced by alternative methods. First, we did a comparison between the results for average blue water of MEDFATE with the average blue water from the Precipitation Runoff Integrated Model (SIMPAL acronym in Spanish) of the Spanish government. SIMPAL model is calibrated with stations that measure stream flows across Spain and it is interpolate a 1 km<sup>2</sup> resolution for the whole country (Estrela et al., 2012). Second, we compared green water patterns predicted by MEDFATE against those of GLEAM, which is derived from satellite data and covers the world with a resolution of 0.25 degrees (Martens et al., 2017). We used the GLEAM v3.8a that defines the evapotranspiration as the sum of transpiration (from short and tall vegetation), interception (from tall vegetation), soil and open water evaporation and snow sublimation.

200 **2.8. Statistical analysis**

Our analyses focused on relative blue water, the ratio between simulated annual mean blue water and the total precipitation as response variable. The variation of relative blue water across biomes and functional groups was analysed using beta regression models (Ferrari and Cribari-Neto, 2004). We used beta regressions because the response variable was a proportion. A post-hoc Tukey's test was applied for pairwise comparisons between groups (i.e., biomes and functional groups).

The effect and importance of climate, topographic and stand structure variables in the partitioning of blue/green water of every functional group were analysed with XGBoost regression. XGBoost is a machine learning system that builds a sequential series of shallow regression trees with a gradient boosting technique (Chen and Guestrin, 2016). XGBoost regression was used because it allows to analyse lineal and non-lineal responses and correlated variables. A regression tree is trained by splitting the input dataset into increasingly homogeneous subsets at each decision nodes and choosing the split that maximizes the distance between different terminal nodes. 14 different climatic variables calculated as the mean annual values of the 10 years of climate data for every plot (mean, maximum and minimum temperature, solar radiation, moisture and continentality indexes) and the mean of seasonal variables (precipitation of spring, winter, summer, and autumn; precipitation seasonality index) were used as predictors. A topographic variable (slope) and two stand structure variables (basal area and LAI of the plot) were also included. Basal area serves as an indicator of canopy cover, as it is calculated by summing the trunk cross-sectional area at breast height of all trees per hectare, and higher basal area values can result in increased interception. LAI determine the transpiration of the trees and shrubs through of the leaf surface. LAI of the plot was calculated from the sum of the LAI of trees and shrubs. One model for each of the five functional groups was computed. The models were tuned for finding the best hyperparameters and they were evaluated using a k-fold cross-validation procedure (Ten-fold with five repetitions), following a stratified random sample into k subsamples of the dataset. A forward feature selection method for selecting the predictor variables with a spatial cross-validation (Meyer et al., 2018) was used. The models were built for each predictor pair combination and the best was selected. The remaining predictors were tested by adding them to the best combination pair. This procedure continued until neither of the remaining predictors resulted in

an improvement of the model. Variable importance in the retained variables was evaluated by computing the fractional  
225 contribution of each feature to the model based on the total gain of these variables splits (*Gain*), the relative number of times  
a feature is used in trees (*Frequency*) and the relative value of the feature observation (*Cover*). We estimated the  $R^2$  to test  
the accuracy of the final models with:  $1 - (\text{Sres}/\text{Stot})$ , being Sres the sum of the squared differences between the observed  
values and the predicted values, and Stot is the total sum of squares, which is the sum of the squared differences between the  
observed values and the mean of the observed values. All statistical analyses were conducted with R v. 4.1.1., with the  
230 packages *xgboost* (Chen et al., 2015) and *caret* (Kuhn, 2008).

### 3. Results

#### 3.1. Model evaluation

The comparative indicated that the blue water of the SIMPAL model and the green water of GLEAM followed the same  
regional patterns that MEDFATE (Figure 1). SIMPAL reaches higher values of blue water in the Atlantic biome and lower  
235 values in west Temperate Mediterranean than MEDFATE. In opposition GLEAM evapotranspiration is higher in the west  
Temperate Mediterranean and lower in the Atlantic forest than MEDFATE. MEDFATE models at stand scale whereas  
SIMPAL and GLEAM models are at regional scale. At stand scale the evapotranspiration is high in the Atlantic forest and  
then the blue water is lower. West Temperate Mediterranean is characterized by forest of low basal area and LAI (Table S2,  
Figure S4). Therefore, the evapotranspiration is lower and blue water higher than surrounding forest. In other words, the  
240 differences observed seem to arise from the fact that MEDFATE takes into account the stand structural characteristics, which  
are difficult to represent in models based on interpolation (SIMPAL) or remote sensing (GLEAM).

