Abstract. Accurate assessment of the probable maximum precipitation (PMP) is crucial in assessing the resilience of high-risk water infrastructures, water resource management, and hydrological hazard mitigation. Conventionally, PMP is estimated based on a static climate assumption and is constrained by the insufficient spatial resolution of ground observations, thus neglecting the spatial heterogeneity and temporal variability of climate systems. Such assumptions are critical, especially for China, which is highly vulnerable to global warming in the premise of existing ~100,000 reservoirs. Here, we use the finest spatiotemporal resolution (1d & 1km) precipitation dataset from an ensemble of machine learning algorithms to present the spatial distribution of 1d PMP based on the improved Hershfield method. Current reservoir design values, a quasi-global satellite-based PMP database, and in-situ precipitation are used to benchmark against our results. The 35-year running trend from 1961-1995 to 1980-2014 is quantified and partitioned, followed by future projections using the Coupled Model Inter-comparison Project Phase 6 simulations under two scenarios. We find the national PMP generally decreases from Southeast to Northwest and is typically dominated by the high variability of precipitation extremes in North China and high intensity in South China. Though consistent with previous project design values, our PMP calculations present underestimations by comparing with satellite and in-situ results due to differences in spatial scales and computation methods. Inter-annual variability, instead of the intensification of precipitation extremes, dominates the PMP running trends on a national scale. Climate change, mainly attributed to land-atmosphere coupling effects, leads to the widespread increase (>20%) of PMP across the country under the SSP126 scenario, which is projected to be higher along with the intensification of CO₂ emission. Our observation- and modeling-based results can provide valuable implications for water managers under a changing climate.

1 Introduction

Over the past six decades, an increase in the frequency and intensity of extreme precipitation events have been documented in both observation- (Guerreiro et al., 2018; Martinez-Villalobos & Neelin, 2018; Visser et al., 2022; Zhao et al.,

30 2023) and modelling-based studies globally (Donat et al., 2016; Kendon et al., 2017; Kunkel et al., 2013; Zhao et al., 2022).
31 This increase will relatively be more pronounced in the majority of the regions worldwide in a warming climate (Hirabayashi
32 et al., 2013; IPCC, 2021; Kim et al., 2022), leading to the enhanced risk of the consequent floods and the associated multi-
33 sectoral damage. Global damages due to floods amounted to an estimated \$651 billion (USD) between 2000 and 2019 alone,
34 which could increase by a factor of 20 by the year 2100 (Devitt et al., 2023; Winsemius et al., 2016). Traditional estimates of
35 such precipitation extremes and subsequent applications reliant on precipitation-sensitive information (e.g., flooding designs)
36 have primarily relied upon the stationary climate assumption, which is inadequate for a large duration and in the warming
37 climate (Visser et al., 2022). Another crucial application is Probable Maximum Precipitation (PMP), which is key to assessing
38 the resilience of high-risk water infrastructures such as large dams and nuclear power plants, efficient water resource
39 management, and impact assessment and strategic management of hydrological hazard adaptation and mitigation.

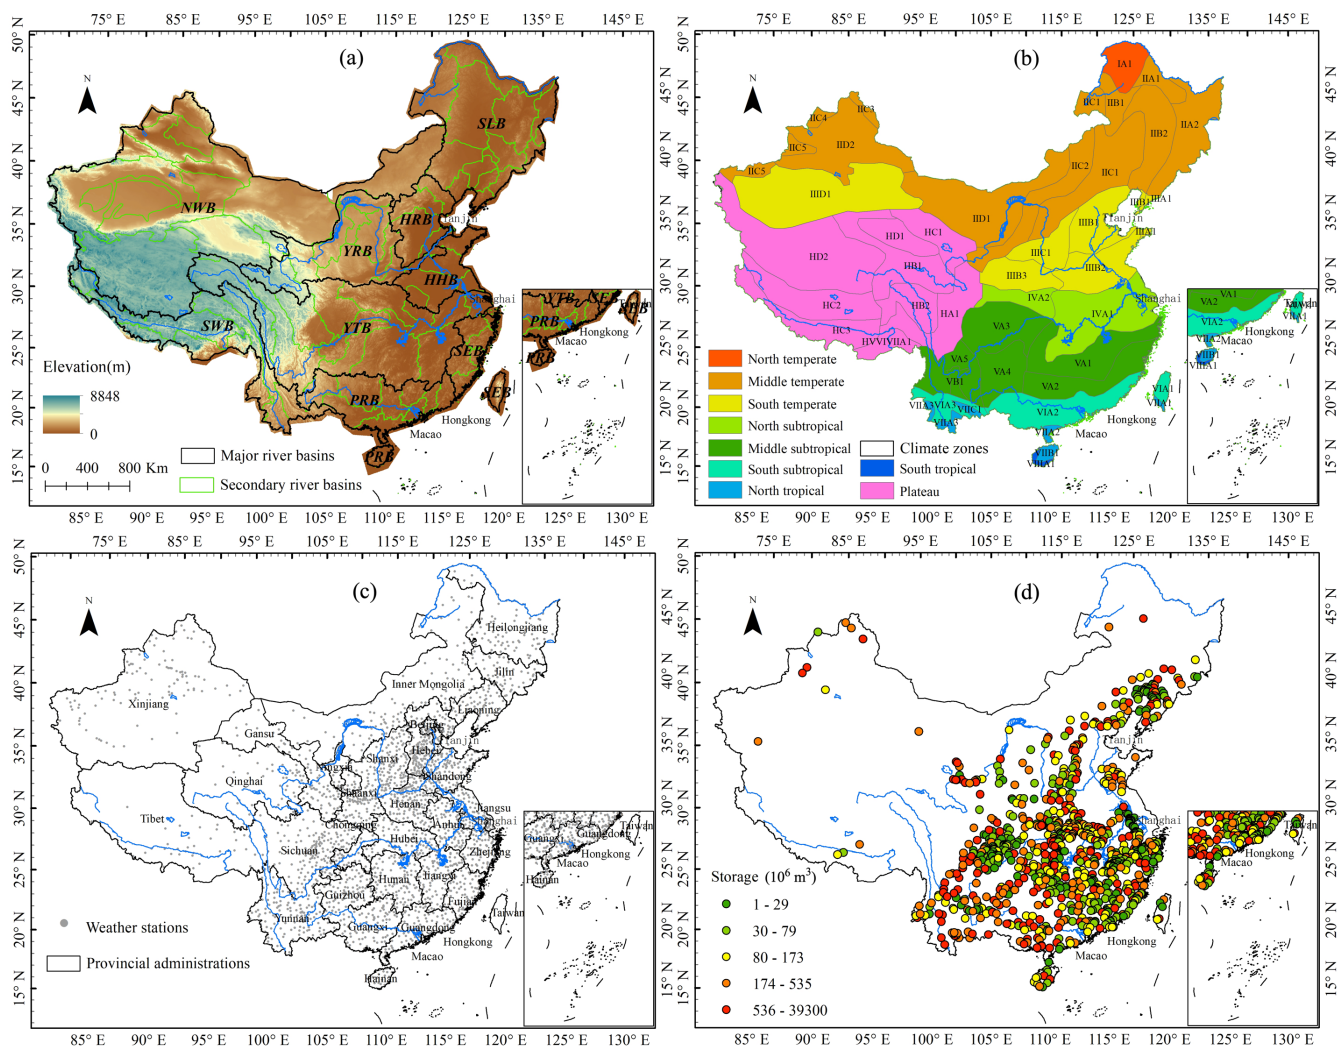

40 PMP, defined as the theoretical maximum precipitation for a given duration under modern meteorological conditions by
41 the World Meteorological Organization (WMO), represents the upper limit of precipitation that is meteorologically possible
42 over a watershed or a storm area of a given size at a certain time of a year (WMO, 2009). As an indicator of regional storm
43 risks, PMP is physically dependent on various meteorological factors such as available atmospheric moisture content, moisture
44 transportation efficiency, and persistent upward strength (Trenberth et al., 2003). In addition to the traditional flood frequency
45 analysis method, PMP also serves as the most severe condition to estimate the associated theoretical maximum flood for a
46 certain project in the area (Hansen, 1987). Therefore, it plays a significant role in both the design of hydraulic structures (e.g.,
47 dams, reservoirs) and routing infrastructure and the assessment of regional weather hazards (e.g., storms) (Luo et al., 2018).

48 An underlying prevalent assumption of PMP estimation is the stationary climate leading to a static PMP value from
49 observed meteorological data, such as wind speed, precipitation, and dewpoint, and maximized using empirical techniques,
50 meaning there is only a fixed PMP on a specific spatiotemporal scale (Visser et al., 2022; WMO, 2009). However, it has been
51 significantly challenged when both observations and models show that the above key factors, i.e., wind and moisture, in
52 forming PMP can change due to climate change and internal variability (Lalk, 2004; Mudd et al., 2014; de Winter et al., 2013;
53 Gimeno et al., 2019; Richter and Xie, 2010; van Dilke et al., 2022). For example, the warming climate-induced increase in
54 atmospheric moisture availability may favour the formation of extreme storm events (Liu et al., 2020). Besides, the natural
55 climate variability from annual to decadal scales (e.g., ENSO) may impact the accurate maximization of regional precipitation
56 extremes, particularly with limited record length (Kenyon and Hegerl, 2010). A few previous studies have discussed the
57 impacts of changing climate on PMP estimations over different regions of the world using global and/or regional climate
58 models (Beauchamp et al., 2011; Rousseau et al., 2014; Rouhani and Leconte, 2016; Afrooz et al., 2015; Park et al., 2013; Lee
59 and Kim, 2016; Visser et al., 2022). Specifically, Jakob et al. (2009) performed an early investigation in Australia and reported
60 increases in moisture availability in coastal regions that had tendencies to experience further projected increases under climate
61 change. A global assessment from Kunkel et al. (2013) projected that future PMP values might intensify in the United States,
62 contributed mainly by the higher levels of atmospheric moisture content. These projected PMP values showed a 20%~30%
63 increase in the United States by the end of the 21st century under a high gas emission scenario. Similar growth caused by a

64 changing climate has been documented in India, Spain, and other parts globally (Sarkar and Maity, 2020; Monjo et al., 2023).
65 However, opposite patterns were also reported in a few regions, possibly due to the reduced actual moisture availability and
66 wind speed by atmospheric dynamic constraints (Afzali-Gorouh et al., 2022; Yin et al., 2023). These inconsistent and
67 contradictory findings imply the complicated mechanism and uncertainty in PMP estimations across regions and underscore
68 the need for a holistic qualification of PMP considering non-stationary climate and at finer spatiotemporal scales.

