13 **Abstract.** This study uses a reduced-order two-dimensional (2-D) horizontal model to
14 investigate the influence of riverbank slope on the sinuosity-driven hyporheic exchange
15 process along sloping alluvial riverbanks during a transient flood event. The Deformed
16 Geometry Method (DGM) is applied to quantify the displacement of the sediment-
17 water interface (SWI) along the sloping riverbank during river stage fluctuation. This
18 new modeling approach serves as the initial step focusing on the impact of bank slope
19 on the hyporheic exchange flux (HEF) and the residence time distribution (RTD) of
20 pore water in the fluvial aquifer for a sinuosity-driven river corridor. Several controlling
21 factors, including sinuosity, alluvial valley slope, river flow advective forcing and
22 duration of flow are incorporated into the model to investigate the effects of bank slope
23 on aquifers of variable hydraulic transmissivity. Compared to simulations of a vertical
24 riverbank, sloping riverbanks were found to increase the HEF. For sloping riverbanks,
25 the hyporheic zone (HZ) encompasses a larger area and penetrated deeper into the
26 alluvial aquifer, especially in aquifers with smaller transmissivity (i.e., due to increased
27 hydraulic conductivity or reduced specific yield). Furthermore, consideration of sloping
28 banks as compared to a vertical river bank can lead to both underestimation or
29 overestimation of the pore water travel time. The impact of bank slope on residence
30 time was more pronounced during a flood event for high transmissivity aquifer
31 conditions, while it had a long-lasting influence after the flood event in lower
32 transmissivity aquifers. Consequently, the impact of bank slope decreases the travel
33 time of water discharging into the river relative to base flow conditions. These findings
34 highlight the need for (re)consideration of the importance of complex riverbank
35 morphology conceptualization in numerical models when account for the HEF and RTD.
36 The results have potential implications for river management and restoration and the
37 management of river and groundwater pollution.

39 **Key words:** hyporheic exchange, sloping riverbank, deformed geometry, numerical
40 simulation, residence time distribution

Nomenclature

ΔL	Nodal spacing [m]
∇	Laplace operator
α_L	Longitudinal dispersivity [L]
α_T	Transverse dispersivity [L]
D	Dispersion-diffusion tensor [L^2T^{-1}]
D_L	Water diffusivity [L^2T^{-1}]
J_x	Base groundwater gradient [-]
K	Hydraulic conductivity [LT^{-1}]
n	Scaling number [-]
n_0	Intensity of flood event [-]
n_d	Skewness of flood event [-]
S_y	Specific yield [-]
t_d	Duration of flood event [T]
t_p	Time to peak river stage [T]
α	Amplitude of the river boundary [L]
Γ_d	Dimensionless aquifer transmissivity [-]
δ	Bank slope angle [$^\circ$]
δ_{ij}	Kronecker delta function [-]
ϵ	Tortuosity [-]
η	Degree of flood event asymmetry [T^{-1}]
θ	Effective porosity [-]
λ	River boundary wave length [L]
σ	River boundary sinuosity [-]
τ	Residence time [T]
ω	Flood event frequency [T^{-1}]
$h(\mathbf{x}, t)$	Transient groundwater head [L]
Δh^*	Dimensionless parameter of ambient groundwater flow [-]

$A^{**}(t)$	Dimensionless variation of HZ area relative to base flow conditions [-]
$C(\mathbf{x}, t)$	Solute concentration in the aquifer [ML^{-3}]
$C_0(\mathbf{x})$	Solute concentration as initial condition [ML^{-3}]
$C_S(\mathbf{x}, t)$	Solute concentration in the river [ML^{-3}]
$d^{**}(t)$	Dimensionless variation of HZ penetration distance relative to base flow conditions [-]
$H(\mathbf{x}, t)$	Thickness of the saturated aquifer [L]
$H_0(\mathbf{x})$	Initial river stage [L]
H_p	Peak river stage during the flood event [L]
$H_r(t)$	River stage at the downstream end [L]
$h_r(x, t)$	Transient river stage [L]
$M(t)$	Displacement of the sediment-water interface [L]
P_e	Péclet number [-]
\mathbf{q}	Specific discharge or Darcy flux [LT^{-1}]
\mathbf{Q}	Aquifer-integrated discharge [L^2T^{-1}]
$Q_{in, HZ}^*(t)$	Dimensionless net flux along the river boundary [-]
$Q_{in, HZ}^*(t)$	Dimensionless exchange flux from the aquifer to the river [-]
$Q_{out, HZ}^*(t)$	Dimensionless exchange flux from the river to the aquifer [-]
$Y(x, t)$	Location of the sediment-water interface boundary [L]
$z_b(\mathbf{x})$	Elevation of the underlying impermeable layer [L]
Γ_d	Dimensionless parameter of aquifer transmissivity [-]
$\mu_r(\mathbf{x}, 0)$	Mean (first order of) residence time distribution [T]
$\mu_{out}^*(x, t)$	Flux-weighted ratio of mean RT to mean RT under baseflow conditions [-]
$\mu_n(\mathbf{x}, t)$	n -th moment of residence time distribution [T^n]
$\mu_r^*(\mathbf{x}, t)$	Mean residence time distribution ratio between slope and vertical river bank model [-]
$\mu_{\tau 0-\max}$	Maximum RT in the domain [T]

$\mu_{\tau-S}(\mathbf{x}, t)$	Mean residence time distribution of slope river bank model [T]
$\mu_{\tau-V}(\mathbf{x}, 0)$	Mean residence time distribution of vertical river bank model [T]
$\rho(\mathbf{x}, t, \tau)$	Residence time distribution [T]

Abbreviations

HZ	Hyporheic zone
HEF	Hyporheic exchange flux

42

43 1. Introduction

44 The hyporheic zone (HZ) can be described as the region that connects the river
45 channel and adjacent aquifer, and includes riverbed and riverbanks. Mixing and
46 transport of different water types (groundwater, surface water) and water ages in the
47 HZ driven by hydrodynamic and hydrostatic factors cause spatially and temporally
48 varying exchange of water and biogeochemical species between river channel, riverbed
49 and aquifer (Cardenas, 2009b; Hester and Gooseff, 2010; Krause et al., 2011, 2017,
50 2022; McClain et al., 2013; Boano et al., 2014). The hyporheic exchange flux (HEF)
51 represents the interaction flux between surface water and groundwater in vertical (e.g.,
52 bedform-driven) and horizontal/lateral (e.g., meander-driven) directions, which can add
53 to general regional groundwater exfiltration and infiltration. The distribution of
54 hyporheic flow paths strongly determines the spatial and temporal distribution of
55 hydrogeochemical characteristics of water within the riverbed and the wider river
56 corridor as well as the formation of so-called hot zones and hot moments (Krause et al.,
57 2013, 2017; Cardenas, 2015; Pinay et al., 2015).

58 HEF is controlled by parameters such as stream discharge dynamics, recharge,
59 riverbed and aquifer hydraulic properties, local hydraulic head fluctuations, as well as
60 river geometry and morphology including sinuosity and riverbank slope (Larkin and
61 Sharp, 1992; Gomez-Velez et al., 2012; 2017; Schmadel et al., 2016). For example,
62 Cardenas et al. (2004) demonstrated how riverbed characteristics and especially the
63 heterogeneity of hydraulic conductivity could increase HEF by 17% to 32%. As such,
64 a better estimation of the relative importance of HEF on catchment water fluxes and
65 biogeochemical processes requires a good understanding of its different drivers and
66 controls. This is imperative as the spatiotemporal progression of HEF, the resulting
67 change in HZ (area) and thus also the residence or travel time (RT) of the exchanged
68 water in the HZ have significant impact on flow dynamics and transient storage along
69 the river continuum and in turn control the capacity for contaminant attenuation

70 (Weatherill et al., 2018) and biogeochemical functions of river corridors (Bertrand et
71 al., 2012; Boulton et al., 2010; Brunke and Gonser, 1997).

72 Both lateral exchange between river and its floodplain, as well as bedform-
73 induced vertical exchange at the streambed interface have been found to be crucial with
74 regards to HEF and the biogeochemical transformation potential along the river corridor
75 (Boano et al., 2010, 2014; Gomez-Velez and Harvey, 2014; Gomez-Velez et al., 2015,
76 2017; Kiel and Cardenas, 2014; Stonedahl et al., 2013). By using numerical simulations,
77 considerable progress has been made with regards to our understanding of how river
78 planform geometry (Boano et al., 2006, 2010; Cardenas 2006; 2008; 2009a, 2009b;
79 Stonedahl 2013), dynamic flood events (Gomez-Velez et al., 2012; 2017) and
80 evapotranspiration (Kruegler et al., 2020) control HEF. Focusing on lateral exchange
81 flow processes, Cardenas (2008; 2009a, 2009b) utilized numerical models to
82 investigate HEF and residence time distribution (RTD) for various river channel
83 morphologies and regional groundwater flow conditions. Their simulations indicate
84 that channel morphology, represented by sinuosity, is a dominant factor controlling HEF,
85 the total HZ area, and RTD. In addition, Boano et al. (2010) used a similar modeling
86 framework to study the relationship between RTD and biogeochemical transformation
87 by introducing surface water as a major source of dissolved organic matter that triggers
88 a sequence of redox reactions within the HZ. Reactive transport simulations showed a
89 good relationship between RTD and denitrification reaction potential. Based on these
90 studies, Gomez-Velez et al. (2012) conducted numerical simulations to investigate the
91 impact of aquifer parameters (water table gradient, hydraulic conductivity, dispersivity)
92 and channel sinuosity on HEF and RTD. The authors analyzed the RTD for various
93 aquifer conditions to study when a meander can play a role as both source or sink of
94 nitrate. More recent modeling studies focused predominantly on the effects of dynamic
95 river/groundwater stage fluctuations on lateral (e.g., Schmadel et al., 2016; Gomez-
96 Velez et al., 2017) and vertical (e.g., Singh et al., 2019, 2020; Wu et al., 2018, 2020,
97 2021) hyporheic exchange and RTD. For example, Gomez-Velez et al. (2017) explored

98 the HZ response to a dynamic river stage due to variable hydraulic conductivity,
99 groundwater flow gradient and river sinuosity conditions. Their results indicate that
100 during a flood event the dynamic forcing greatly influences net HEF, the area of the HZ
101 as well as mean RTD across different settings, whereby the aquifer transmissivity is one
102 of the key parameters.