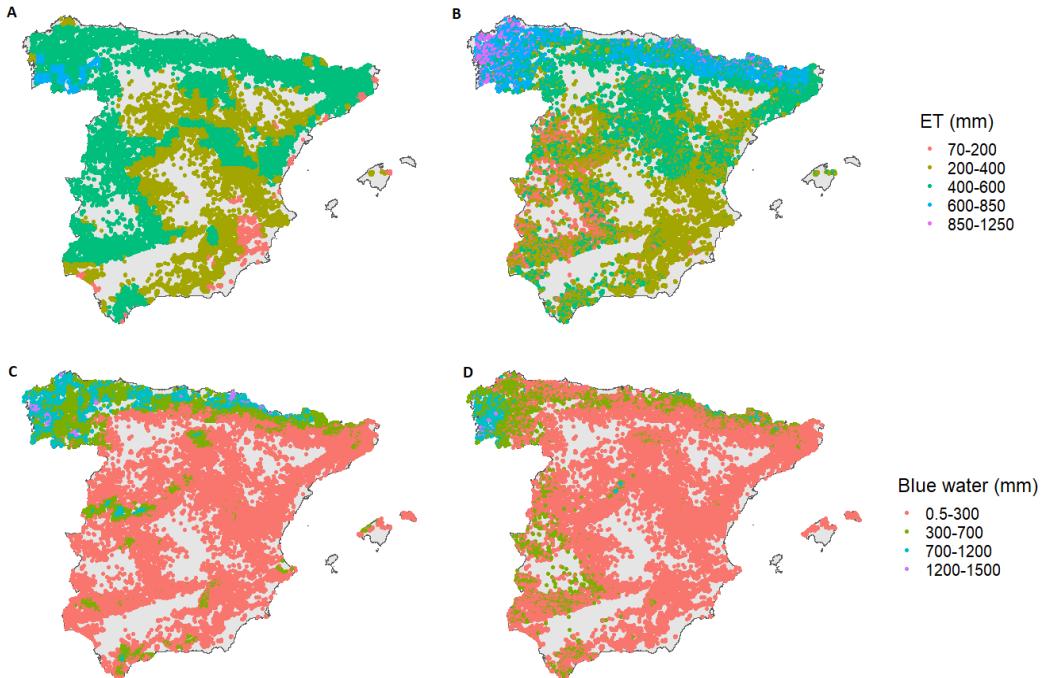

Figure 1. Average evapotranspiration (ET) maps for SFI3 plots according to GLEAM (A) and MEDFATE (B) (Spearman correlation=0.62,  $R^2=0.218$ ) and average blue water maps for SFI3 plots according to SIMPAL (C) and MEDFATE (D)

245

(Spearman correlation=0.70,  $R^2=0.354$ ).

### 3.2. Spatial patterns of blue water in the Spanish biomes

Forests with the highest absolute amount of blue water ( $> 500$  mm) were mostly concentrated in the coast of the Atlantic Sea and in the Pyrenees (Figure 2A). The south of the Spanish Peninsula in the Temperate Mediterranean biome and some areas inside the Continental Mediterranean biome had values between 300-500 mm. The rest of the country had lower blue water values ( $< 300$  mm), mainly in the eastern and Mediterranean regions. Relative blue water showed a very similar spatial pattern, with the highest values located in the coast of the Atlantic Sea and the Pyrenees (Figure 2B). In the southwest of Spain and in the Mediterranean mountain regions the relative blue water was also high ( $> 50\%$ ). Forests in the eastern Mediterranean region had the lowest values. The Arid and Continental Mediterranean biomes showed a very large percentage of plots ( $> 70\%$ ) with low relative blue water ( $< 15\%$ ), whereas the Atlantic and Alpine biomes showed higher plots ( $> 50\%$ ) with high blue water ( $> 30\%$ ) (Table S3). Temperate Mediterranean and Submediterranean biomes showed more intermediate values, although the Temperate had the percentage of plots with highest blue water ( $> 60\%$ ) among all

biomes. The results of the beta regression model and post-hoc Tukey's test indicated that there were differences among biomes in the percentage of blue water (Table 1, Figure 3, see Figure S5-S6 for interception and soil evaporation 260 differences): relative blue water was higher in the Atlantic and Alpine biomes (mean over 25 %) followed by the Temperate Mediterranean and Submediterranean biomes, with the Arid and Continental Mediterranean biomes showing the lowest values (mean of 10-15 %). The absolute values showed a similar pattern that the relative blue (see Figure S7).