69 Despite that the changeable PMP under a changing climate has attracted wide attention from hydrologists, most of the
70 previous studies primarily focus on the static scenario comparisons between history and the future (Jakob et al., 2009; Kunkel
71 et al., 2013; Sarkar and Maity, 2020; Monjo et al., 2023; Afzali-Gorouh et al., 2022). Since the return periods corresponding
72 to the PMP values outpace the longest return periods traditionally used in applied climatology products, major water retention
73 and routing structures will likely experience the acute impact of climate change. It thus highlights the elusive sense of security
74 inferred from the assessments ignoring the climate-change-induced probabilities of extreme events (Kunkel et al., 2013).
75 Furthermore, the gradual transformation of the past climate and the partitioned contributions from various climate change
76 sources also remain largely unexplored in the literature. Accounting for such realistic and crucial attributes and mechanisms
77 is thereby necessary and topical, particularly for China, which has experienced persistent precipitation disasters over the past
78 few decades (Gu et al., 2022). Covering a wide range of geophysical elevations and climate zones (Figures 1a and 1b), the
79 country has faced increasingly significant spatial heterogeneities in extreme precipitation (Sun et al., 2017). It implies the
80 potentially intensified hydrological risk in different regions, which is more evident given the approximately 100,000 dams and
81 reservoirs constructed until 2015, mainly for flood control (Figures 1c and 1d, MWR, 2016; Song et al., 2022). However, the
82 systematic investigation of PMP in China was previously limited by inadequate spatiotemporal resolution and duration of
83 precipitation measurements over the country and related climate modelling experiments.

84 Here, for the first time, we use the precipitation dataset with potentially the finest spatiotemporal resolution (1d & 1km)
85 covering 1961-2014 to calculate the long-term average PMP distribution in China using the modified statistical method. The
86 national estimations of PMP are benchmarked with a quasi-global PMP dataset based on satellite products and in-situ data
87 from 2417 weather stations across the country (Figure 1c). The historical tendency in changing PMP is detected based on a
88 35-year running window method (consistent with the period of historical run of global climate models during 1980-2014).
89 Moreover, the respective contribution from climate change and internal variability to the PMP variability is partitioned. The
90 role of land-atmosphere coupling, which is an important contributor to climatic extremes, is further evaluated via an ensemble
91 of global climate models. Finally, we project future changes in PMP in both the near and far future periods in both low-
92 emission and high-emission scenarios relative to the baseline period (i.e., 1980-2014). All the results are separately discussed
93 on different scales from river basins to country for efficient and effective policymaking inferences for the regional to national
94 water managers.

95

96 **Figure 1: (a)** The national map, major rivers, major river basin boundaries, and 1-km elevation of China. The digital elevation map
 97 is provided by A Big Earth Data Platform for Three Poles (Tang, 2019). The divisions of nine major river basins excluding a few
 98 coastal islands are provided by the Resource and Environment Science and Data Centre of China (<https://www.resdc.cn/>),
 99 which include Haihe River basin (HRB), Yellow River basin (YRB), Huaihe River basin (HHB), Yangtze River basin (YTB), Southeast
 00 basin (including Taiwan Province, SEB), Pearl River basin (including Hainan Province, PRB), Northwest basin (NWB), Southwest
 01 basin (SWB), and Songhua and Liaohe River basin (SLB). The divisions of the 80 major secondary river basins outlined in green
 02 colour are based on the regulations for the compilation of water resources protection planning of the Ministry of Water Resources
 03 (GIWRHPD et al., 2013). (b) The climate zones of China are produced by the China Meteorological Administration. The map is
 04 accessible on the Resource and Environment Science and Data Centre of China (<https://www.resdc.cn/>), which is calculated using
 05 the national daily temperature and water measurements. The inserted abbreviations in the map represent the secondary climate
 06 zones, and more details can be found in previous references (Zhu, 1962; WCNR, 1959; Zhu, 1931). (c) The provincial administrative
 07 regions and locations of 2417 weather stations of China. The national map and provinces are made under the guidance of the
 08 standard map service of the Ministry of Natural Resources of the People's Republic of China (<http://bzdt.ch.mnr.gov.cn/index.html>).
 09 (d) The spatial distribution of 933 dams and reservoirs included in the Global Reservoir and Dam Database (GRaND) in China
 10 (Lehner et al., 2011).

11 **2 Materials and Methods**

12 **2.1 High-resolution precipitation data**

13 A daily gridded precipitation data at a fine 1km spatial resolution covering the period 1951-2014 (namely the HRLT
14 dataset) is used to estimate PMP over China (Qin et al., 2022). The HRLT precipitation data were interpolated using the best
15 ensemble among various machine learning methods (i.e., boosted regression trees, random forests, neural network, multivariate
16 adaptive regression splines, support vector machines, and generalized additional models; see Qin et al., 2022 for details) from
17 the $0.5^{\circ} \times 0.5^{\circ}$ observation-derived gridded precipitation from the China Meteorological Administration. Multiple external
18 variables related to elevation, location, topography, and climate conditions have also been combined for HRLT data
19 preparation (Zhao and Zhu, 2015). The superior spatial resolution of the HRLT dataset (i.e., 1 km) can prevent the effects of
20 spatial heterogeneity in regional climate conditions on grid-scale PMP estimations. Apart from the major advantages of a
21 longer period (1951-2019) and higher resolution, it has shown better accuracy than other widely used meteorological datasets
22 in China like the China Meteorological Administration Land Data Assimilation System (CLDAS, from 2017 to 2019 with ~ 7.5
23 km resolution) version 2 and China Meteorological Forcing Dataset (CMFD, from 1979 to 2018 with ~ 12 km resolution) (Shi
24 et al., 2014; He et al., 2020). However, we selected the period 1951-2014 in this study to avoid the several unrealistic high
25 precipitation values starting the year 2015 in the HRLT due to errors in the raw precipitation records, which could consequently
26 lead to significant PMP overestimations (see Table S1 for details). Moreover, the locations and basic attributes (e.g., year of
27 construction, year of decommissioning, and storage capacity) of dams and reservoirs from China are collected from the GRanD
28 dataset (Lehner et al., 2011) to analyse the temporal variations of total storage capacity of China. It is calculated as the ratio
29 between the total storage capacity of dams within a certain region (e.g., river basin and the whole country) to the area, with
30 the same unit as our PMP estimations (i.e., mm). Years of construction and decommissioning are also considered in the
31 computation. The GRanD dataset contains a total of 7320 dams worldwide based on the existing global lakes and wetlands
32 database and national/continental statistics from different sources, of which 933 are located in China (Figure 1d). All the
33 records of the GRanD dataset are georeferenced and have undergone manual inspection and validation to avoid spatial
34 inconsistency (between locations and attributes of dams) and redundancy. Since it only considers the dams with large sizes
35 ($>0.1 \text{ km}^3$), the number of included dams in China is much less than other similar collections (e.g., 97435 dams in CRD, see
36 Song et al., 2022). However, the total storage capacity of dams in GRanD (670 km^3) accounts for $\sim 70\%$ of the CRD (980 km^3),
37 the latter of which does not contain the necessary attributes for temporal analysis (e.g., year of construction). By comparing
38 the changes in PMP and the available storage capacity of dams with time, we can qualitatively measure the total capability of
39 anthropogenic efforts to store water from extreme precipitation. A higher difference between PMP and total dam storage
40 capacity means more water cannot be stored in the basin reservoirs (needs to be consumed via evaporation and/or streamflow),
41 and therefore, greater potential to translate to regional floods.

42 **2.2 Validation of PMP estimations**

43 Two independent data sources are collected to validate our 1d and 1 km PMP estimations using the HRLT dataset,
44 including a quasi-global PMP dataset based on remote sensing products and a suite of national PMP results using in-situ
45 precipitation records. The quasi-global PMP dataset is calculated based on the Integrated Multi-satellite Retrievals for GPM
46 (Global Precipitation Measurement, namely GPMM hereafter) during 2000-2022 using the conventional Hershfield method
47 (Ekpetere et al., 2023). GPMM applies two existing corrections for the removal of the inversion problem caused by the
48 relatively short period of IMERG product (i.e., 23 years) and for the correction of missing maximum precipitation samples. It
49 has shown reasonable accuracy compared with NOAA ground gauges in Kansas, USA, from various time scales of 30 minutes
50 to 24 hours (Ekpetere, 2021). Though sharing the same 1d timescale with the PMP estimations using HRLT, several key
51 differences between GPMM and our methods are worth mentioning. First, the GPMM is calculated using the classic Hershfield
52 algorithm combined with two statistical corrections above, which is different from our modified Hershfield algorithm (see
53 details in Section 2.3). Second, the spatial scale of the GPMM is 0.1° (~11 km at the equator), which is much coarser than the
54 HRLT dataset (1 km). Third, the period used for calculation in GPMM is 2000-2022, which is much shorter than our
55 estimations that are based on HRLT data from 1961-2014. We additionally calculate the 1d PMP purely based on in-situ daily
56 precipitation during 1961-2014 from 2417 weather stations of the country using the same modified Hershfield method (Figure
57 1c). The raw precipitation observations are provided by the China Meteorological Administration
58 (<https://www.cma.gov.cn/en2014/m/pc/>) and the Resources and Environmental Science Data Centre, Chinese Academy of
59 Sciences (<http://www.resdc.cn/>, last access: 29 October 2023) upon research request. Despite the strict quality control (e.g.,
60 inspection of unphysical records) performed by the data providers, the spatial distribution of in-situ stations is uneven. The
61 number of available data decreases from south-eastern to north-western parts of China, especially in the Qinghai-Tibetan
62 Plateau due to extreme natural environments to install and maintain the measuring stations. We use the bilinear interpolation
63 method to extrapolate the PMP results based on the HRLT dataset to the locations of each grid cell of the GPMM and each
64 field station of the precipitation network to facilitate inter-comparisons. The same procedure is repeated between GPMM and
65 the in-situ precipitation results for better justification of our HRLT-based PMP estimations. However, we note such spatial
66 interpolation may introduce significant bias for the comparison of PMP estimations at different resolutions (Rajulapati et al.,
67 2021), in addition to the systematic differences implicit to the methods and data sources (e.g., gauge vs satellite data).