103 Although there is a considerable body of numerical research on the lateral
104 hyporheic response to the various geometrical (e.g., geometry of river channel, river
105 slope, etc) and dynamic drivers (e.g., fluctuation of river/groundwater, gaining and
106 losing stream conditions, etc.), many HZ studies do not specifically consider
107 floodplain-driven processes or they assume vertical riverbanks with straight river
108 planimetry in an attempt to reduce model complexity in line with the analytical or
109 numerical solutions used (Cooper and Rorabaugh, 1963; Hunt, 1990; Schmadel et al.,
110 2016; Gomez-Velez et al., 2017;). However, riverbanks are usually sloping (inclined)
111 rather than vertical (Liang et al., 2018) as they undergo erosion (by surface and
112 subsurface water) and gravity collapse (Osma and Thorne, 1988; Fox and Wilson, 2010).
113 Previous research has proven that bank erosion and bank collapse are controlled by
114 various factors, such as initial bank slope angle (Zingg, 1940; Lindow et al., 2009),
115 surface flow forces (Hagerty et al., 1995; Fox and Wilson, 2010), vegetation cover
116 (Mayor et al., 2008; Gao et al., 2009; Puttock et al., 2013) and sediment properties
117 (Millar and Quich, 1993). Previous studies have demonstrated that neglecting bank
118 slope when modelling riverbank hyporheic exchange may have significant impact on
119 model prediction accuracy (Doble et al. 2012a, 2012b; Liang et al. 2020) and RTD
120 (Derx et al., 2014; Siergieiev et al., 2015) in an unconfined floodplain aquifer. Thus, a
121 detailed analysis of the floodplain drivers of HEF should require a more detailed
122 consideration of the floodplain geometry including riverbank slope in bank storage
123 conceptual models (Sharp, 1977).

124 A few previous studies have used numerical modeling where the model is bounded
125 by a sloping riverbank to assess the influence of bank slope on HEF for a vertical section

126 of an alluvial aquifer. In such cases, the aquifer was considered variably saturated,
127 homogenous, and isotropic, while flow in the unsaturated zone was calculated using the
128 Richards equation (Li et al., 2008; McCallum et al., 2010; Doble 2012a; b). These
129 studies have confirmed that neglecting bank slope can lead to an underestimation of the
130 bank storage volume as well as the temporal HEF in vertical cross-sectional profiles,
131 especially under relatively small bank angles.

132 In turn, river sinuosity and ambient groundwater gradient (along the river channel)
133 have not been studied as potential drivers of sinuosity-driven lateral HEF and RTD and
134 their biogeochemical implications when a sloping river bank exists and it needs to be
135 determined whether considering both drivers can lead to significantly different findings
136 as compared to previous cross-sectional profile models (Doble et al., 2012; Siergieiev
137 et al., 2015; Derx et al., 2014). In this study, we therefore quantify the effect of bank
138 slope on the spatial extent (area) of the HZ in sinuosity-driven river meanders in
139 response to a flood event and how it impacts the progression of HEF and RTD under
140 varying aquifer transmissivity conditions to better understand lateral HEF through the
141 alluvial plain. The RTD represents the distribution of average pore water travel time
142 since the infiltration of river water into the system for a given time (Gomez-Velez et al.,
143 2012; Singh et al., 2019). We build on the numerical modeling approach introduced by
144 Gomez-Velez et al. (2017) and consider lateral bank slope by coupling the deformed
145 geometry method (DGM) to the flow (Liang et al. 2020), the solute transport and the
146 residence time distribution equation. Our results reveal how and when bank slope plays
147 an important role in sinuosity-driven meandering rivers with respect to HEF and RTD,
148 which in turn will lead to an improved understanding of the river channel-aquifer-
149 floodplain system and provide guidance on the placement of monitoring locations in
150 river management studies.

151

152 2. Methodology

153 2.1 Model setup using deformed geometry method

154 The modeling approach and dimensionless parameterization used by Gomez-Velez
155 et al. (2017) can represent most riverbank-aquifer situations and dynamic flood
156 conditions. In our study, we use their conceptual model to set up a baseline case with
157 the same model frame, equations and parameterization metrics. Additional information
158 regarding the implementation of this baseline case can be found in the SI. However,
159 where their previous research assumed a vertical river bank for sinuosity-driven HEF,
160 we consider a sloping riverbank and use the Deformed Geometry Method (DGM)
161 approach to capture the dynamic progression of the surface water interface (SWI) along
162 the river course. A constant sloping angle (δ [°]) along the alluvial riverbank of a
163 sinusoidal river was implemented in our model (see blue lines of conceptual model in
164 Figure S1 and the corresponding mathematical model in Figure S2a) while the SWI was
165 assumed to be always vertical (vertical solid red and green lines in Figure S2c). As such,
166 the contraction or expansion of the simulated domain, i.e., displacement of the SWI can
167 be characterized by the sloping angle (there is no movement of the SWI for the vertical
168 riverbank case) and river stage. As the river stage changes, so does the location of the
169 SWI.

170 When the river stage changes in our model, the sinusoidal boundary will migrate
171 towards or away from the floodplain meaning that the submerged part of the riverbank
172 is considered contracted and our model only considers the alluvial aquifer that is not
173 submerged. The changes of the SWI during a flood event can be calculated by
174 considering river stage and bank slope via:

$$175 \quad Y(x, t) = Y_0(x) + M(t) \quad (1)$$

176 where $Y(x, t)$ [L] is the location of the SWI boundary while $Y_0(x)$ [L] is the initial

177 location of the SWI. $M(t) = [h(t) - h(0)]/\tan(\delta)$ is the displacement of the SWI in y -
178 direction due to river stage fluctuation and bank slope angle (see the horizontal distance
179 between the vertical red and green solid line in Figure S2c). In contrast to the vertical
180 riverbank models of Gomez-Velez et al. (2017), $M(t)$ is added in Eq. (1) to simulate
181 sloping riverbank conditions.

182 To simulate the model domain deformation and mesh displacement, we use the
183 DGM interface in COMSOL Multiphysics (COMSOL) (COMSOL Multiphysics, 2019).
184 In this interface, the deforming feature of a specified domain can be defined as a
185 boundary condition with a given moving velocity or displacement. DGM is based on
186 the arbitrary Lagrangian–Eulerian (ALE) method, which is a hybrid method that allows
187 both the model domain and mesh to move or deform simultaneously in a predefined
188 manner. More details on ALE can be found in Donea et al. (2014). While it has
189 previously been used for simulating general free-surface problems (e.g., Duarte et al.,
190 2004; Maury, 1996; Pohjoranta and Tenno, 2011), to our knowledge, DGM has not yet
191 been implemented to solve moving boundary problems in hyporheic exchange studies.
192 Here we used Eq. (1) as an input to the DGM interface to simulate the displacement of
193 the SWI (water flow) during a dynamic flood event. Infiltration and seepage face before
194 and after the peak time of the flood event, respectively, were neglected (Boano et al.,
195 2006; Cardenas. 2009a, b; Kruegler et al., 2020). Fig. 1 illustrates the river stage
196 hydrograph of this study (Fig. 1a, calculated by Eq. (S2), where $t^* = t/t_d$, t_d is the
197 duration of flood event) and the diagram of the displacement of the SWI (Fig. 1b)
198 during the flood event after coupling DGM into the model. The colored river boundaries
199 in Fig. 1b are corresponding to the times of colored dots in Fig. 1a. Additionally, solute
200 transport and mean RTD were simulated based on the extent of the flow field according
201 to Gomez-Velez et al. (2017), as shown in the SI (S2 and S3, respectively).