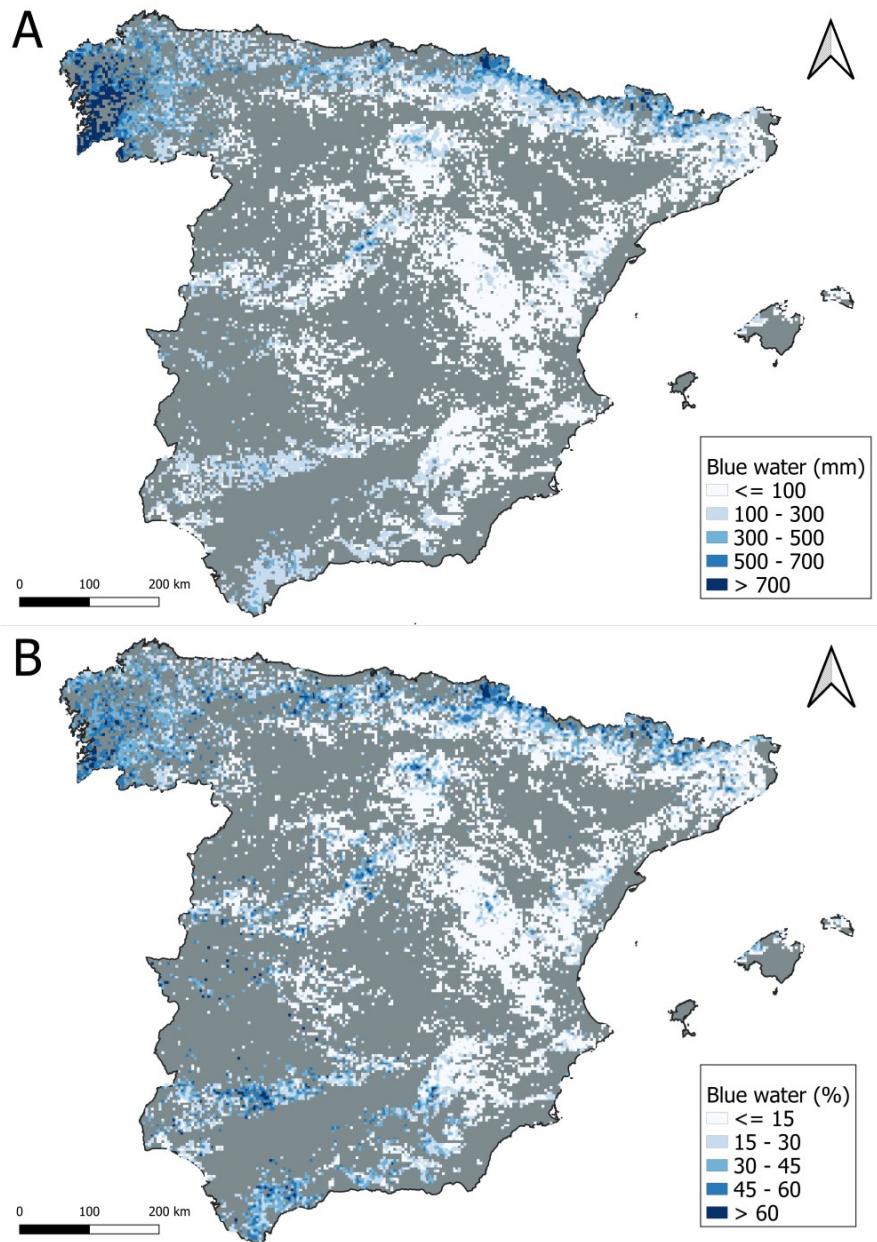

Figure 2. Total (A) and relative (B) blue water in the Spanish Peninsula and Balearic Islands. In grey, no forest covers. Maps were realized  
 265 with a rasterization of the SFI3 plots results at 1 km<sup>2</sup>.

Table 1. Results of the beta regression models on relative blue water (%): for the different biomes, indicating the estimate, standard deviation (SE), statistic and p-value of each of them. A positive value indicates that an increment occurred in the biome with respect to the observed values in the intercept.

| Variable                  | Estimate | SE   | Statistic | p-value |
|---------------------------|----------|------|-----------|---------|
| Intercept (Arid)          | -1.90    | 0.02 | -71.1     | < 0.001 |
| Temperate Mediterranean   | 0.49     | 0.02 | 17.6      | < 0.001 |
| Continental Mediterranean | -0.28    | 0.02 | -10.1     | < 0.001 |
| Submediterranean          | 0.22     | 0.02 | 7.8       | < 0.001 |
| Atlantic                  | 1.21     | 0.02 | 41.8      | < 0.001 |
| Alpine                    | 1.06     | 0.03 | 33.0      | < 0.001 |