68 **2.3 Statistical estimation of PMP**

69 The methods of estimating PMP are generally classified into meteorological methods and statistical methods. The
70 essence of the meteorological methods is the maximization of moisture factor and/or dynamic factor for a typical storm or an
71 ideal storm model. However, it requires abundant hydro-meteorological data like dew point temperature and wind speed (Wang,
72 1999). The statistical approach is therefore recommended by WMO owing to its simplicity since it only needs precipitation
73 data (WMO, 2009; Casas et al., 2008; Yang et al., 2018). The traditional statistical method was originally developed by

74 Hershfield (Hershfield, 1961) based on Chow's frequency equation where a quantile of a probability distribution is expressed
 75 as a function of the mean, standard deviation, and a frequency factor K_m (Chow, 1951). The frequency factor K_m was estimated
 76 based on records of 24-h rainfall for 2700 stations in the United States (90% of the total stations) and subsequently modified
 77 to account for the effects of the sample size, outliers, and the difference between daily maximum and 24-h recorded data set
 78 (Hershfield, 1965, 1977). Salas et al. (2020) pointed out that the Hershfield method needs proper modification for applications
 79 in different climatic zones. Here, we employ an adjusted approach that has been widely applied for PMP design in China with
 80 the sampling bias and calendar day errors corrected (Lin, 1981; Hershfield, 1961):

$$81 \quad PMP = (1 + K_m \cdot C_v) \cdot X'_n \quad (1)$$

$$82 \quad X'_n = \left(1 + \frac{3 \cdot C_v}{\sqrt{n}}\right) \cdot X_n \quad (2)$$

$$83 \quad C_v = \frac{\sigma_n}{\bar{X}_n} \quad (3)$$

$$84 \quad K_m = \frac{X_m - \bar{X}_{n-1}}{\sigma_{n-1}} \quad (4)$$

$$85 \quad T_m = \frac{X_m - \bar{X}_n}{\sigma_n} \quad (5)$$

$$86 \quad N_m = T_m^2 + 2 \quad (6)$$

87 where Eqs. (1) – (4) represent the generalized formula of Hershfield's algorithm (Hershfield, 1961), which is based on the
 88 product of mean annual maximum precipitation and the maximization factor K_m . X_m is the annual maximum precipitation
 89 series, and $\sigma_n(\bar{X}_n)$ is its standard deviation (mean) value, with $\sigma_{n-1}(\bar{X}_{n-1})$ meaning the same as the series but excluding the
 90 maximum value. Lin (1981) revised the expression of X_n to correct the sampling error in averaging annual maximum
 91 precipitation (X'_n). C_v is the coefficient of variation of the annual maximum precipitation series. An additional constraint is
 92 given to the ultimate PMP estimations in Eqs. (5) – (6) to determine if the length of the precipitation series has satisfied the
 93 requirement to capture the inter-annual variability of precipitation extremes, serving as quality checks of PMP results. We
 94 perform all the PMP calculations for each 1 km grid of China, which can reasonably be considered as a hydro-meteorological
 95 homogeneous region to capture consistent characteristics of precipitation extremes. The ultimate PMP estimates are
 96 additionally multiplied by 1.13 to reflect the influences of a single fixed precipitation record frequency on yielding true maxima
 97 (WMO, 2009). The above computations are performed for each 1 km grid cell over the country (~1,400,000) during each
 98 running period, generating a comprehensively high-resolution and time-varying detection of national PMP (see details in the
 99 next section). Apart from the traditional statistical methods to calculate PMP, many other methods have been proposed to
 00 describe the probabilistic nature of extreme precipitation events, though the assumptions are shown to be unrealistic (Salas et
 01 al., 2014).

02 2.4 Detection and partition of PMP trends

03 Given the fact that the changing climate may influence the PMP estimates of a specific region over a specific period, we
04 separately compute the PMP of each grid during different 35-year running windows (i.e., 1961-1995, 1962-1996, ..., 1980-
05 2014). It is selected to be consistent with the period of the historical run of global climate models during 1980-2014 (refer to
06 Section 2.5 for details). We consequently obtain a total of 20 subsets of PMP estimations for each 35-year period during 1961-
07 2014, which are subsequently used to calculate trend slopes using the linear regression method, with the significance level
08 identified based on Mann Kendall's Z -statistics (5% in our study) (Xiong et al., 2020; Mann, 1945; Yin et al., 2021).
09 Furthermore, looking back at Eq. (1), we reformulate the formation of PMP as two key factors of intensity and inter-annual
10 variability of extreme precipitation and write it as.

$$11 \quad PMP = K \cdot X'_n \quad (7)$$

12 where K is the integrated maximization factor equivalent to the item $(1 + K_m \cdot C_v)$ in Eq. (1). We consider X'_n to reflect the
13 intensity of extreme precipitation events since they are closely related to the available atmospheric moisture and persistent
14 upward motion that are sensitive to atmospheric warming (Loriaux et al., 2016). The K factor is an indicator of inter-annual
15 variability of precipitation extremes during a certain period as it is derived from the standard deviation and maximum value of
16 annual maximum precipitation (standardized by the long-term mean). Eq. (7) can further be transformed into a logarithmic
17 form:

$$18 \quad lg_{PMP} = lg_K + lg_{X'_n} \quad (8)$$

19 In such case, a multiple regression model between these logarithmic items can be constructed to quantify the respective
20 contributions from intensity (X'_n) and variability (K) factor, where the trend of lg_{PMP} can be sourced from the constituent $lg_{X'_n}$
21 and lg_K . Their relative contribution rates (%) of trends can thereby be estimated as $\frac{S_{lg_K}}{S_{lg_{PMP}}}$ and $\frac{S_{lg_{X'_n}}}{S_{lg_{PMP}}}$, respectively (S is the
22 trend slope). Note all the actual trend slopes are calculated using the original variables, while the logarithmic transformation
23 is only applied to calculate the relative contribution rates of both X'_n and K factor.

24 Furthermore, as a major contributor to precipitation extremes, land-atmosphere coupling effects have received special
25 attention by comparing ensemble global climate model (GCM) simulations from the historical simulations of Coupled Model
26 Inter-comparison Project phase 6 (CMIP6) and the Land Surface, Snow and Soil Moisture Model Inter-comparison Project
27 (LS3MIP) during 1980-2014 (a time slice of the observational 35-year running results 1961-1995, 1962-1996, ..., 1980-2014)
28 (van den Hurk et al., 2016). Their only difference lies in the prescription of dynamic land states of the LS3MIP (namely
29 LFMIP-pdLC experiment), including snow and soil moisture based on the long-term climatology during 1980-2014. This
30 experiment does not consider the seasonal variability of soil moisture, thus diminishing the influences of land's feedback on
31 the atmosphere, providing a good way to remove the land-atmosphere coupling. The GCMs we selected include CMCC-ESM2,
32 CNRM-CM6-1, EC-Earth3, IPSL-CM6A-LR, MIROC6, and MPI-ESM1-2-LR models, which are the only models that
33 provide the daily precipitation in both CMIP and LFMIP-pdLC experiments currently. However, we note a few models do not

34 provide specific flux variables (e.g., latent heat flux) that can be used to further explain the potential mechanisms of land-
35 atmosphere coupling to influence PMP, which are also included in our analysis to extend the data availability and reduce the
36 uncertainty of a single model (Table S2).

37 **2.5 Projection of PMP under climate change**

38 Using the daily precipitation data of the same GCMs from the Scenario Model Inter-comparison Project (SMIP) and
39 LFMIP-pdLC as those in the historical CMIP experiments, we project the temporal variations of PMP during 1980-2099 under
40 the Shared Socioeconomic Pathways 1-2.6 (SSP126) and 5-8.5 (SSP585) scenarios. These correspondingly represent the least
41 and most extreme pathways with high greenhouse gas emissions (2.6 and 8.5 W/m² of forcing in the year 2100), together with
42 the slow and rapid social-economic growth (O'Neil et al., 2016; Eyring et al., 2016; Pörtner et al., 2022). Comparisons between
43 future and historical periods for the two most extreme scenarios allow the understanding of the bounding influences of climate
44 change on future PMP conditions. Specifically, we quantify the percentage changes in PMP between the middle and end of
45 the 21st century (2030-2064 and 2065-2099, respectively) and the reference historical baseline (1980-2014) using the same
46 models from the CMIP and SMIP projects, which represent the predicted PMP changes in the near and far future. Moreover,
47 we conduct the inter-comparison between SMIP and LFMIP experiments to examine the potential influences of land-
48 atmosphere coupling effects on PMP shifts under climate change. Although the raw CMIP6 models can contain a large bias
49 for precipitation extremes, we could not perform the bias correction or the post-processing adjustments due to unavailable in-
50 situ observations under the LFMIP scenarios. Alternatively, the multi-model mean method is applied to constrain the individual
51 model uncertainties in simulating precipitation extremes (e.g., Zhou et al., 2022; Qiao et al., 2023). The deviations across
52 models are additionally illustrated in the supplementary files to reflect the model variance. Our findings provide a large-scale
53 assessment of the future PMP changes over the country for policymaking and the local-scale investigations may further be
54 supplemented by future field observations and climate models for informed decision-making.