202

203

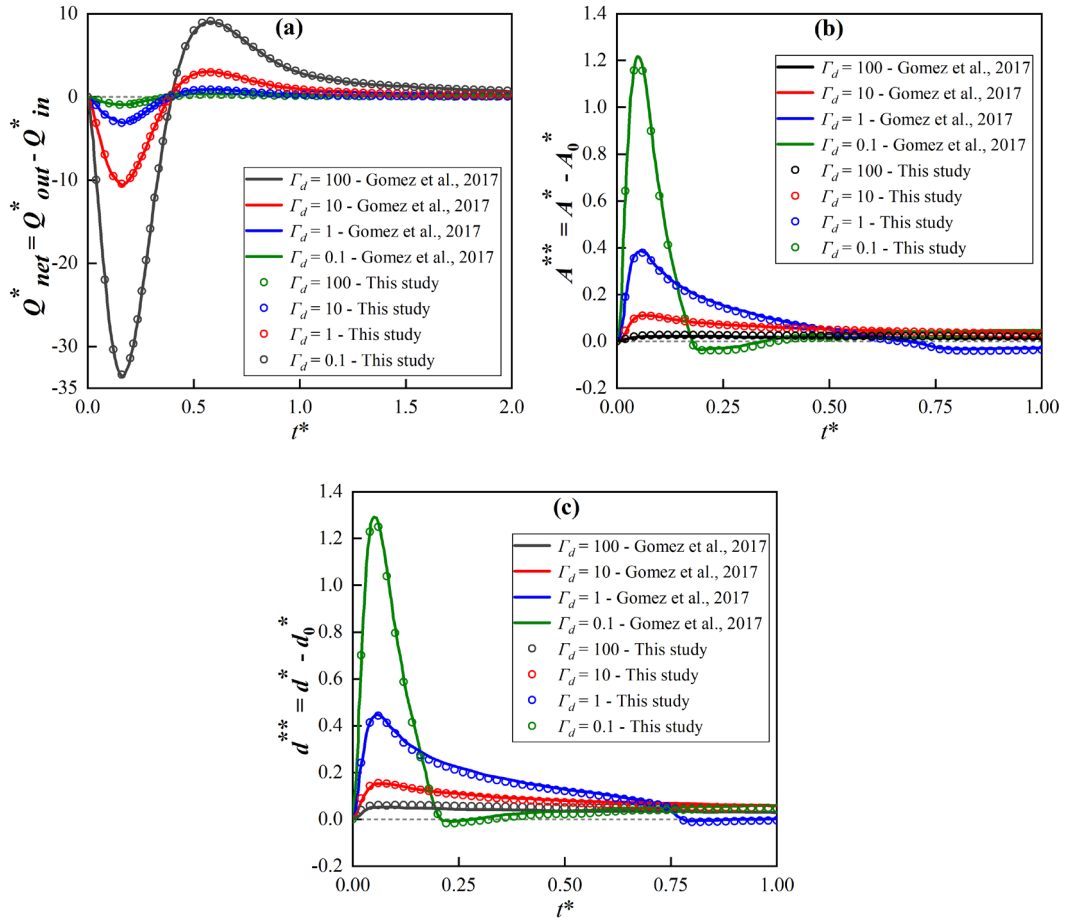

204 **Figure 1.** (a) River stage hydrograph during the flood event; (b) diagram showing
 205 displacement of SWI during the flood event. The colored SWIs in (b) correspond to the
 206 times of colored dots in (a). When the river stage increases, the river boundary migrates
 207 into the aquifer and recovers to its initial location as river stage decreases as also
 208 indicated by the arrows.

209

210 2.2 Model parameterization, testing and scenarios

211 Hydraulic conditions used in our numerical modeling study are based on values
 212 from Gomez-Velez et al. (2017), who conducted a Monte Carlo analysis. They found
 213 that the dynamic variations of HEF and mean RTD are mainly determined by ambient
 214 groundwater flow and the ratio of aquifer hydraulic conductivity to the duration of the
 215 flood event, referred to as dimensionless constant $\Gamma_d = \frac{S_y \lambda^2}{0.5K(1+n_0)H_0 t_d}$ (see Table 1 and Fig.
 216 S2), where S_y is specific yield [-]; λ is wave length of sinuous river; K is hydraulic
 217 conductivity [LT^{-1}]; n_0 is intensity of the flood event [-] H_0 is base river stage [L]; t_d
 218 duration of the flood event [T]).

219 After setting up the baseline model case with a vertical riverbank ($\delta = 90^\circ$), we
 220 compared our model results for that case with those obtained by Gomez-Velez et al.
 221 (2017) for (a) net HEF represented by $Q_{net, HZ}^*(t)$; (b) area of HZ, $A^{**}(t)$; (c) penetration
 222 of the HZ, $d^*(t)$ for $\Gamma_d = 0.1, 1, 10$ and 100 , and found that our model simulated those
 223 cases with high accuracy (Fig. 2). Parameters $A^{**}(t)$ and $d^*(t)$ are based on modeling the
 224 transport of a conservative solute while $Q_{net, HZ}^*(t)$ is based on modeling water flow.
 225 Slight differences between our model and that of Gomez-Velez et al. (2017) might be
 226 due to the use of a much more refined mesh in this study as well as different length
 227 scales.
 228

230
 231 **Figure 2.** Comparison of results obtained in this study with those of Gomez et al. (2017)
 232 for the baseline case with a vertical river bank and variable Γ_d : (a) net hyporheic
 233 exchange flux represented by $Q_{net, HZ}^*(t)$; (b) extent of the hyporheic zone $A^{**}(t)$ and (c)

234 penetration distance $d^*(t)$ of the hyporheic zone into the alluvial valley. A more refined
235 mesh and different length scales used in this study can explain slight variations between
236 our model and that of Gomez et al. (2017). Information regarding model fits can be
237 found in the SI.

238 To test, whether our assumption of considering a vertical SWI and using the DGM
239 to characterize the migration of the SWI was appropriate, we compared the vertical 2-
240 D model with a 1-D model coupled with the DGM. Detailed information on this
241 comparison as well as validation results are provided in the SI in section S4. The results
242 show that our approach is reasonable when simulating HEF in a sloping riverbank
243 aquifer.

244 We then considered a series of riverbank scenarios where the bank slope angle
245 was varied, ranging from $\delta = 90^\circ$ (vertical riverbank) to 10° (nearly horizontal case)
246 and Γ_d values ranged from 0.1 to 100, corresponding to aquifer hydraulic conductivity
247 ranging from 480 to 0.048 m/d, indicating high to low transmissivity. Table 1 presents
248 the parameters used in our numerical modeling study. The finite-element models
249 proposed in this study were set up using the COMSOL Multiphysics (COMSOL)
250 software. Eq. (S1), Eq. (S3) and Eq. (S6) were implemented by using a customized
251 Partial Differential Equation (PDE) interface to include the Boussinesq equation,
252 vertical integrated solute transport equation and equation for calculating residence
253 (travel) time distributions (RTD), respectively. The model domain was discretized into
254 about 0.5 million variably-sized triangular elements, with refinement imposed near the
255 river boundary. Mesh-independent numerical solutions are achieved by limiting grid
256 size (ΔL) to less than 0.2 m. Thus, the transverse and longitudinal Peclet numbers
257 (calculated by $Pe = \Delta L/\alpha_L$ and $Pe = \Delta L/\alpha_T$, respectively) in both advection and diffusion
258 dominated zones are less than 1, which is smaller than the upper limit of $Pe = 4$ to
259 effectively avoid numerical oscillations and instabilities.

260

261 **Table 1.** Parameters and values used in our numerical model simulations.

Parameters	Value	Description
Constant model parameters		
S_y	0.3	Specific yield [-]
λ	40	River boundary wave length [L]
α	5	River boundary amplitude [L]
θ	0.3	Efficient porosity [-]
J_x	0.0025	Base groundwater gradient [-]
σ	1.14	River boundary sinuosity [-]
t_d	10	Duration of flood event [T]
n_d	0.25	Skewness of flood event [-]
t_p	$n_d t_d$	Time to peak river stage [T]
H_0	1	Base river stage [L]
n_0	1	Intensity of flood event [-]
α_L	2	Longitudinal dispersivity [L]
α_T	$0.1 \alpha_L$	Transverse dispersivity [L]
Variable model parameters		
Γ_d	0.1 1 10 100	Dimensionless aquifer transmissivity [-]
δ	90 70 50 20 10	Bank slope angle [°]

262

263 Similar to Gomez-Velez et al. (2017), we evaluated the impact of bank slope by
264 comparing the net hyporheic exchange flux ($Q_{net, HZ}^*(t)$), area of HZ ($A^{**}(t)$),
265 penetration distance of the HZ ($d^{**}(t)$) and mean RTD ($\mu_r^*(\mathbf{x}, t)$) between vertical and
266 sloping river bank models. A detailed definition of these variables is provided in the SI
267 (section S5).

268

269 **3. Results**

270 **3.1 Effect of bank slope on hyporheic exchange flow and HZ extent**

271 **3.1.1 Hyporheic exchange flow**

272 The flow field (velocity magnitude and direction) and net HEF ($Q_{net, HZ}^*(t)$)
 273 changed dynamically during and after the simulated flood event. Fig. 3a – 3d show the
 274 progression of net HEF for different aquifer transmissivity (Γ_d) and bank slope angle
 275 (δ) conditions. Snapshots of the flow field and the boundary of the HZ area (isolines of
 276 $C(\mathbf{x}, t) = 0.5$ as concentration of a conservative solute) for different δ conditions at
 277 different times (pink dots in Fig. 3a) for $\Gamma_d = 1$ are shown in Fig. 4a - 4f.