270

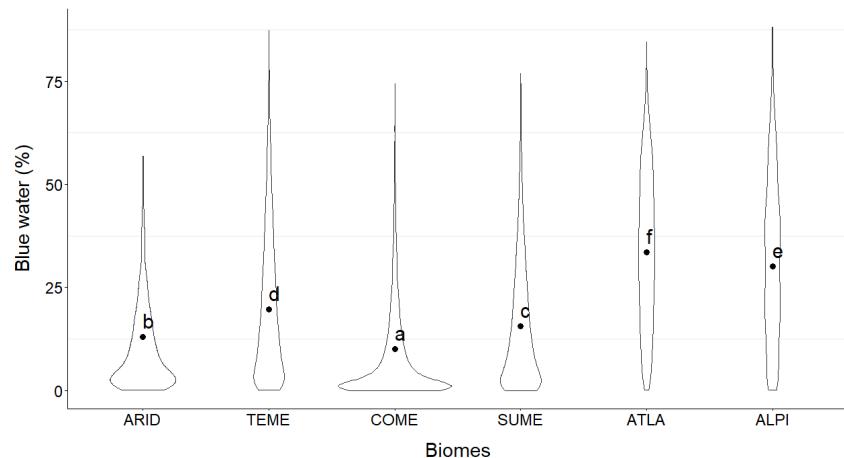

Figure 3. Percentage of blue water in the different biomes. Different letters denote significant differences among biomes ( $p<0.01$ ) after  
 285 Tukey's test. Abbreviations of the biomes: ARID, Arid; TEME, Temperate Mediterranean; COME, Continental Mediterranean; SUME,  
 Submediterranean; ATLA, Atlantic; ALPI, Alpine.

### 3.3. Patterns of blue water among forest functional groups

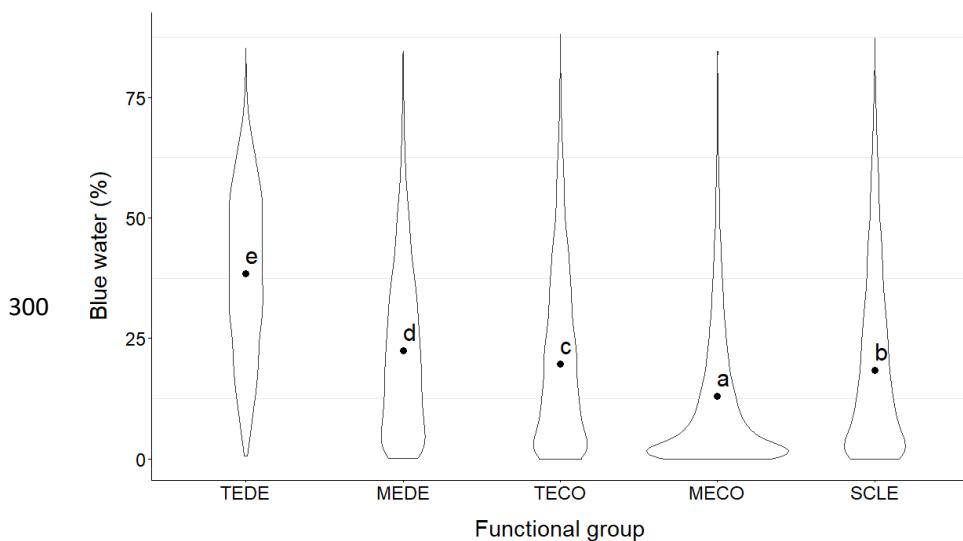

Beta regressions models and post-hoc Tukey's test indicated that there were also differences among functional groups in the percentage of blue water (Table 2, Figure 4, see Figure S8-9 for interception and soil evaporation differences).

290 Relative blue water was high in temperate deciduous (35 %) followed by temperate coniferous, Mediterranean deciduous and sclerophylls (20-25 %). Mediterranean coniferous had the lowest value (close to 10 %). The absolute values showed a similar pattern that the relative blue with the temperate deciduous with the highest values (see Figure S10).

Table 2. Results of the beta regression models on relative blue water (%) for the different forest functional groups, indicating the estimate, standard deviation (SE), statistic and p-value of each of them. A positive value indicates that an increment occurred in the functional group