55 **3 Results**

56 **3.1 Spatial distribution of PMP**

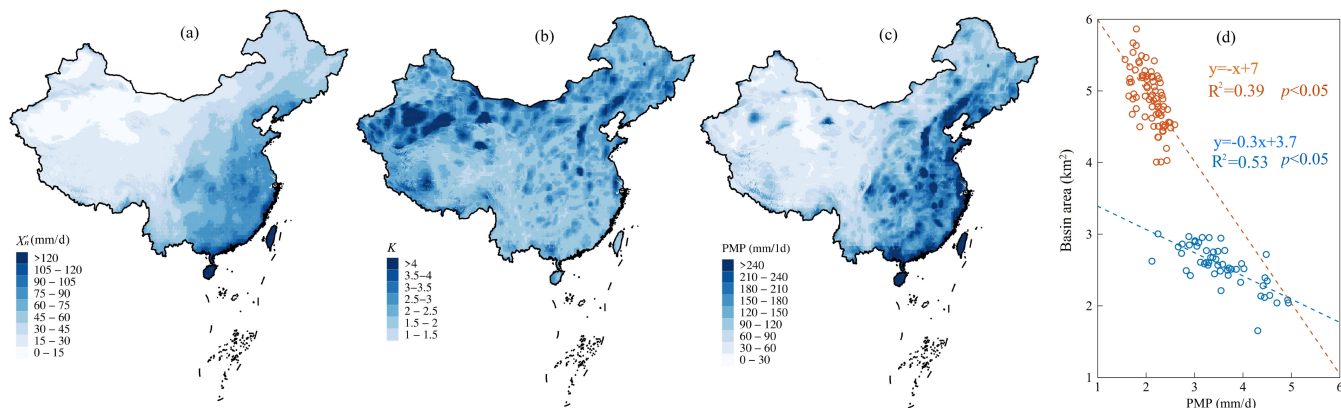

57 Long-term average 1d PMP and its constituting factors (X'_n and K) during 1961-2014 are estimated over China to reveal
58 their spatial patterns (Figure 2). We observe a general three-step spatial distribution with X'_n generally decreasing from
59 southeast to northwest, especially high for the coastal regions of Hainan and Taiwan islands (refer to Figure 1c for their
60 locations) (>120 mm/d locally). High values are also discovered in mountainous areas like the southern Himalayan region and
61 the middle and lower reaches of the Yangtze River basin (Figures 1a and 2a). However, the regional X'_n keeps below 15 mm/d
62 over the majority of northwestern China due to the arid climate (Figures 1b and 2a). Contrary to the variable X'_n representing
63 the intensification of precipitation extremes, the K factor captures a gradually decreasing tendency from north-western to south-
64 eastern China, ranging from 17.2 to 1.2. It indicates that the inter-annual variability of precipitation is stronger in arid north-

65 western China than in the humid regions in the south-eastern parts. A few regions with significant variability are discovered
66 in North China, the southern part of the Qinghai-Tibetan Plateau, and scattered regions of South China (Figure 2b), which are
67 possibly related to the local geophysical and climatic conditions (e.g., elevated terrain and coastal storm). Consequently, the
68 contributions of divergent spatial patterns in X'_n and K leads to the complex distribution of PMP over China. It is characterized
69 by the overall 'high in south-eastern and low in north-western' distribution similar to X'_n , with a few regions highlighted by
70 overwhelming PMP strengthened by local K factor (e.g., Huaihe and Haihe River basins of North China) (Figure 2c). The
71 Central Yangtze River basin, where both factors forming PMP (X'_n and K) present relatively high values, is highlighted by the
72 large amplitude of PMP. Specifically, the area-averaged values for the Yangtze, Southeast, and Pearl River basins are 131,
73 225, and 196 mm/d, respectively (109 mm/d for the whole of China). Overall, it coincides with the national dam and reservoir
74 distribution to imply the regional flood potential and consequential human interventions to alleviate such impacts (Figures 2c
75 and 1d). The negative linear regression between the upstream drainage area and PMP of 52 major water conservancy projects
76 of China ($R^2=0.53$, $p<0.05$) is reasonably reconstructed from our PMP results from over 80 major secondary river basins
77 ($R^2=0.39$, $p<0.05$) (Table S3 and Figure 2d). Differences in the slopes are mainly induced by varying spatiotemporal scales
78 for calculations and equip us with improved insights into the scale dependencies of the estimated PMP.

79 Comparisons in the spatial distribution of PMP with previous estimates demonstrate the robustness of our HRLT-based
80 results. Our estimations of X'_n well reproduce the national distribution of historical records of daily precipitation maxima,
81 except for the Inner Mongolia Province, where a historical precipitation extreme of ~1400 mm/d occurred in 1977 (Figures 1c,
82 2a, and 3b). However, scale differences between ground stations and grid cells lead to neglecting such events in PMP
83 calculations, which should deserve more attention for future regional investigations. Furthermore, the spatial distribution of
84 our PMP results corresponds well with a previous preliminary estimation of the national PMP map based on in-situ data, which
85 has been transformed from the original contour line to a gridded rendering map for better visualization (Figure 3a). The
86 coherent high PMP is not only located in East China along the coastline but also in a few arid regions in north-western China,
87 as well as the southernmost part of Xizang Province (Figure 1c). Independent comparisons with two suites of PMP estimations
88 over China additionally suggest that our HRLT-based PMP can illustrate a similar spatial distribution to that of in-situ results,
89 where abundant ground precipitation is available (e.g., East and South China) (Figure 3c). More importantly, it depicts the
90 PMP distribution for data-scarce regions like Xinjiang and Tibet Provinces in Western China, where very limited information
91 can be extracted from in-situ results (Figure 1c), which is supported by the GPMM results that are derived from remote sensing
92 precipitation product (e.g., relatively high PMP in South Tibet) (Figure 3d). However, the GPMM data presents obvious
93 overestimations of PMP for nearly the whole of the country, reaching ~4300 mm/d by comparing with previous investigations
94 and the in-situ results (Figures 3a-3c). They result from the systematic overestimation of GPM IMERG products in China,
95 especially in the northern parts (Pan et al., 2023; Tang et al., 2020). Such overestimation can propagate into the calculation of
96 the K factor and, therefore, further unrealistically amplify the PMP. The differences in the computation methods with GPMM
97 and the relatively short period (i.e., 2000-2022) may also contribute to the overestimated PMP. Moreover, more specific
98 regional distributions of PMP, e.g., the high PMP values in the south-north Taihang Mountains in North China, are highlighted

99 by the HRLT-based PMP. This is not seen in the GPMM because HRLT-based PMP was calculated on a much finer spatial
00 resolution (1 km) than GPMM (0.1° , ~ 11 km).

01 Quantitative validation is performed on various scales among PMP estimations from HRLT, GPMM, and in-situ results
02 (Figure 4). Relatively good correlations between PMP estimations from HRLT and the other two subsets are found on the grid
03 scale, with the Pearson Correlation Coefficient (CC) of 0.65 and 0.66 to GPMM and in-situ results, respectively (Figures 4a
04 and 4b). However, the significant overestimation of GPMM is reported by comparing it to HRLT results, where a line with a
05 slope of 2.51 is fitted, consistent with the overall estimation of spatial distributions (Figures 2c and 3d). This slope is apparently
06 higher than that between in-situ results and HRLT data (1.54), indicating the effectiveness of our HRLT results. We also report
07 similar overestimations of GPMM to the in-situ results and decreased correlations ($CC=0.52$) (Figure 4c). Examination results
08 on the region scale also reveal a similar situation, with better agreement between HRLT and in-situ results ($CC=0.96$) than
09 that with GPMM due to its significant overestimations at a regression slope of 3.67 (Figures 4d-4e). The regional estimate of
10 PMP from GPMM is nearly double the in-situ results over different river basins, fitting a line of 0.55 between both subsets
11 (Figure 4f). Therefore, the HRLT-based PMP shows relatively better accuracy than the GPMM dataset in China by comparing
12 with the in-situ-based results, though it also presents moderate overestimations than in-situ data.

13

14 **Figure 2: Spatial distribution of (a) X'_n , (b) K factor, and (c) PMP based on HRLT dataset during 1961-2014. The grid cells and**

Figure 4: Scatter plots between PMP estimations from (a, d) HRLT and GPMM, (b, e) HRLT and in-situ precipitation, and (c, f) GPMM and in-situ precipitation dataset on (a, b, c) the grid/station scale and (d, e, f) the basin scale. The dashed grey and solid black lines represent the 1:1 line and fitted linear regression line, respectively. Sub-figures (a-c) are heatmaps where high (low) point density is translated to yellow (blue) colours. CC means the Pearson Correlation Coefficient. Black dots and red triangle in sub-figures (d-f) represent the different river basins and the whole country, respectively.

29 3.2 Variations and attributions of PMP

30 Firstly, based on the assumption of a static climate, the spatial distribution of PMP over China is evaluated using the
31 high-resolution HRLT dataset and validated with in-situ results and GPMM data. However, since the changing climate is a
32 widely acknowledged fact by the community, it significantly challenges the accurate estimation of PMP (Piao et al., 2010).
33 Secondly, we estimate the changes in PMP and its constituting factors (i.e., X'_n and K) over different time slices of 35 years
34 from 1961-1995 to 1980-2014 to detect such influences (Figure 5). On a national scale, we observe a reduction of K from the
35 period 1961-1995 (2.3) to 1971-2005 (2.23), followed by an increase until the period 1977-2011, and nearly stable at around
36 2.28 in the following years (Figure 5a). Contrary to K , X'_n presents a stably increasing tendency over all the periods, meaning
37 a relative increase of 3% if compared to the first period, i.e., from 43.5 (1961-1995) to 44.6 mm/d (1980-2014) (Figure 5b).
38 Consequently, the national PMP shows a pattern that is dominated by the K factor, including a minor decline before the period
39 1971-2005 and a continuous increase afterward. The accelerated rise of PMP from 1977-2011 should be highlighted, which
40 results from the joint contribution of the increase in X'_n and K factor (Figure 5c). It can be the result of the intensification of
41 both climate variability (e.g., El Niño–Southern Oscillation events) (Huang and Stevenson, 2023) and anthropogenic forcing
42 (e.g., irrigation and urbanization) (Wu et al., 2021; Han et al., 2022). Overall, the national average PMP increased from 106.5
43 to 109.5 mm/d between the period 1961-1995 to 1980-2014, equivalent to a 3% increase with baseline from the first period.
44 This growth also coincides with the steady rise of the total storage capacity of the dams and reservoirs, implying the artificial
45 efforts to alleviate the impacts of increasing and more intense precipitation extremes. On the other hand, it also provides
46 advance warning to the water resource managers that more constructions are needed in the future in case of the overwhelming
47 increase rate of PMP than reservoir and dam constructions, even though the total reservoir capacity of the country has increased
48 by ~80% from 1961 (35.9 mm) to 2014 (64 mm) (Figure 5d).