278

279

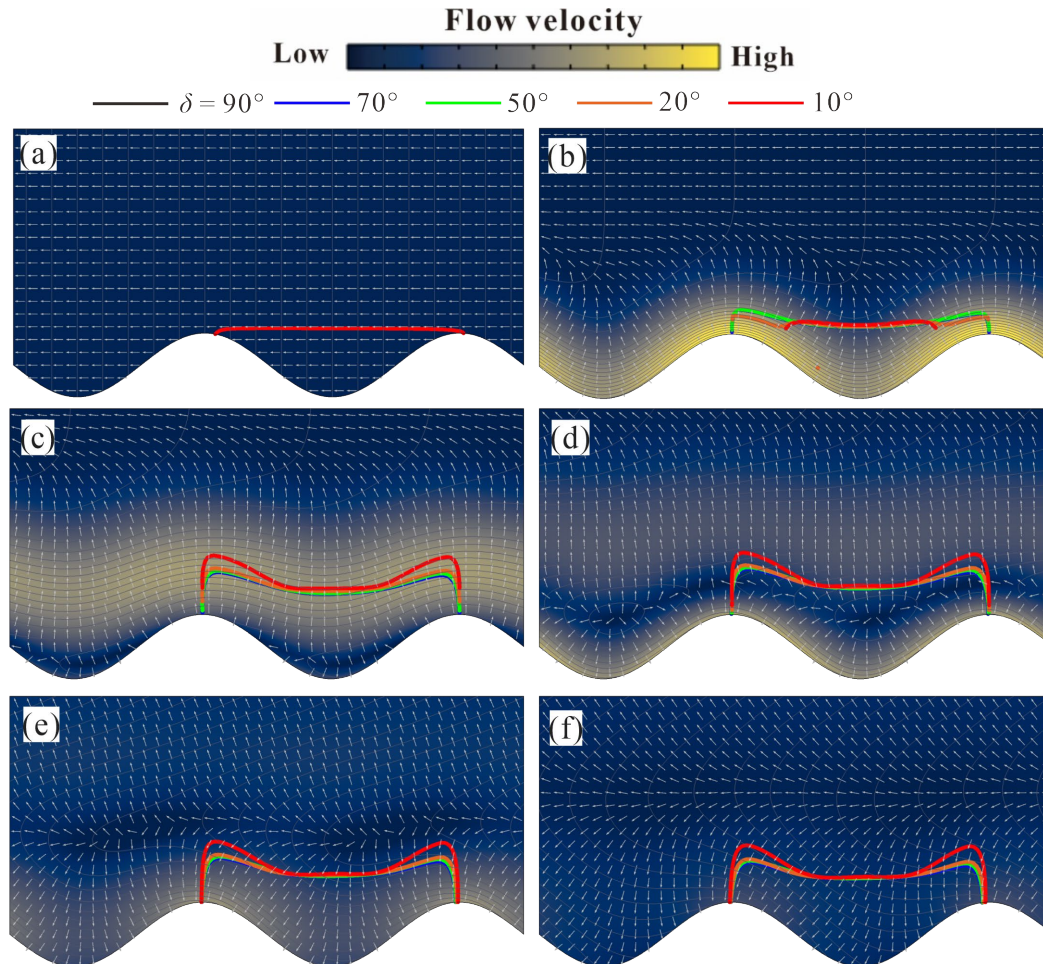

280

281 **Figure 3.** Temporal progression of dimensionless net HEF ($Q_{net, HZ}^*(t)$) for four
 282 different aquifer transmissivity values (represented by Γ_d) and bank slopes angles (δ ,
 283 from 10-90 degrees). Time-to-peak flood (t_p) and flood duration (t_d) are marked by
 284 vertical dashed lines. Pink dots in (a) marked by (a) - (f) correspond to the snapshots of
 285 the flow field shown in Fig. 4. A negative flux value here represents water flow from

286 the river to the aquifer. Note that I_d negatively correlates with the transmissivity of the
 287 aquifer.

288

289

290 **Figure 4.** Plan view of the river channel and aquifer showing the temporal progression
 291 of the alluvial flow field and spatial extent of the HZ. (a)-(e) are snapshots of the flow
 292 field at different time steps ($t^* = 0, 0.16, 0.39, 0.57, 1, 1.5$) during the simulated event
 293 (pink dots in Fig. 3a). Colored surfaces represent the magnitude of the Darcy flux vector
 294 (blue is low and yellow is high) and white isolines the dimensionless hydraulic head.
 295 Bold colored lines correspond to the HZ extent for different bank slope conditions.

296

Before the flood event ($t = 0$), steady-state base flow conditions are assumed, as
 297 shown in Fig. 4a. The inflow and outflow (along the upstream and downstream meander
 298 bend, respectively) are in balance. The bank slope has no effect on the HZ boundaries
 299 before the flood event. Before peak river stage of the flood event is reached ($0 < t <$

300 $0.25t_d$), the onset of the flood event is indicated by the rising river stage and forces the
 301 river to infiltrate into the aquifer along the SWI (negative values of $Q_{net, HZ}^*(t)$ in Fig.
 302 3), resulting in the expansion of the HZ as shown in Fig. 4b. The influx of river water
 303 into the HZ ($-Q_{net, HZ}^*(t)$) reaches its maximum before the time-to-peak river stage ($t =$
 304 $0.25t_d$) because the pressure wave propagates into the aquifer and decreases the head
 305 gradient between the river and the connected aquifer. For higher transmissivity aquifers
 306 (Lower Γ_d values in Fig. 3), bank slope has a reduced impact on net outflux as the fast
 307 propagation of the pressure wave results in the hydraulic head near the SWI to be very
 308 similar. Among different aquifer transmissivity conditions. As aquifer transmissivity
 309 decreases, the ability of the aquifer to transmit the pressure wave becomes limited, and
 310 the interaction flux is dominated by the location (displacement) of the SWI and the river
 311 stage. On the other hand, a smaller slope angle induces a longer displacement of the
 312 SWI ($M(t)$) away from the river, where the groundwater head adjacent to the SWI is
 313 always relatively high (i.e., the head in base flow condition). This, consequently, leads
 314 to a larger head gradient near the SWI as well as larger dimensionless net fluxes under
 315 increasing Γ_d conditions as shown in Fig. 3.

316 The maximum dimensionless flux ratios $Q_{max, var}^* = Q_{max, s}^* / Q_{max, v}^*$ of sloping (δ
 317 $< 90^\circ$, $Q_{max, s}^*$) vs vertical ($\delta = 90^\circ$, $Q_{max, v}^*$) riverbank cases are shown in Fig. 5, which
 318 indicates the deviation in predicting peak net flux when neglecting the slope of the
 319 riverbank. The bank slope is found to increase infiltration by up to 120% ($Q_{max, var}^* \approx$
 320 2.2) for $\Gamma_d = 100$ with $\delta = 10^\circ$ while for larger slope angles or higher hydraulic
 321 transmissivities the dimensionless infiltration gradually decreases.

322

323

324 **Figure 5.** Ratio of maximum net flux for slope to no-slope (vertical river bank)
 325 conditions $Q_{max,var}^* = Q_{max,s}^*/Q_{max,v}^*$ for four aquifer transmissivities and slope angles.
 326 Note that Γ_d negatively correlates with aquifer transmissivity.

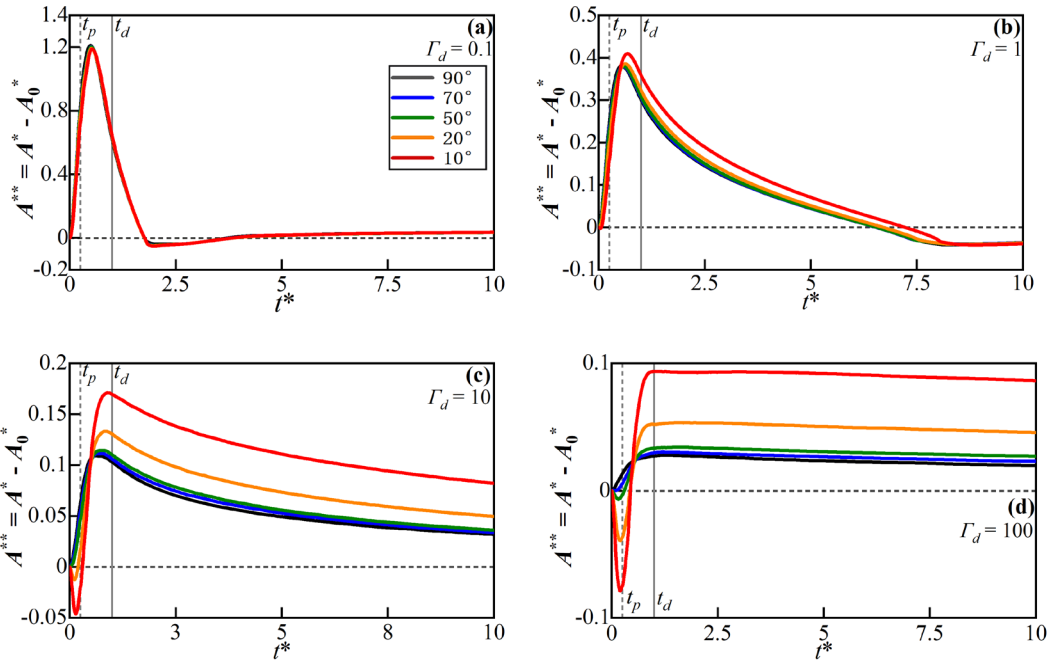

327 As the river stage decreases after t_p , the head gradient near the SWI gradually
 328 reverses and the net outflux starts increasing (the river is gaining water) as shown in
 329 Fig. 3. This is associated with the river stage declining below the groundwater level
 330 (see Fig. 4c - 4f). For the lowest hydraulic transmissivity condition ($\Gamma_d = 100$), bank
 331 slope can slightly extend the time required for the system to recover to initial conditions
 332 after t_p but in general, the response of the net outflux to bank slope is negligible when
 333 compared to that of the influx. Eventually, the net flux converges to zero, which
 334 indicates the flow field within the aquifer recovers to the initial conditions. The bank
 335 slope has no impact on the HEF after the duration of the flood event.