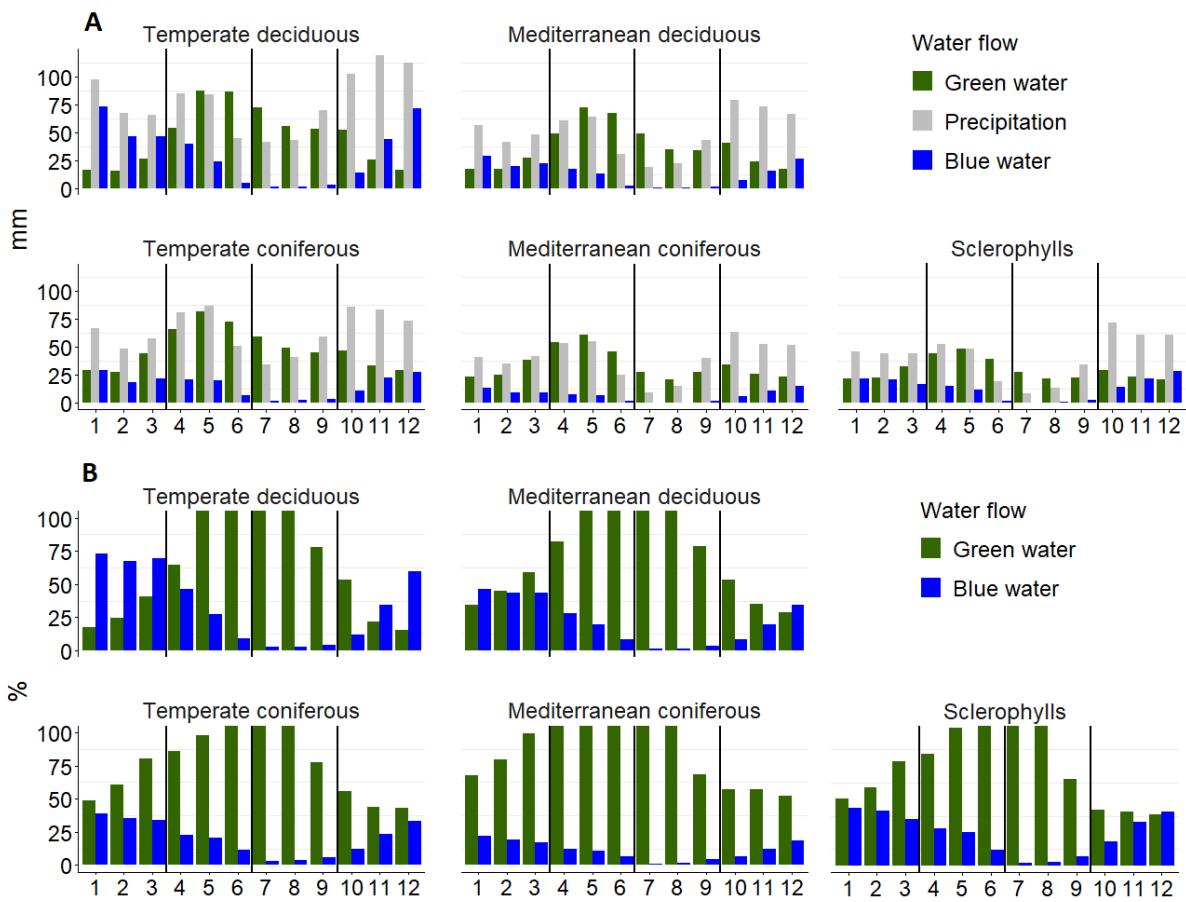

295 with respect to the observed values in the intercept.

| Variable                        | Estimate | SE   | Statistic | p-Value |
|---------------------------------|----------|------|-----------|---------|
| Intercept (Temperate deciduous) | -0.47    | 0.01 | -33.2     | < 0.001 |
| Mediterranean deciduous         | -0.76    | 0.02 | -33.7     | < 0.001 |
| Temperate coniferous            | -0.93    | 0.02 | -42.4     | < 0.001 |
| Mediterranean coniferous        | -1.42    | 0.01 | -85.7     | < 0.001 |
| Sclerophylls                    | -1.02    | 0.01 | -53.8     | < 0.001 |

305 Figure 4. Percentage of blue water of the different functional groups of species. Different letters denote significant differences among forest types ( $p<0.01$ ) after Tukey's test. Abbreviations of the functional groups: TEDE, Temperate deciduous; MEDE, Mediterranean deciduous; TECO, Temperate coniferous; MECO, Mediterranean coniferous; SCLE, sclerophylls.

The analysis of seasonality using monthly-aggregated data showed that the amount of blue water in forests of the different functional groups strongly varied throughout the year. In the Temperate deciduous forests, total blue water was  
310 higher than total evapotranspiration in autumn and winter (Figure 5A), whereas in other functional groups, the values of the two flows were similar along the year, except in spring-summer, when the green water was higher. In the Mediterranean coniferous forests, evapotranspiration was higher than blue water all year long. Relative flows showed that blue water was minimum in the summer season in all groups and higher than evapotranspiration only in autumn-winter in temperate deciduous forests (Figure 5B).