49 The inter-annual trend of 1d PMP during the 35-year running window from 1961-1995 to 1980-2014 is firstly estimated
50 for each grid cell (Figure 6a). The spatial distribution of national PMP trend is featured by the widespread increase of PMP
51 across North China with regional hotspots in Inner Mongolia and Heilongjiang Provinces (>5 mm/d/a) (refer to Figure 1 for
52 their location). The region-averaged result for the Yellow and Songliao River basins where they are distributed is 0.41 and
53 0.14 mm/d/a, respectively. Another region with a significant PMP increase is in the Southern part of the country, comprising
54 mainly the central Yangtze and Pearl River basins (0.7 and 0.27 mm/d/a, respectively), where slopes are higher than 7.5 mm/d/a
55 locally. In addition, both significant ($p<0.05$) increasing and decreasing trends are detected in the scattered regions of
56 Northwest and East China. Such a distribution provides a piece of evidence on the necessity of incorporating the non-
57 stationarity of a climate system in the calculation of PMP as well as the pressing need to consider its long-term change
58 behaviours.

59 The drivers of the PMP trend are attributed to its two contributors (i.e., X'_n and K) according to Eq. 8. It is found the
60 national distribution of PMP is mainly controlled by the latter in the spatial domain (Figures 6b to 6e). The relative contribution
61 of the trend in the K factor accounts for higher than 100% of both increasing and decreasing trends of regional PMP over most

62 of the country and rises up to 400% for certain areas in Northern and Western China (Figure 6e). Another variable, the X'_n ,
63 presents a divergent pattern in the remaining parts of the country, with contribution rates lower than 50% (Figure 6d). However,
64 apart from the consistent growth of the X'_n in Southeast China (trend rates: 0.25 to 0.75 mm/d/a), there are significant increases
65 over the Northwest part, though the change slopes are generally lower than 0.25 mm/d/a (Figure 2b). Differently, the K factor
66 mainly illustrates growth in Northern China and the neighbouring Qinghai-Tibetan Plateau, even though a few regional
67 hotspots with rapid decline are found in the Yangtze and Pearl River basins (Figure 6c). We observe the opposite trends in X'_n
68 and K nationwide, resulting in the patterns of extremely high (low) relative contribution of K (X'_n) over regions where PMP
69 changes are controlled by the former (Figures 6d and 6e). These findings underpin our hypothesis that a static climate
70 assumption to calculate PMP is not appropriate for most areas of China due to significant increasing/decreasing trends, which
71 are overall caused by the changes in the inter-annual variability of precipitation extremes instead of its intensity, though the
72 latter has demonstrated widespread increase over most of the country. On the national scale, the PMP increases at a rate of
73 0.08 mm/d/a, of which 71% (29%) is caused by the increasing K factor (X'_n). It is also the governing factor in most river basins
74 of the country, where the highest contribution of 98% is in the Pearl River basin (Figure 6f), with the opposite pattern observed
75 in the Haihe River basin, where the X'_n contributes most, up to 38%.

76

 82 **to 1980-2014 over China. Contribution of (d) X'_n and (e) K factor to the changing 1d PMP. The grid cells whose trend values do not**
 83 **reach a 0.05 significance level are masked out. (f) Scaled contribution of different variables to the changing PMP in different river**
 84 **basins. Please refer to Figure 1 for details of the regional abbreviations.**

85 **3.3 Response of PMP to the changing climate**

86 A static period from 1980-2014 is chosen to evaluate the prediction capability of ensemble GCMs. By comparing the
 87 historical PMP results from the CMIP experiment with the HRLT PMP results during the same period, we observe coherent
 88 distributions among them in terms of X'_n , K factor, and PMP (Figure 7). However, differences in the amplitude of these
 89 variables exist due to divergent spatial scales (1 km vs 1°) upon PMP calculation, causing the larger cells (1°) to generally
 90 possess lower values, with more local details found in the former (1 km). No significant differences are observed between
 91 CMIP and LFMIP-pdLC experiments, meaning the subtle effects of land-atmosphere coupling in the past. Individual

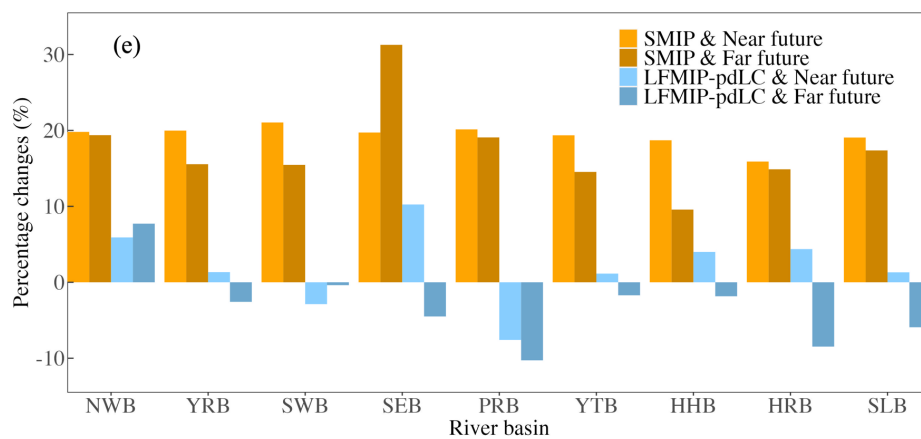

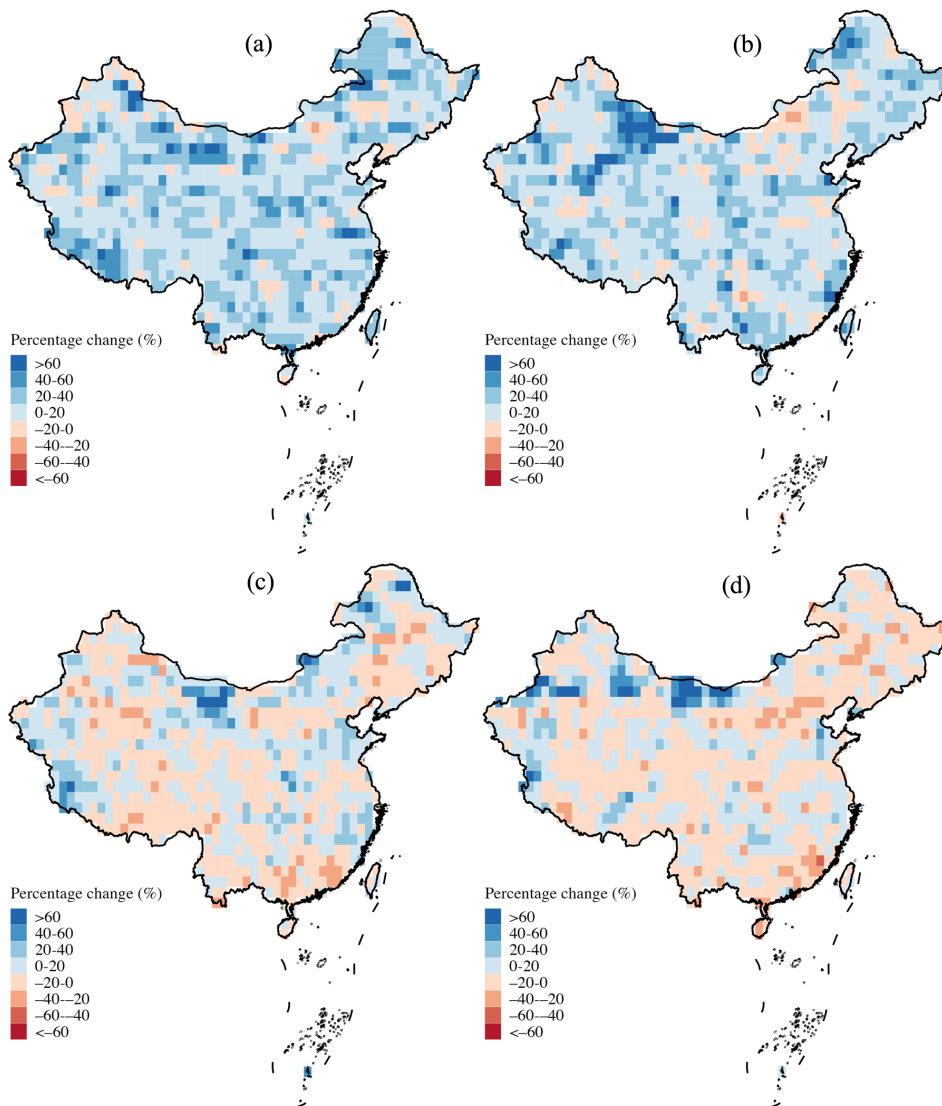

92 simulations from single models are presented to analyse the inter-member uncertainty (Figure S1). We find the ensemble mean
93 PMP is the balanced result of overestimated values from CMCC-ESM2 and MIROC6 and the underestimated values from
94 MPI-ESM1-2-LR, which is caused by the requisite interpolation from the native coarse model resolution ($\sim 2^\circ$). Historical
95 evaluations have also shown the relatively better performance of EC-Earth and MPI-ESM1-2-LR than the remaining models
96 with wet or dry biases over China (Dong and Dong, 2021; Jia et al., 2023). Despite the bias in raw CMIP6 outputs of different
97 models, the multi-model ensemble has been shown as a useful method to reduce the uncertainty than individual models, which
98 have the potential to further improve with future model evolution (Qiao et al., 2023; Zhu et al., 2020). Overall, the consistent
99 PMP distributions in the ensemble mean of models and observational results indicate the effectiveness of GCM predictions,
00 which are, therefore, further applied to project future changes under climate warming.