336 3.1.2 Patterns of hyporheic area and penetration distance

337 Fig. 6 and Fig. 7 show the temporal progression of the dimensionless HZ area
 338 ($A^{**}(t)$) and penetration distance ($d^{**}(t)$) into the alluvial valley relative to the initial
 339 condition for varying aquifer transmissivity (Γ_d) and slope angles.

340

341

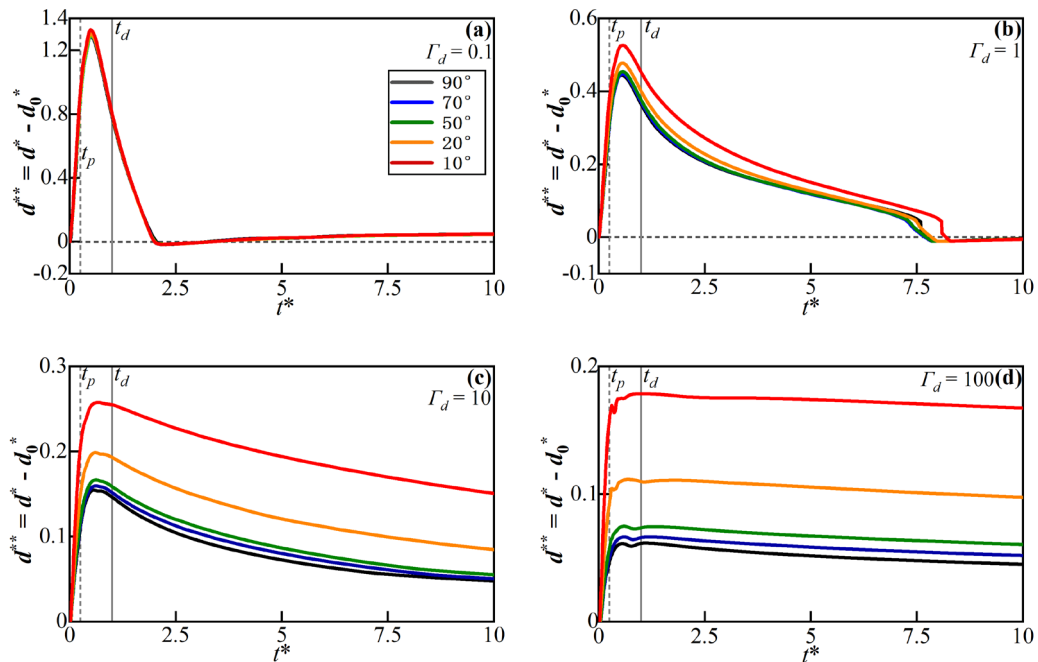

342

343

344 **Figure 6.** Temporal progression of dimensionless HZ area for different values of Γ_d and
 345 δ (colored lines). Time-to-peak (t_p) and flood duration (t_d) are marked by vertical dashed
 346 lines.

347

348

349

350 **Figure 7.** Temporal progression of dimensionless HZ penetration distance into the
 351 alluvial valley (d^{**}) for different values of Γ_d and δ (color lines). Time-to-peak (t_p) and
 352 flood duration (t_d) are marked by vertical dashed lines.

353 For vertical banks ($\delta = 90^\circ$, black lines in Fig. 6), the HZ area increases
354 synchronously with the river stage ($t < t_p$). After the peak time of the flood event ($t >$
355 t_p), the HZ area continues to extend as river water still recharges the aquifer. After the
356 flood event ($t > t_d$), the river water that was stored in the aquifer ($C(\mathbf{x}, t) > 0$) slowly
357 discharges back into the river channel. Thus, the HZ area and penetration distance
358 gradually rebound to initial conditions.

359 Under sloping riverbank conditions, the riverbank will at times be submerged by
360 the rising river stage. Fig. 6a and 7a show that the effects of bank slope on HZ area
361 ($A^{**}(t)$ in Fig. 6) and penetration distance ($d^{**}(t)$ in Fig. 7) are almost counteracted by
362 the high transmissivity of the aquifer while the influence of bank slope was negligible.
363 At the beginning of the flood event, Fig. 6b – 6d show that for conditions with smaller
364 sloping angle, HZ area can be less than zero (HZ at these times are smaller than the
365 initial condition). This is due to the fact that the movement of the SWI during a rising
366 river stage towards the alluvial valley will submerge parts that were previously
367 unsaturated as the aquifer with low transmissivity will propagate water more slowly.
368 As aquifer transmissivity decreases from Fig. 6b – 6d, the relative HZ area remains
369 negative for a longer time for smaller bank slopes. This indicates that bank slope has a
370 more pronounced effect on HZ extent in cases where aquifer transmissivity is large as
371 a low-transmissivity aquifer takes more time to propagate infiltrating river water.

372 After about half the flood duration ($t > 0.5t_d$), the HZ area (A^{**}) becomes positive
373 in all scenarios as the model domain previously submerged during the flood event re-
374 emerges. As aquifer transmissivity decreases (Fig. 6a – 6d and Fig. 7a – 7d), the impact
375 of bank slope gradually increases especially in low aquifer transmissivity conditions,
376 where smaller bank slope can increase the peak values of area and penetration distance,
377 and delay the arrival time-to-peak value of the relative HZ area. After the flood event
378 ($t > t_d$), the effect of bank slope is counteracted by the higher aquifer transmissivity and
379 only lower transmissivities have a significant impact on the HZ resulting in larger $A^{**}(t)$
380 and $d^{**}(t)$ as shown in Fig. 6b – 6d and Fig. 7b – 7d. For low transmissivity scenarios,

381 the bank slope can increase the peak area and penetration of the HZ by almost 200%.

382 3.2 Spatiotemporal progression of mean residence time distribution

383 The progression of spatiotemporal patterns of mean RTD (i.e., travel time of river
 384 water in aquifer) is a useful evaluation method for identifying the dynamic variation of
 385 aging and rejuvenation of hyporheic water. Here we use the mean RT ratio between a
 386 sloping model and a vertical model $\mu_r^*(\mathbf{x}, t) = \log_{10}(\mu_{\tau-S}(\mathbf{x}, t)/\mu_{\tau-V}(\mathbf{x}, 0))$ to evaluate the
 387 influence of bank slope on the prediction of mean RTD for a given location and time.
 388 Fig. 8 presents mean RTDs for the initial condition, where $\mu_{\tau 0-\max}$ is the maximum RT
 389 in the domain. It can be seen that the isolines representing the RT are almost horizontal
 390 in the area extending from the river but RT near the upstream river bend is smaller than
 391 downstream because the initial flow direction is towards the negative direction of the x
 392 axis. Notably, $\mu(\mathbf{x}, 0)$ grows almost exponentially as y increases, and a positive
 393 correlation to Γ_d at a given location is observed.

394

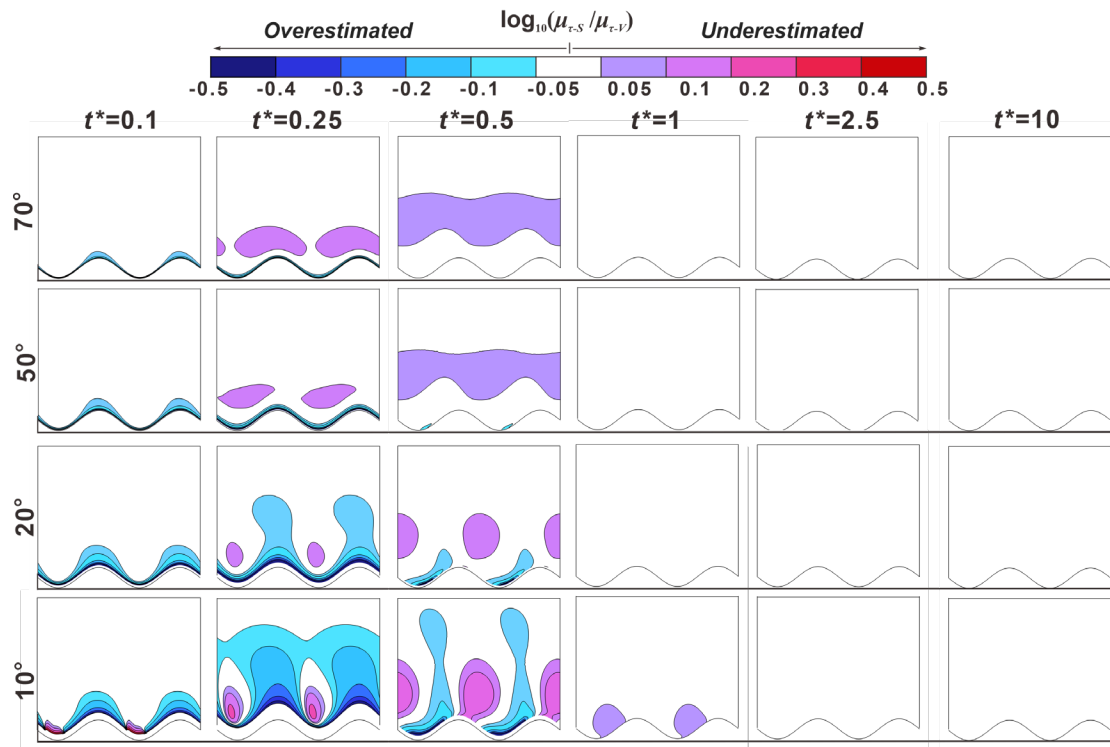

395

396 **Figure 8.** Plan view of relative mean residence time distributions [-] for baseline flow
 397 conditions (no bank slope), which are represented by $\log_{10}\mu_{\tau}(\mathbf{x}, 0)/\log_{10}\mu_{\tau-\max}(\mathbf{x}, 0)$ to
 398 show the distribution pattern. The value of the contour lines grows exponentially with
 399 the distance from the river meander.