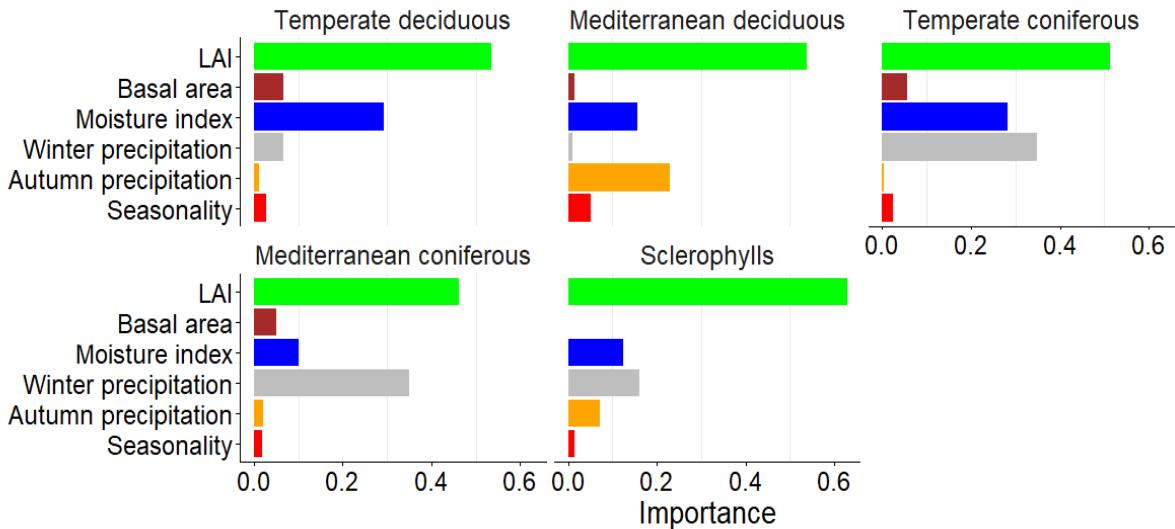

315

Figure 5. Total (A) and relative (B) green water and blue water, and total precipitation by different functional groups throughout the year. Note that evapotranspiration can be higher than precipitation during summer months, due to plant transpiration and bare soil evaporation of water available in the soil. Relative evapotranspiration has been truncated to 100 % of precipitation with the aim to improve the visualization of water export. A line marks the seasons in the months.

320 **3.4. Main drivers of the partitioning between blue and green water**

XGBoost models showed high accuracy, with  $R^2 > 75\%$  in most functional groups (Table S4). These analyses revealed that LAI was the most important predictor of relative blue water in all functional groups (Figure 6). The second and third most important variables were climatic moisture index and winter precipitation, except for Mediterranean deciduous, which was autumn precipitation (see Figure S11-12 for spatial variation of climatic moisture and winter precipitation). The 325 other variables retained in the models had low significance.

330 Figure 6. Average importance from Gain, Cover and Frequency values for every predictor variable retained in the XGBoost models for the  
335 functional groups.

Partial dependence plots showed that LAI had a strong and negative effect on relative blue water (Figure 7). Nevertheless, this effect was different depending on the functional group. The temperate deciduous forest showed the highest percentage of blue water for the whole LAI gradient, being always with a value over 20 %. The other forest types showed similar patterns among them, with a larger drop until  $LAI < 3$  and values around 10 % afterwards. The only exception was the group of Mediterranean conifers, which showed lower % of blue water than the other groups throughout the LAI gradient. Climatic moisture index showed a positive effect in all groups. The three angiosperm groups had similar slope and showed higher values than the two gymnosperm groups (Figure 7B). Winter precipitation had a positive effect in all functional groups except in the Mediterranean deciduous (Figure 7C). Temperate deciduous forests showed higher values through the whole winter precipitation gradient.

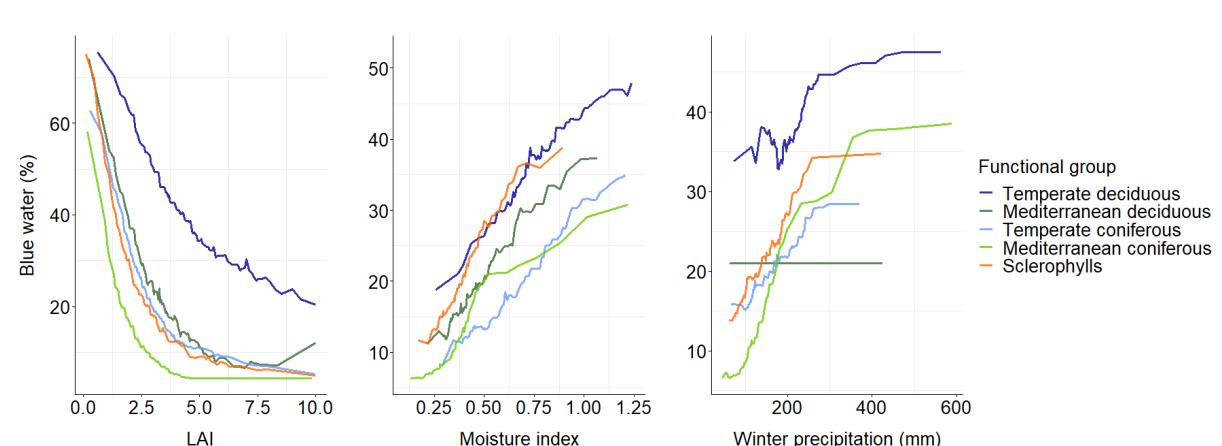

Figure 7. Partial dependence plots for the three main predictor variables (A, LAI; B, Climatic moisture index; C, Winter precipitation) and their effect on blue water percentage for the different functional groups.