01 We quantify the relative changes in 1d PMP between future periods and baseline (1980-2014) under two climate change
02 scenarios (Figure 8). A widespread increase during the near future (2030-2064) is projected across nearly the whole country
03 from the SMIP experiment under the SSP126 scenario. In particular, the regions witnessing such an increase include the
04 Southern coastal region, Northeast China, the Central part of the Yangtze River basin, the West of Inner Mongolia, and the
05 Yarlung Zangbo River basin located in Southwest China (Figure 8a). The percentage change generally exceeds 20% and
06 reaches up to 60% for certain regions, which results from the intensification of both X'_n and K factor (Figures. S2a and S4a).
07 Specifically, the overall increasing PMP is mainly caused by the growth of X'_n at the national domain, with the intensification
08 of the K factor over specific regions. However, such an increase is significantly dampened (and even reversed) in the LFMIP-
09 pdLC experiment due to the widespread reduction of X'_n except for a few regions around the western and northern boundaries
10 of China (Figures 8c, S2c, and S4c), with the K factor almost unchanged during the same period (Figure S4). The overestimated
11 PMP results between SMIP and LFMIP-pdLC are mainly located in the Southern tropics and arid and semi-arid zones of
12 Northwest and Northeast China, which are caused by the underestimated X'_n in the LFMIP-pdLC with K factor slightly reduced
13 (Figures 8a and 8c). However, the increase in PMP of the scattered regions in the Northwest China persistently exists in both
14 experiments. No significant differences between near (2030-2064) and far future (2065-2099) projections are discovered in
15 both SMIP and LFMIP-pdLC experiments (Figures 8a-8d). To conclude, the projected PMP increase reaches 20% and 17%
16 for the whole country during the near and far future periods, respectively, according to the SMIP experiment, of which the
17 Southwest (31%) and Southeast (21%) basins are, correspondingly, the highest. The percentage changes are reduced to only
18 2% (near future) and 0% (far future) for the LFMIP-pdLC experiment. Furthermore, we observe the continuous intensifications
19 of PMP in the SSP585 scenario compared to the SSP126 scenario in the SMIP experiment, with the overall decrease of PMP
20 in the LFMIP-pdLC experiment (Figures 9, S3, and S5). These changes are caused by the increase/decrease in the X'_n from the
21 SSP126 to SSP585 scenario during the SMIP/LFMIP-pdLC experiments, with the K factor almost unchanged among scenarios.
22 The PMP increases to 51% and 43% for the SSP585 scenario from the SMIP experiment during the near and far future
23 compared to the baseline period, much higher than the LFMIP-pdLC results (-1% and -5% for the near and far future) (Figure
24 9e). These findings suggest that the land-atmosphere coupling controls the increase in PMP for the majority of China mainly
25 by influencing the intensity of precipitation extremes (i.e., X'_n). However, the climatic change unrelated to the land-atmosphere

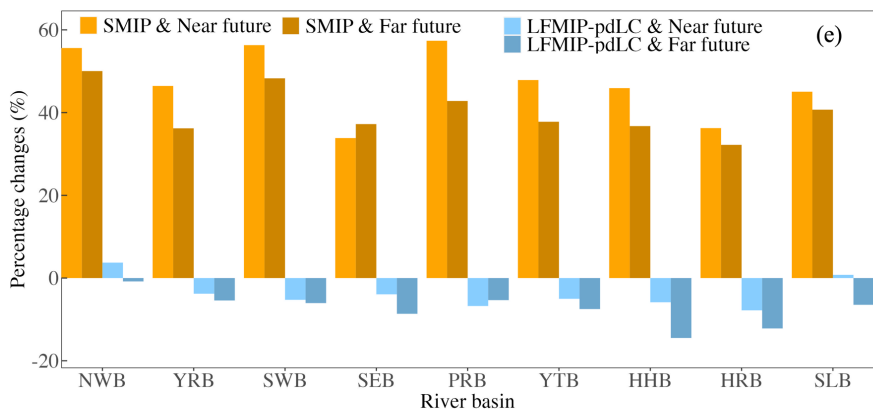

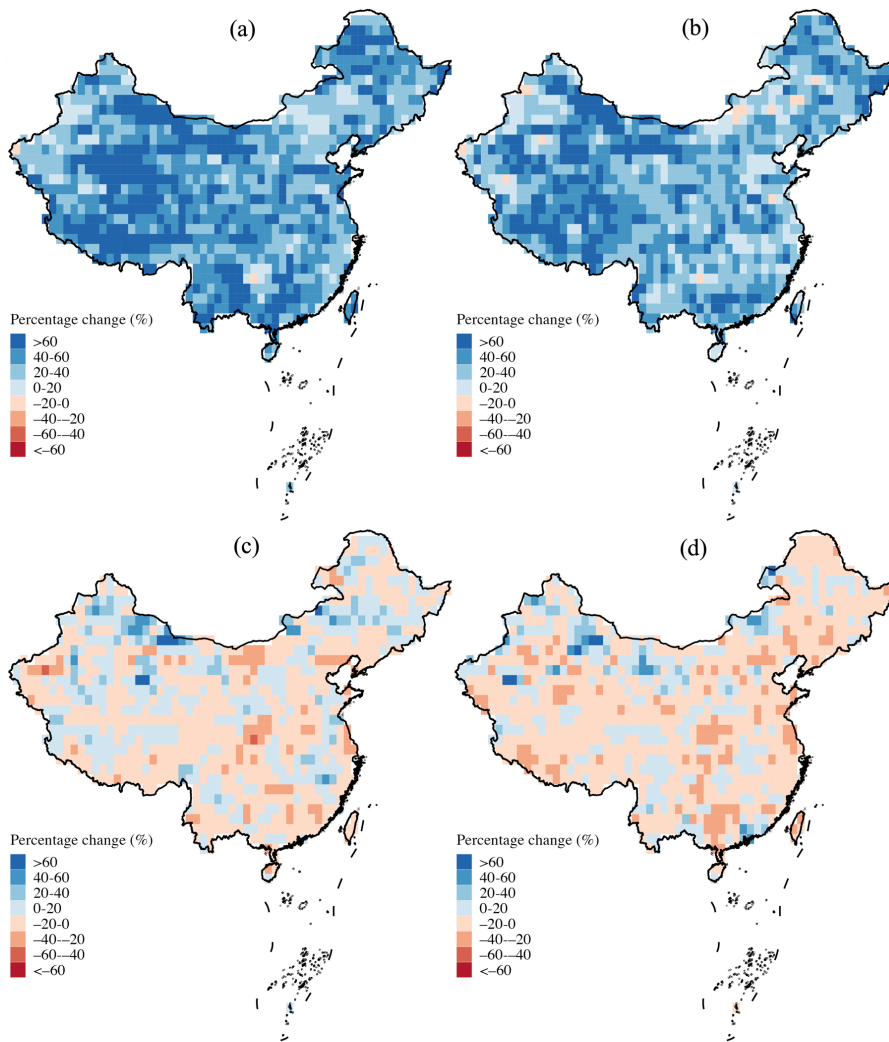

26 coupling governs the strengthened PMP in Northwest China, where significant increases in PMP are detected due to the
 27 growing variability of precipitation extremes (i.e., K factor). They imply the compound risk of increasing intensity and
 28 variability of precipitation extremes under climate change. These findings are consistent with previous global assessments
 29 using the GLACE-CMIP5 framework, which found a decrease in the annual sum of daily precipitation (>95 percentile) after
 30 removing soil moisture variability (i.e., representative of land-atmosphere coupling) in South China (Lorenz et al., 2016).
 31 However, it also indicated enhanced variability of heavy precipitation in water-limited regions due to increased latent heat flux
 32 that tends to increase evaporation and precipitation (Berg et al., 2014). It is different from our examinations over the semi-arid
 33 and arid zones across the country (Figure 1b), possibly due to the divergent response of latent/sensible heat flux to atmosphere
 34 states spatially (Wu et al., 2023).

35

44 **4 Discussions**

45 **4.1 Comparisons with previous studies**

46 Quantitative assessment with design values of large hydropower projects and in-situ estimations of PMP has presented
47 a contradictory conclusion, i.e., overestimation of the water projects (Figure 2f) and underestimation of in-situ results and the
48 GPMM database (Figure 4). This fact suggests more justification should be carried out by comparing with previous research.
49 A few regional studies have calculated 1d PMP over different parts of China (Svensson & Rakhecha, 1998; Yang et al., 2018;
50 Zhou et al., 2020). For example, Svensson & Rakhecha (1998) used the moisture maximization factor to estimate PMP over
51 the Hongru River basin of the Huaihe River basin in eastern China, resulting in a result of 460 mm/d that is generally within
52 the range of our 1km PMP map of the corresponding area (200~600 mm/d, Figure 2c). Zhou et al. (2020) applied the storm
53 transposition method to estimate PMP for a small ungauged catchment in northern China from 118°20'E~118°26'E and
54 40°26'N~40°30'N. The results change from 397 to 570 mm/d at most stations, with an extreme value of 1026 mm/d in
55 Zhangmu, Hebei Province (see Figure 1c). They are overall higher than our gridded estimations using HRLT, with PMP
56 approximately fluctuating between 80 and 200 mm/d. Such difference may arise from the distinctive calculation methods (i.e.,
57 hydrometeorological method vs statistical method) and data length with our study, as most historical maximum precipitation
58 occurred prior to the beginning year of the HRLT dataset (1961). It suggests the sensitivity of PMP estimations on different
59 computation methods and data representativeness for valid precipitation extremes. Another example in western China is the
60 calculation of PMP for the Nujiang River basin (part of the Southwest basin, Figure 1a) (Liu et al., 2016). The study uses a
61 gridded precipitation dataset to estimate PMP based on the model storm amplification approach. It discovered the PMP
62 increases from upstream to downstream within the basin, and the value changes from 15.4 to 99.7 mm/d. The spatial
63 distribution (Figure 2c) and amplitude (28.7~87.8 mm/d) are quite similar to our findings. Using three remote sensing
64 precipitation products and the statistical method, Yang et al. (2018) discussed the potential of gridded precipitation extremes
65 to estimate PMP in poorly gauged regions by taking the Dadu River basin in western China (located in the upstream Yangtze
66 River basin, Figure 1a) as an example. They pointed out the huge disparity among PMP values based on various satellite
67 products (ranging between 51.88–519.11 mm, 90.16–417.61 mm, 122.41–391.79 mm, and 128.37–740.45 mm for CGDPA,
68 CMORPH, PERSIANN-CDR, and TRMM 3B42V7, respectively) and recommended the PMP of 52~519 mm/d over the
69 region, nearly two-fold higher than our result of about 29~279 mm/d. The large differences among global precipitation products
70 highlight the lack of consistent PMP representations in different areas, which may partly be solved by merging multiple data
71 sources based on their regional performance and uncertainty quantification (Rajulapati et al., 2020). However, a consistent
72 spatial variability and distribution is reported where PMP generally increases from upper to lower reach. We also find lower
73 PMP values of HRLT PMP (~350 mm/d) in the Hong Kong Island of South China than results based on site data (e.g., 1753
74 mm/d in Lan et al., 2017 and Liao et al., 2020). Such underestimations, on the one hand, are the consequence of different