400 Fig. 9 - 12 present five snapshots of μ_r^* for different bank slope angles and different

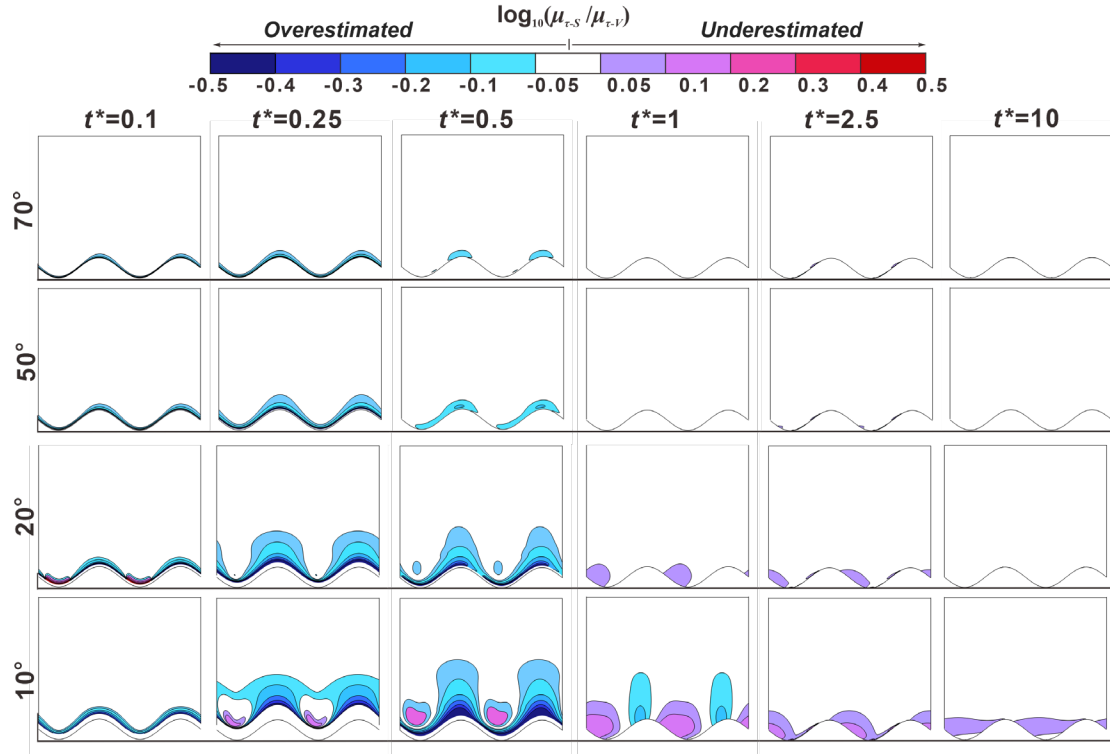

401 aquifer transmissivity values ($\Gamma_d = 0.1, 1, 10$ and 100 , respectively). The five snapshots
 402 represent the rising limb of the flood event ($t^* = 0.1$), the peak of the flood event ($t^* =$
 403 0.25), the falling limb of the flood event ($t^* = 0.5$) and a time after the flood event (t^*
 404 $= 1, 2.5$ and 10). The differences in residence time between sloping and vertical
 405 riverbank models are within 12.2% in the white-colored areas ($-0.05 < \mu_r^* < 0.05$) of
 406 Fig. 9 - 12, which indicates a minor effect of bank slope on mean RTD. The colored
 407 areas in Fig. 9 – 12 indicate model results where neglecting bank slope will lead to an
 408 overestimation ($\mu_r^* < -0.05$) or underestimation ($\mu_r^* > 0.05$) of residence (travel) times.
 409

410

411 **Figure 9.** Five snapshots for the mean RTD ratio ($\mu_r^*(\mathbf{x}, t) = \mu_{r-S}^*(\mathbf{x}, t) / \mu_{r-V}^*(\mathbf{x}, t)$)
 412 between sloping ($\mu_{r-S}^*(\mathbf{x}, t)$) and vertical riverbank conditions ($\mu_{r-V}^*(\mathbf{x}, t)$) at different
 413 times t^* as a function of δ for $\Gamma_d = 0.1$. The horizontal lines beneath each figure are the
 414 reference lines to show the initial location of the peak point of the point bar. The lower
 415 sinuous lines at the reference lines are the initial SWIs. The colored areas indicate where
 416 the bank slopes have significant impact on RT (difference in RT between sloping and
 417 vertical model larger than 12.2%) and residence (travel) times of river water in the

418 aquifer would be overestimated (cold color area) or underestimated (warm color area)
 419 if the effect of the bank slope was ignored.
 420

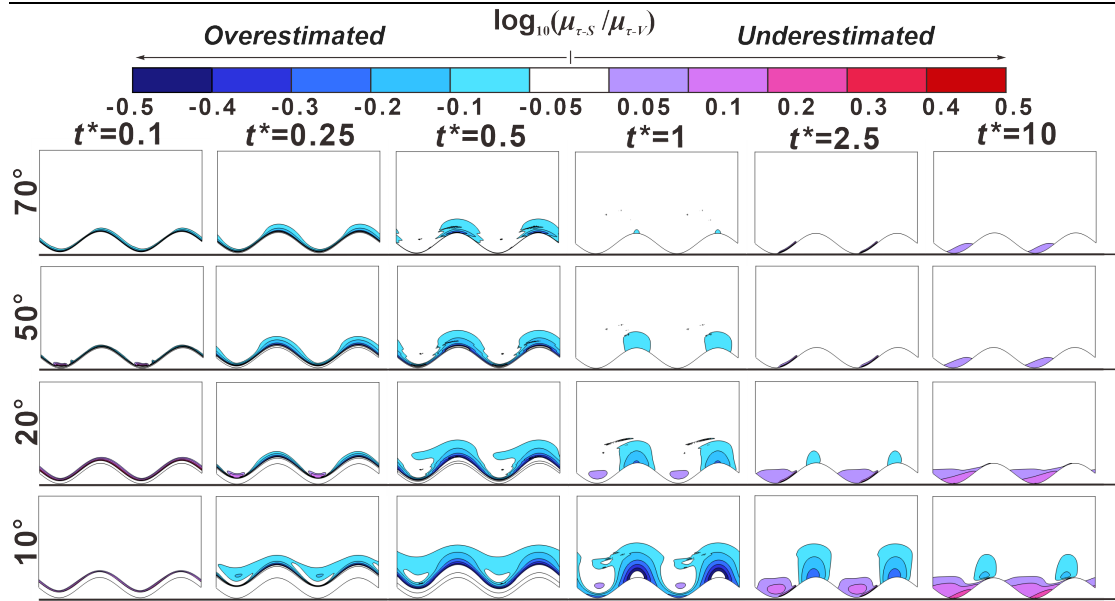

421

422 **Figure 10.** Five snapshots for the mean RTD ratio ($\mu_r^*(\mathbf{x}, t) = \mu_{r-S}^*(\mathbf{x}, t) / \mu_{r-V}^*(\mathbf{x}, t)$)
 423 between sloping ($\mu_{r-S}^*(\mathbf{x}, t)$) and vertical riverbank conditions ($\mu_{r-V}^*(\mathbf{x}, t)$) at different
 424 times t^* as a function of δ for $\Gamma_d = 1$. The horizontal lines beneath each figure are the
 425 reference lines to show the initial location of the peak point of the point bar. The lower
 426 sinuous lines at the reference lines are the initial SWIs. The colored areas indicate where
 427 the bank slopes have significant impact on RT (difference in RT between sloping and
 428 vertical model larger than 12.2%) and residence (travel) times of river water in the
 429 aquifer would be overestimated (cold color area) or underestimated (warm color area)
 430 if the effect of the bank slope was ignored.