#### 4. Discussion

##### 355 4.1. Spatio-temporal patterns

Blue water spatial patterns showed that most Spanish forests have a proportion of the precipitation below 15 % as blue water (Figure 3). This pattern was expected, since most of the Spanish forests are in Mediterranean climate, and in these dry environments the evaporative demand is high and the majority of water evapotranspired or intercepted by the canopy (Ungar et al., 2013). In contrast, in the Atlantic and alpine biomes, the proportion of rainfall as blue water can be higher than 360 25 %, because these biomes are wetter and colder than the Mediterranean and, thus, the evapotranspiration is lower and precipitation is higher (Kosugi and Katsuyama, 2007; Mastrotheodoros et al., 2020). Moreover, in some mountain areas in the continental Mediterranean biomes (e.g., Sierra Nevada, Sierra de la Demanda), the amount and proportion of blue water is also high (Figure 2A, 2B). These regions are wetter than the rest of Mediterranean biomes and an increase of precipitation determines an increase in blue water (Helman et al., 2017). Interestingly, in other areas of southern Spain, in the temperate 365 Mediterranean biome, the proportion of blue water can also be higher than 20 % (e.g., Sierra Morena; Table S3), not because they have a higher rainfall but because this biome has very open forests, with LAI values lower than the rest of biomes (Table S1). Transpiration is the main component of the green water in arid environments and decrease in wetter regions where the interception increases their importance (see Figure S13). This result is concordant with the global patterns of green water flux where the transpiration is bigger in arid environments (Good et al., 2017).

370 The analysis of seasonal dynamics by forest type showed that, in forests of all functional groups, there is more blue water during autumn and winter months. In contrast, the evapotranspiration was higher in spring-summer. In Mediterranean climates there is a decoupling between rainfall and temperature (Baldocchi and Xu, 2007), with higher rainfall in spring and autumn and higher temperatures in summer. For this reason, plants have more photosynthetic activity and growth in spring (when rainfall is high) and more transpiration in summer (when temperature is highest) (Baquedano and Castillo, 2006; Link 375 et al., 2014), when trees use the groundwater stored in the soil (Jost et al., 2005). Water loss by run off or deep drainage is higher in autumn-winter because water is not fully exploited by the forest in this lower-photosynthetic period and, thus, green water is lower than would be possible by falling rain (Helman et al., 2017; Williams et al., 2012). According to our results (Figure 5) blue water is concentrated in this period of lower or dormant vegetation activity (i.e., late autumn and winter).

## **4.2. Differences of blue water between forest functional groups**

The analysis of the percentage of blue water of the different functional groups of species showed that temperate deciduous forests had the highest value, followed by Mediterranean deciduous forests (Figure 4). The rest of forest types had lower values (Figure 4), mainly the Mediterranean coniferous, which have shown a high green water of almost 90 %, as also observed in studies at the plot level (Ungar et al., 2013). The seasonal dynamics of these flows in the different forest types show that deciduous forests have more blue water in autumn and winter months than evergreen forests (Figure 5). This indicates that the main factor that explains the differences in relative blue water between forest types is the shedding of leaves (or its lack of shedding) during the cold part of the year. Although deciduous trees are mainly water-spender since their transpiration is higher than that of evergreens (Baldocchi et al., 2020), they shed their leaves in autumn and their interception and evapotranspiration are lower than those of evergreens in autumn/winter (Figure 5). Moreover, due to their shape coniferous needles intercept more the rainfall than the deciduous ones for the same area of leaves (Carlyle-Moses, 2004). Although green water is higher in deciduous than in evergreen forests in summer (Figure 5), total annual blue water seems to be more determined by leaf phenology, which conditions the destination of the autumn-winter precipitation and determines the differences between deciduous and evergreen forests. Also, climate partial plots showed that at the same level of climatic moisture index and winter precipitation, deciduous forests have greater relative blue water than coniferous and sclerophylls (Figure 7B-C).

But once the differences between deciduous and evergreen forests are highlighted, the next aspect that stands out when comparing the different types of forests is that, for each category of leaf phenology, the proportion of blue water depends mainly on climate. Thus, temperate deciduous forests have more relative blue water than Mediterranean deciduous ones (Figure 4). Temperate deciduous forests, which are the ones exporting most blue water in relation to their precipitation, are mainly concentrated in the Atlantic and alpine biomes, where precipitation is higher and transpiration is lower, while Mediterranean deciduous forests are concentrated in Mediterranean biomes, where precipitation is lower and transpiration is higher (Table S2). The same pattern happens in evergreen forests: temperate coniferous forests have percentage of blue water higher than Mediterranean coniferous forests because precipitation in the biomes where they are more abundant is also higher than in the Mediterranean. The lowest value of blue water in Mediterranean coniferous forests is particularly relevant, because this is the most abundant forest type in Spain, and it is predominant in the Mediterranean biomes (Table S1). Finally, sclerophyll forests produce more blue water than Mediterranean coniferous forests, although both are situated in Mediterranean biomes and are evergreen. Sclerophyll forests have higher transpiration than Mediterranean coniferous ones (del Campo et al., 2019; Sánchez-Costa et al., 2015) but the total LAI of their stands is lower (Table S2), which determines the different pattern obtained (as explained in the next section).