75 calculation algorithms, data sources, and uncertainties. On the other hand, they reflect the differences in spatial scales between
76 field and grid cell PMP estimations. Previous studies generally take the highest estimation among various weather stations in
77 a region as the final PMP, while the HRLT highlights the average PMP for each high-resolution 1km grid cell. Indeed, our
78 approach tends to follow the definition of PMP more strictly, i.e., the theoretical maximum precipitation for a given duration
79 under modern meteorological conditions, which should happen on an area scale instead of a point domain (WMO, 2009). This
80 scale difference is further highlighted in a global study that quantified the change of 1d PMP and mean annual maximum daily
81 precipitation (AMDP) using a 0.5° resolution global precipitation dataset (Sarkar & Maity, 2021). The mean AMDP of grid
82 cells over tropical zones with high precipitation and low seasonality (e.g., Southeast Asia near Hong Kong and Taiwan Islands)
83 generally ranges from 50 to 150 mm/d (see Figure 5 of Sarkar & Maity (2021)). It is much lower than our HRLT estimates
84 (Figure 2a) and previous station-based estimates (e.g., Table 5 of Lan et al., 2017) due to larger grid cells for computation (~50
85 km). Moreover, it indicated a significant increase of PMP in the southern and north-eastern parts of China by comparing the
86 PMP results of two periods (i.e., 1948-1977 and 1979-2012), which coincide with our spatial distribution of PMP trends (Figure
87 6a), even though over different calculation periods.

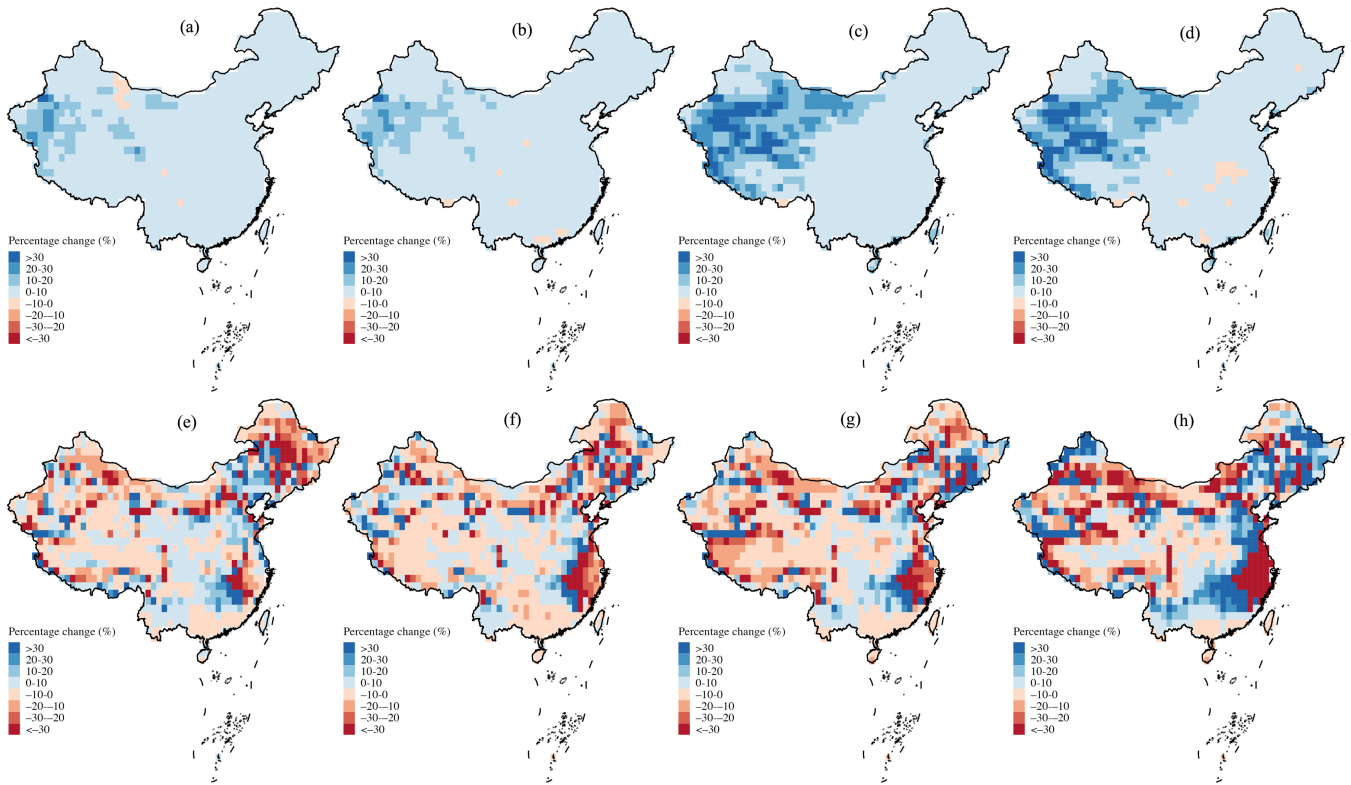

88 Despite some differences between previous regional investigations that are derived from divergent datasets, methods,
89 and spatial scales, our first high-resolution (1 km) PMP map generated over China captures the spatial distribution at a local
90 scale very well. Moreover, all the previously mentioned studies estimate PMP under the assumption of a static climate and
91 neglect the variability of climate systems. This point is addressed in this study by separately calculating the PMP for each
92 moving 35-year time period, along with an attribution framework proposed to track the sources of PMP changes.
93 Anthropogenic climate change, which is not adequately discussed in previous studies, is also investigated using an ensemble
94 of global climate models under different scenarios and periods. In a nutshell, this study constructs the first national high-
95 resolution PMP map and quantitatively detects the changing climate influences on PMP estimations in the past and future.

96 **4.2 Potential pathways of land-atmosphere coupling to PMP**

97 Linkages between land-atmosphere coupling and climate extremes have received much attention from the community
98 over the years by means of observations and models (e.g., Koster et al., 2004; Zhou et al., 2019). However, most previous
99 analyses focus on the mechanisms of land-atmosphere coupling to induce the hot extremes in the near-surface interface, leaving
00 the rationales behind the extreme precipitation events (and PMP) still poorly understood (Lorenz et al., 2016). Nevertheless, a
01 basic consensus is that land surface states (typically soil moisture) alter the atmospheric processes by modulating the allocation
02 of sensible and latent heat flux of the energy budget in a positive and/or a negative way (Seneviratne et al., 2010). On the one
03 hand, the increasing wetness of soil can provide more available moisture to be evaporated into the near-surface atmosphere,
04 leading to higher evaporation (or upward latent heat flux); on the other hand, the increased evaporation can inversely reduce
05 the available soil moisture. This reduction in available soil moisture should be lower than the increased soil moisture to
06 maintain the interactions between soil and precipitation; otherwise, the soil would become drier. In this case, the elevated net
07 evaporation can further influence the precipitation, by enhancing the moisture supply for the planetary boundary layer (PBL)

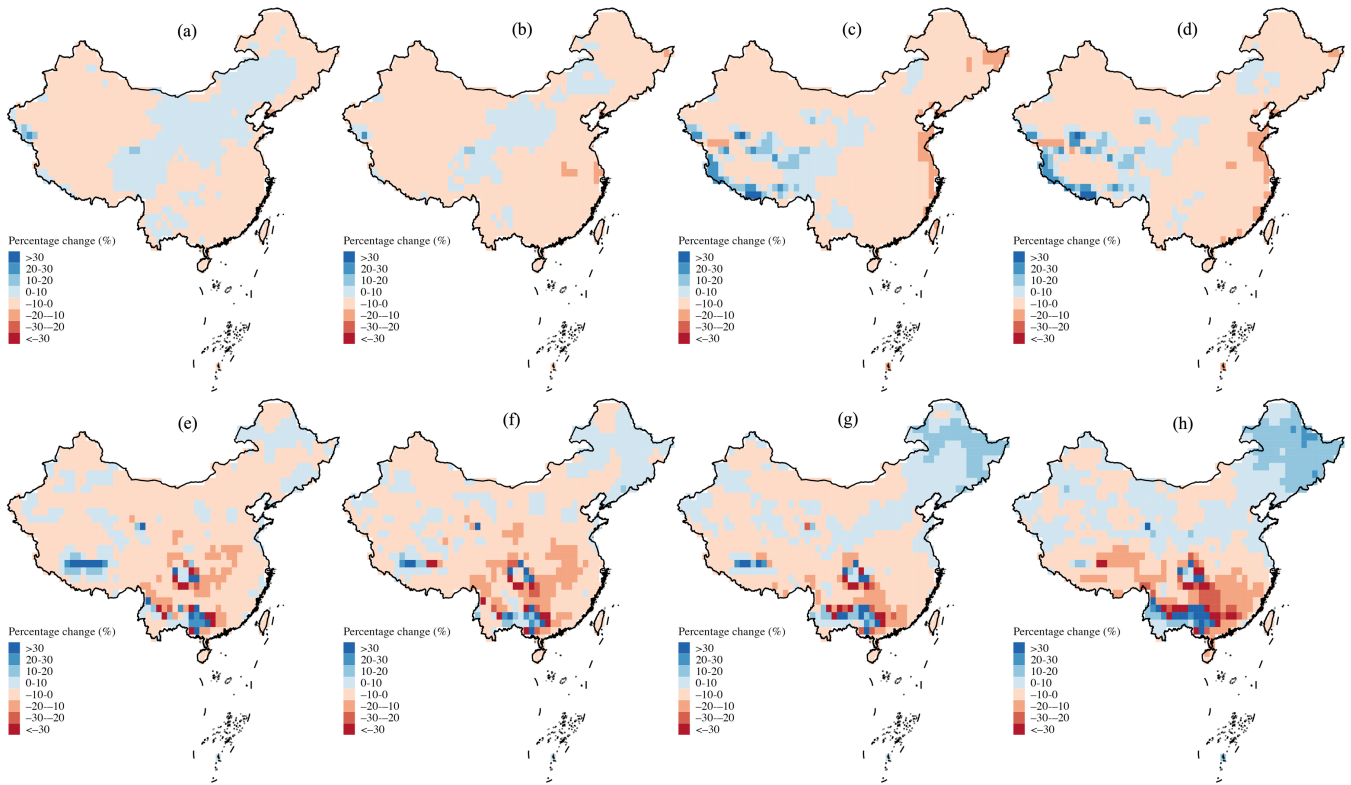

08 to affect the atmospheric heating rates and cloud formation (Zheng et al., 2015). However, such ‘second-hand’ influences are
09 complex due to the multiple dynamic and thermal processes involved. Both positive and negative correlations have been
10 reported from the previous modelling outputs and observed results depending on different regions and seasons (Diro et al.,
11 2014; Wu et al., 2023).