431

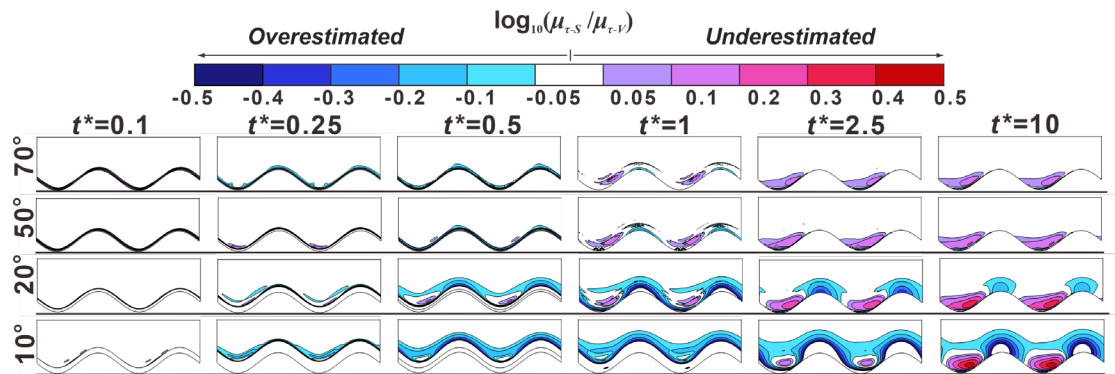

432

433

434 **Figure 11.** Five snapshots for the mean RTD ratio ($\mu_r^*(\mathbf{x}, t) = \mu_{r-S}^*(\mathbf{x}, t) / \mu_{r-V}^*(\mathbf{x}, t)$)
 435 between sloping ($\mu_{r-S}^*(\mathbf{x}, t)$) and vertical riverbank conditions ($\mu_{r-V}^*(\mathbf{x}, t)$) at different
 436 times t^* as a function of δ for $\Gamma_d = 10$. The horizontal lines beneath each figure are the
 437 reference lines to show the initial location of the peak point of the point bar. The lower
 438 sinuous lines at the reference lines are the initial SWIs. The colored areas indicate where
 439 the bank slopes have significant impact on RT (difference in RT between sloping and
 440 vertical model larger than 12.2%) and residence (travel) times of river water in the
 441 aquifer would be overestimated (cold color area) or underestimated (warm color area)
 442 if the effect of the bank slope was ignored.

443

444

445 **Figure 12.** Five snapshots for the mean RTD ratio ($\mu_r^*(\mathbf{x}, t) = \mu_{r-S}^*(\mathbf{x}, t) / \mu_{r-V}^*(\mathbf{x}, t)$)
 446 between sloping ($\mu_{r-S}^*(\mathbf{x}, t)$) and vertical riverbank conditions ($\mu_{r-V}^*(\mathbf{x}, t)$) at different
 447 times t^* as a function of δ for $\Gamma_d = 100$. The horizontal lines beneath each figure are the

448 reference lines to show the initial location of the peak point of the point bar. The lower
449 sinuous lines at the reference lines are the initial SWIs. The colored areas indicate where
450 the bank slopes have significant impact on RT (difference in RT between sloping and
451 vertical model larger than 12.2%) and residence (travel) times of river water in the
452 aquifer would be overestimated (cold color area) or underestimated (warm color area)
453 if the effect of the bank slope was ignored.

454 At $t^* = 0.1$, a smaller bank slope can lead to a shorter travel time of river water in
455 the aquifer (negative values of μ_r^*) near the SWI compared to the vertical riverbank
456 scenario. The area of shorter travel time caused by bank slope was positively related to
457 aquifer transmissivity. The effect of bank slope is small for $\Gamma_d = 10$ and 100 because the
458 groundwater mound (the raised groundwater stage) piles up around the river boundary,
459 but that small area extended deeper into the alluvial valley for smaller slope angles.
460 Due to the scattered and nested flow paths near the cut bank and point bar, respectively,
461 the area of the negative value of μ_r^* at the cut bank of the SWI is larger than that at the
462 point bar. The change of flow direction near the point bar leads to a prolonged flow path
463 for the water in the river channel as well as to forced groundwater mixing with the
464 slightly older water (Fig.8 shows that the water was potentially older in y direction
465 compared to $-x$ direction in the point bar). This effect was amplified with decreasing
466 bank slope angle, but it is only statistically significant ($\mu_r^* < -0.05$ or $\mu_r^* > 0.05$) when
467 $\delta = 10^\circ$ at $t^* = 0.1$.

468 At the time of peak flood ($t^* = 0.25$), the river still infiltrates into the aquifer. For
469 $\Gamma_d = 0.1$, results of μ_r^* in Fig. 9 show that bank slope can lead to both overestimated and
470 underestimated RT areas. Both magnitude of relative RT (μ_r^*) and associated area
471 increase with decreasing slope due to the longer travel distance of river water into the
472 aquifer. As the slope angle decreases, the underestimated travel time area was located
473 closer to the peak of the cutbank. The impact of bank slope on mean RTD for $\Gamma_d = 1$
474 was rather similar in its pattern compared to $\Gamma_d = 0.1$, but the degree of that impact was
475 reduced. For $\Gamma_d = 10$ and 100, only overestimated travel time area can be seen near the

476 river bank with a smaller area of impact compared to smaller Γ_d conditions, because the
 477 groundwater has not sufficiently propagated into the aquifer due to lower transmissivity.

478 At $t^* = 0.5$, part of the aquifer that was submerged at $t^* = 0.25$ reemerges due to
 479 the decline in river stage. In most cases, smaller bank slopes can lead to wider
 480 reemergence of the aquifer, which therefore results in overestimated travel time area
 481 near the river boundary; however, this was not the case for $\Gamma_d = 0.1$ where bank slope
 482 can both lead to overestimated and underestimated RT area. Furthermore, compared to
 483 when $t^* = 0.25$, the impact of bank slope becomes weaker for $\Gamma_d = 0.1$, but more relevant
 484 for the larger Γ_d values.

485 After the flood event ($t^* > 1$), the influence of bank slope on mean travel time is
 486 nearly eliminated for $\Gamma_d = 0.1$ and 1 due to the high aquifer transmissivity. However,
 487 for aquifers with lower transmissivity ($\Gamma_d = 10$ and 100), bank slope still has a
 488 significant effect on RT at $t^* = 10$ and leads to underestimated and overestimated RT
 489 areas near the point bar and the cut bank, respectively.

490 Overall, Fig. 9-12 indicate that the time when bank slope was relevant in predicting
 491 RT (travel time of groundwater in aquifer) was determined by the transmissivity of the
 492 aquifer. For more transmissive aquifers, the impact of bank slope on the prediction of
 493 groundwater travel time cannot be neglected during the flood event ($0 < t < t_d$), but that
 494 impact will be eliminated after the flood event due to the quick recovery of the aquifer
 495 to baseline conditions. For lower transmissivity aquifers, bank slope plays an important
 496 role on groundwater travel time after $t > 0.5 * t_d$ and has a more lasting influence on
 497 aquifer RT, as more time is required to recover to initial conditions.

498 3.3 Relative flux-weighted residence time

499 Fig. 13 shows the progression of the flux-weighted relative RT $\mu^*_{out}(x, t) = \mathbf{n} \cdot \mathbf{Q}^*_{out}(x,$
 500 $t) \log_{10}(\mu_t(x, t) / \mu_t(x, 0))$ for different slopes and aquifer transmissivities. $M^*_{out}(x, t)$
 501 represents the difference in flux-weighted RT of the water discharged into the river
 502 compared to the initial condition. At the start of the flood event, there is no μ^*_{out} as river

503 water infiltrates the aquifer. Following the decline in river stage, the aquifer begins to
 504 discharge the mixed water with different RT back into the river (see Fig. 4c).

505

506

507 **Figure 13.** Temporal progression of flux-weighted ratios of RT to the RT for baseline
 508 conditions ($\mu^*_{out}(x, t) = \mathbf{n} \cdot \mathbf{Q}^*_{out}(x, t) \log_{10}(\mu_{\tau}(x, t)/\mu_{\tau}(x, 0))$) along the river meander as a
 509 function of δ and Γ_d . $\mu^*_{out}(x, t)$ indicates the difference of flux weighted water RT (travel
 510 time) that the aquifer discharges into river compared to the initial condition.

511 For vertical riverbank conditions ($\delta = 90^\circ$, top row in Fig. 13), upstream ($0.5\lambda <$
 512 $x < \lambda$) and downstream ($0 < x < 0.5\lambda$) boundaries of the meander bend discharge older
 513 and younger water, respectively. The rejuvenated or aged waters that represent shorter
 514 and longer travel times compared to the baseline condition, respectively, were mostly
 515 discharged before the flood event ($t^* < 1$) due to the greater outflux as shown in Fig.
 516 3a. It can also be seen that water was aged along the upstream bend compared to the
 517 more rejuvenated water along the downstream bend. After the flood event, μ^*_{out}
 518 gradually disappears along the upstream meander (blank areas) for $\Gamma_d = 0.1$ and 1,
 519 because the flow fields were recovering to baseline conditions. Therefore, the upstream
 520 meander gradually becomes the inflow boundary.

521 For cases with lower values of Γ_d (left columns in Fig. 13), μ^*_{out} reaches equilibrium
522 earlier compared to cases with higher Γ_d as an increasing bank slope angle causes μ^*_{out}
523 to gradually decrease the travel time of the outflowing water during the flood event.
524 For larger Γ_d , μ^*_{out} was totally dominated by rejuvenated water during the flood event.
525 Furthermore, smaller bank slope angles can both extend the time that younger water is
526 discharging along the downstream meander, and increase the difference in residence
527 times of these younger waters between sloping and vertical conditions.