## **4.3. Differences in stand structure determining blue water**

The analysis of the drivers affecting relative blue water showed that LAI is the most important predictor of blue water (Figure 6). In our simulations, relative blue water was often very high (> 60 %) when LAI was < 1. Transpiration and 415 interception are higher when the LAI of the stand is higher and, therefore, the water is transpired and intercepted by leaves. But the temperate deciduous forests showed higher blue water for the same LAI values. Deciduous trees present higher evapotranspiration than evergreens at the same level of LAI (Baldocchi et al., 2010) but, as described previously, LAI effect is modulated by leaf phenology, since blue water in these forests is concentrated in winter. When LAI is very low, evergreen 420 forests can show a higher relative blue water. For instance, the temperate Mediterranean biome showed more % of plots with a higher relative blue water than Atlantic or alpine biomes (Table S3) because the mean LAI of their forests is lower than the rest of biomes (see Table S1). This points out the importance of stand structure and composition, since in a drier environment, LAI values higher than 2-3 sq m/sq m can strongly reduce the relative blue water. This effect is higher if the forest is evergreen, which is the predominant type in the Mediterranean. Relative blue water of Mediterranean deciduous 425 forests is higher than that of evergreens, because a decrease of LAI in evergreen forests decreases tree transpiration but increases evaporation from the soil surface, which is high in the Mediterranean climate even in winter (Raz-Yaseef et al., 2010). Management of blue water in forests has been focused in modifying the basal area of the stand (del Campo et al., 2014). Nevertheless, in this study basal area was a limited predictor of the blue water in comparison with LAI. LAI of the stand increases with basal area until a threshold and then it remains stable (Figure S14). Although the increase of basal area 430 through time reduces blue water (Caldwell et al., 2016), a plateau is expected in the long term, since LAI will not increase more after a maximum is reached. For this reason, blue water did not reduce excessively when LAI was higher than 3 (Figure 7A). The reduction of basal area in the forest through thinning is a recurrent way of increasing blue water (Ameztegui et al., 2017; del Campo et al., 2018; Simon and Ameztegui, 2023), but this non-linear relationship between basal area and LAI implies that only a heavy management for reducing basal area would be effective for reducing the LAI of the stand and, thus, increasing blue water.

435

#### 4.4. Limitations

Model simulations to estimate water flows is not the same as observing them and can lead to artifactual results. In this sense, it is necessary to continue improving the ecohydrological model design parametrization to improve their accuracy, including the completion of traits of many species for the parameterization, a better soil database, or the inclusion of lateral 440 water flows (in the case of MEDFATE model). Model evaluation is another key aspect to increase realism and usefulness of predictions. The model MEDFATE has been validated in Mediterranean forests at local scale with field ground data, but it has not been validated at country scale with field data like eddy flux or sap flow data, and it might have lower accuracy in the Atlantic or alpine biome or with some tree species. Nevertheless, the comparison between MEDFATE results and another land surface products showed a similar regional patterns. Despite accepting these limitations, the lack of field data at 445 bigger scales encourages the use of models to study water flows at country or continental scale.

## 5. Conclusion

Ecohydrological models like MEDFATE allow to model different species and stand structures, improving our insights about the role of forests in water flows. Thus, we can split the fluxes of water at stand level and understand the role 450 of species, climate and stand structure variables in the different water flows: transpiration, interception, runoff, etc. Moreover, the incorporation of forest inventories to these models allows to do analyses at large spatial scales across multiple climates, forest typologies and species composition. In the current context of global change, the knowledge of water fluxes in forests is essential to be able to define strategies to improve the water budget, and especially in dry environments like the 455 Mediterranean, where water is scarce and the previsions are in the line of increasing drought periods. Thus, in the context of global change we are suffering (Hoerling et al., 2012; Lionello et al., 2014), the low amount and proportion of blue water in great part of Spain is an important problem in the water supply for the agriculture or human consumption in the region (Ellison et al., 2012). The consequences that this lack of blue water might have on the entire silvoagropastoral system in the whole region, aggravated by the harsher conditions expected in the future, should make us reflect on what kind of forest management could be more effective in the next decades.

460

**Code availability.** The model code of MEDFATE is available at <https://github.com/emf-creaf/medfate>. The MEDFATE model code is explained in De Cáceres et al. (2023).

**Data availability.** Spanish forest inventory data are available at <https://www.miteco.gob.es/es/biodiversidad/temas/inventarios-nacionales/inventario-forestal-nacional/>.

### 465 Author contributions:

JSD, MC, JV and JR contributed to the study conception and design. JSD conducted the modelling with the support of MC. JSD wrote the manuscript with the assistance of the rest of the authors. All authors discussed the results and edited the manuscript.

### Competing interests:

470 The authors declare that they have no conflict of interest.

### Acknowledgements

The present study was supported by the Spanish Ministry of Science and Innovation project “GREEN-RISK” (PID2020-119933RB-C21/AEI/10.13039/501100011033) and “BOMFORES” (PID2021-126679OB-100/AEI/10.13039/501100011033).