12 Based on prior knowledge of the mechanisms of land-atmosphere coupling, we detect the percentage changes of the
13 annual daily maximum of heat fluxes of future scenarios compared to the baseline (Figures 10 and 11). We discover the
14 national increase in the annual daily maxima of latent heat flux that is most obvious in western parts of China according to the
15 SMIP experiment, which is spatially consistent with the increase in X'_n (Figures 10 and S2). Such increase disappears in the
16 LFMIP-pdLC experiment and keeps a similar spatial pattern to the X'_n , i.e., the decrease in the majority of the country with the
17 regional increase in the West and South. Furthermore, these reported changes in the latent heat flux show no apparent deviation
18 between the near and far future; however, they show significant positive sensitivity along with the enhancement of the gas
19 emission scenarios. In addition, we also find the corresponding variations in the sensible heat flux that are opposite to the latent
20 heat flux, except for Northeast China, where both fluxes increase in the LFMIP-pdLC experiment (Figures 10 and 11).
21 Moreover, the strengthened changes in the sensible heat flux are observed in both ensembles. Based on the above analysis, it
22 can be inferred that the land-atmosphere coupling can enhance the intensity of precipitation extremes by increasing the supply
23 of latent heat flux (i.e., evapotranspiration) at the expense of reduced sensible heat flux and such impacts can be relatively
24 stronger under a higher gas-emission-scenario.

25

31 **4.3 Limitations and future outlooks**

32 Although this study has provided the first national high-resolution PMP map and the quantitative evaluation of the effects
 33 of the changing climate on PMP estimations, it suffers from a few inevitable limitations associated with the inconsistent spatial
 34 scales between precipitation data and models and the lack of adequate ground information for physical attributions. As shown
 35 before in the comparisons with previous studies, the discrepancies between statistical methods and hydrometeorological
 36 methods are evident (see Section 4.1 for details). They are mainly derived from the different rationale behind the maximization
 37 framework, e.g., maximization of wind or moisture, and the uncertainty in the metrological data (e.g., dew point temperature,
 38 wind speed). Basically, these different methods of computing PMP have different storylines. For example, the
 39 hydrometeorological methods are characterized by the maximization of a single or several atmospheric factors, and emphasize
 40 the physical mechanisms behind the storms (Gu et al., 2022). While the statistical methods estimate an unprecedented extreme
 41 value from a probabilistic perspective (Papalexiou and Koutsoyiannis, 2006; Papalexiou et al., 2016). The hydrometeorological
 42 methods may be somewhat more physically realistic than statistical methods but they neglect the interaction of different factors
 43 and heavily rely on the meteorological data. These shortcomings hinder the large-scale assessment of PMP and accurate future
 44 projections using hydrometeorological methods. Overall, the sensitivity of PMP estimation to different calculation methods is
 45 worthy to be detected. However, we are unable to evaluate at this stage due to the lack of sufficiently long-term storm event

46 records and related meteorological data for the maximization, especially on a national scale. Although we have validated our
47 estimates with the auxiliary quasi-global PMP dataset and the in-situ observations, additional measures for quantitative
48 validation, such as various methods, may further be employed in the future. Another limitation lies in the mathematical partition
49 and subsequent attribution of the statistical PMP estimation into two main components following Eq. 8. Though the framework
50 can conveniently be implemented for the attribution of PMP trends to different factors, no more insights into the dynamic and
51 thermal atmospheric processes can be provided. Recent studies have shown the applications of numerical weather models (e.g.,
52 Weather Research and Forecasting Model) in modelling the regional PMP (Hiraga et al., 2021). Such attempts can assess the
53 sensitivity of PMP to different atmospheric (e.g., moisture) and geophysical factors (e.g., topography) and climate change from
54 a physical perspective (Rastogi et al., 2017). Moreover, the scale difference of resolutions between the HRLT dataset (1 km)
55 and GCM simulations ($\sim 1^\circ$, 100 km) may introduce regional disagreement between our historical assessment and future
56 projections (Figure 7). This difference is caused by the relatively coarse spatial resolution in the parameterization of GCMs,
57 highlighting the fact that caution should be taken when explaining the linked spatial distribution between past and future.

58 Corresponding to the above-mentioned limitations, several strategies can be adopted to alleviate their impacts in future
59 studies. A feasible solution is the use of multi-source meteorological data, for example, remote sensing product (e.g., MODIS-
60 based vapor pressure data) and reanalysis predictions (e.g., ERA5 and JRA55), in the estimation of large-scale PMP using the
61 meteorological method, which can serve as a useful tool to verify the independent statistical estimations. Moreover, fully
62 coupled regional-scale simulations can be performed using the numerical weather simulation and data assimilation techniques,
63 of which WRF from NOAA has achieved much in the simulation and prediction of PMP (e.g., Rastogi et al., 2017). In addition
64 to this, high-resolution global climate models such as the High-Resolution Model Intercomparison Project (HighResMIP v1.0)
65 for CMIP6 provide another way for the PMP analysis on continental and global scales (Haarsma et al., 2016). However, inter-
66 member uncertainties implicit in the models are inevitable, possibly considerable and deserve relatively more efforts to
67 constrain and alleviate. This point is highlighted by the comparison between historical CMIP PMP estimations and HRLT
68 results (Figure 7) as well as the cross-comparison between CMIP and LFMIP-pdLC simulations in the past (Figure S6). The
69 overestimated PMP and its components of the LFMIP-pdLC than the CMIP experiment during the baseline period can be a
70 result of model sensitivity and uncertainty for the past climate. All of the issues discussed, including the unclear physical
71 mechanisms of changing PMP and divergent spatial scales among datasets and uncertainties therein, deserve to be studied in
72 the future with the advancement of observation systems and earth system models.

73 **5 Conclusions**

74 Given the lack of knowledge in the spatial distribution of PMP in China and the potential influences of the changing
75 climate on PMP formation, this study uses the existing most high-resolution (1 km) precipitation dataset to compute the 1d
76 PMP during 1961-2014 for the whole of China using the improved Hershfield method. The spatial distribution of PMP is
77 generated on a national scale and has been validated with a satellite-based quasi-global PMP dataset and in-situ-based PMP

78 results. Changes in PMP and its constituting factors (X'_n and K) are presented in each 35-year time window from 1961-1995
79 to 1980-2014. Inter-annual trends are subsequently estimated during these periods and are attributed to the changes of these
80 two contributors. An ensemble of GCMs is used to project the response of PMP to climate change under two scenarios (i.e.,
81 SSP126 and SSP585) in the near (2030-2064) and far future (2065-2099) of the 21st century relative to the baseline (1980-
82 2014). The main findings are as follows:

83 (1) We find the approximately opposite spatial distribution of two constituting factors to form PMP (X'_n and K) over the
84 country, of which the variable X'_n (K) generally decreases (increases) from the south-eastern to the north-western sections.
85 They jointly result in a unique spatial distribution of PMP, which is featured by both the typical ‘three steps’ distribution from
86 southeast to northwest and regional hotspots in coastal regions, mountainous areas, and northern arid zones. Our PMP
87 estimations are generally consistent with previous precipitation compilations and project design results. However,
88 overestimations are discovered when comparing with the in-situ-based PMP results and GPMM dataset, with correlation
89 coefficients ranging from 0.65 to 0.96. The differences might be caused by the different calculation methodologies and varying
90 spatial resolutions.

91 (2) Different temporal variations of X'_n and K are observed during moving time windows from 1961-2014. K shifts from
92 decrease to increase after the turning period of 1971-2005, while X'_n keeps growing and achieved a 3% increase for the country.
93 Consequently, PMP also increases from 106.5 to 109.5 mm/d from 1961-1996 to 1980-2014 period, with an accelerated speed
94 after 1977-2011. The pattern suggests the increased flood control pressure in the context of simultaneously increasing reservoir
95 capacity. The running trend of the 35-year PMP mainly lies in northern China, including inner Mongolia and Heilongjiang
96 Provinces, which are predominately caused by the changes in the inter-annual variability (represented by the K factor) together
97 with the intensity of extreme precipitation (represented by X'_n). The PMP increases at a rate of 0.08 mm/day/a for the whole
98 country, of which 71% (29%) is caused by the increasing K factor (X'_n).

99 (3) The historical simulations of the CMIP ensemble spatially agree with the HRLT results. Land-atmosphere coupling
00 dominates the widespread increase in PMP over China under both SSP126 and the SSP585 climate change scenarios by
01 modulating the intensity of daily precipitation extremes (X'_n), except for scattered regions in Northwest China, where a
02 significant increase in precipitation variability (K) is observed. No obvious differences in the future projections during the
03 middle and end of the 21st century are discovered by comparing with the baseline. Nationally, the projected PMP changes are
04 17~20% and 0~2%, according to the SMIP and LFMIP-pdLC experiments under the SSP126 scenario, respectively. The
05 percentages change to 43%~51% (SMIP) and -1~-5% (LFMIP-pdLC) for the SSP585 climate change scenario, indicating the
06 strengthened modulations of land-atmosphere coupling to PMP with anthropogenic forcing.

07 Our study provides the first high-resolution map of PMP (1d & 1km) for China and quantitatively challenges the reliability
08 of the static climate assumption in conventional PMP estimation. Climate change and land-atmosphere coupling impacts are
09 further projected using state-of-the-art ensemble models from CMIP6. Our results can provide scientific inferences to regional
10 and national water managers and decision-makers for effective and efficient water resource management in the area.