528 4. Discussion

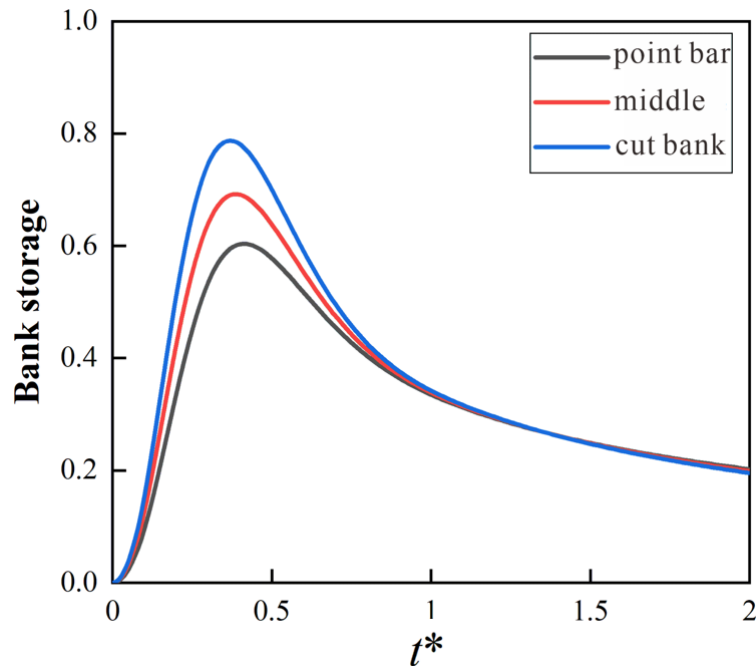

529 4.1 Why we should account for bank slope

530 Tilted riverbanks are common in nature and caused by erosion and bank collapse,
531 as has been observed at multiple scales (Zingg, 1940). Previous studies have shown that
532 bank erosion is stronger where the river planimetry is more sinuous, river stage varies
533 more frequently, or where the riverbank has larger sloping angles, ultimately leading to
534 a flatter bank (Zingg, 1940; Hagorty et al., 1995; Mayor et al., 2008; Puttock et al.,
535 2013). Yet, the impact of riverbank geometry and in particular bank slope on sinuosity-
536 driven lateral hyporheic exchange was ignored in most previous studies. Our results
537 clearly indicate that HZ characteristics (HEF, area and penetration distance of HZ into
538 the alluvial valley) can be underestimated along a meandering river depending on bank
539 slope conditions.

540 We show that not accounting for bank slope and river sinuosity can lead to an
541 underestimation of the infiltration rate of water from the river to the alluvial aquifer (by
542 up to 120%), as well as the area and penetration distance. This effect is more
543 pronounced for smaller bank slope angles (Fig 5), which can be more likely found in
544 lowland streams (Laubel et al., 2003), especially in areas with extensive cattle grazing
545 streamside (Trimble, 1994).

546 Doble et al. (2012), Siergieiev et al. (2015) and Liang et al. (2018), assessed the
 547 influence of bank slope on HEF using a vertical cross-sectional profile. Siergieiev et al.
 548 (2015) found that the impact of bank slope on HEF was proportional to the hydraulic
 549 conductivity of the aquifer. However, we argue here that bank slope is more relevant in
 550 rivers connected to aquifers with low hydraulic transmissivity (high hydraulic
 551 conductivity or low specific yield). Furthermore, we show (Fig. 14 as example) that
 552 using only one cross-sectional river profile perpendicular to the river axis does not
 553 capture the effect of river sinuosity on HEF as bank storage decreases from point bar to
 554 cut bank. This indicates that the accuracy of bank storage estimates can be improved
 555 by including river sinuosity, which has often been omitted in the past. In a meandering
 556 river with variable bank slope, river geometry thus has a sizable effect on bank storage
 557 progression and HEF, and should be included in any scenarios.

558

559

560 **Figure 14.** Bank storage versus time for $\Gamma_d = 1$ and $\delta = 90^\circ$ condition at: the peak of
 561 point bar ($x = 0$); middle ($x = 0.25\lambda$); peak of cut bank ($x = 0.25\lambda$). Dimensionless bank

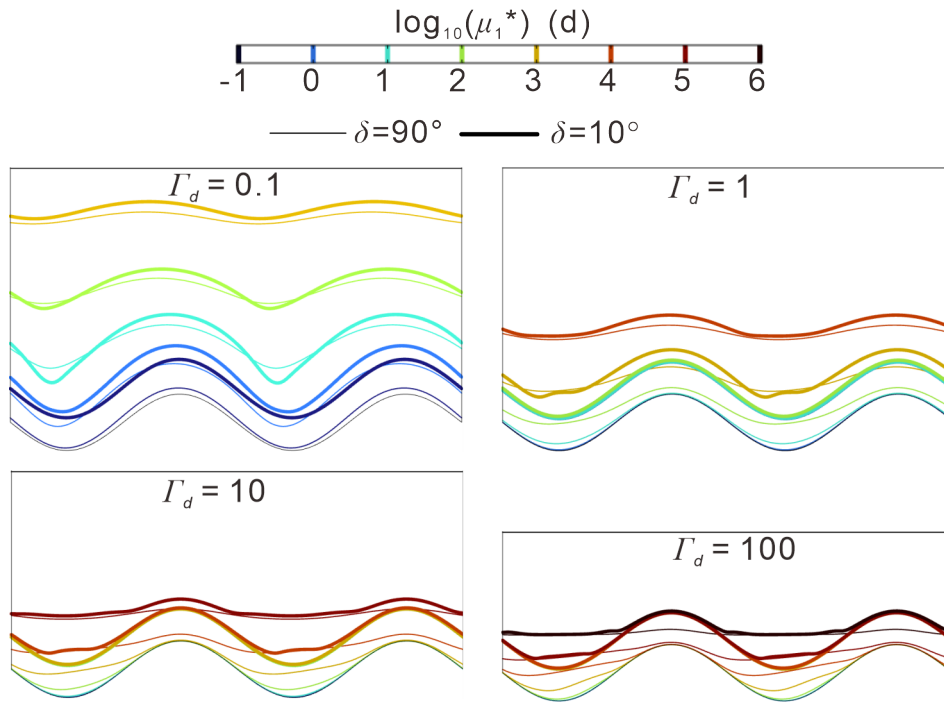

562 storage was calculated by $\frac{\int_{Y(x,t)}^{Y(x,t)+4\lambda} [h-z_b-H_0] dy}{\lambda H_p}$.

563 4.2 Implications of bank slope on biogeochemical reactions

564 Under rather stable flow conditions, hyporheic exchange rate and river sinuosity
565 control the biogeochemical zonation (RTD) in the HZ. A higher hyporheic exchange
566 rate (caused e.g., by a larger hydraulic conductivity in the aquifer or a more sinuous
567 meander) will reduce the mean RTD promoting biogeochemical reactions (Boano et al.,
568 2010; Gomez-Velez et al., 2012). However, for a transient flood event, the mean RTD
569 could be both extended and reduced depending on the location with respect to the
570 meander, due to variations in the complex flow paths (Gomez-Velez et al., 2017). Our
571 results indicate that smaller bank slope angles could not only increase HEF and thus
572 lead to increased transport of oxygen and nutrient rich stream water into the aquifer, but
573 also alter the location and the residence time of this water within the aquifer system.

574 Mean RTDs of river water in the alluvial aquifer have been used to evaluate the
575 potential for biogeochemical reactions by comparing the RT with biogeochemical
576 timescales (BTS) for given solutes (Boano et al., 2010b; Gomez-Velez et al., 2012).
577 Locations where the ratio of RT to BTS (expressed by Damköhler numbers) is small
578 indicate a high reaction potential for that specific chemical species (Gomez-Velez et al.,
579 2015; Pinay et al., 2015). It has been documented that the BTS for dissolved organic
580 matter (DOC) can vary over ten orders of magnitude ($10^{-1} - 10^9$ d) (Hunter et al., 1998),
581 while BTS for oxygen and nitrate have been found to vary over eight orders of
582 magnitude ($10^{-2} - 10^6$ d) (Gomez-Velez et al., 2012). Here, we compare the mean RTD
583 within the overlapping ranges of these two BTS for vertical and sloping riverbank
584 conditions ($\delta = 10^\circ$) at the peak time of the flood event ($t^* = 0.25$) for different aquifer
585 transmissivity conditions, and show the zonation of residence times by using a BTS
586 range of $10^{-1} - 10^6$ d (Fig. 15).

587

588

589 **Figure 15.** Plan view of the zonation of biogeochemical timescales (BTS, range of 10^{-1} – 10^6) for common HZ constituents such as DOC, oxygen or nitrate for different
 590 aquifer transmissivities at $t^* = 0.25$. thick and thin lines indicate the comparison of
 591 vertical vs sloping riverbank ($\delta = 10^\circ$) conditions, while the different colors indicate the
 592 different exponents. Unlike the previous mean RTD figures in which the relative mean
 593 RTD expressed in dimensionless form, the spatial scales of mean RTD in this figure are
 594 dimensional in days.
 595

596 Fig. 15 indicates that neglecting bank slope impacts the prediction of reaction
 597 potentials during hyporheic exchange processes, especially for locations with short time
 598 scales. The reaction hot spots (areas indicated by the overlapping BTS ranges) for
 599 sloping riverbank conditions expanded further into the aquifer compared with the
 600 vertical bank conditions, similar to the overestimated areas in Fig. 9 to Fig. 12. Note
 601 that we did not aim to include specific reaction models in our study but instead used
 602 mean RTD as an indicator for various biogeochemical reactions in the aquifer.
 603 Furthermore, the wavelength of the river sinusoid in Fig. 15 was $\lambda = 40$ m to offer a
 604 representative riverbank-aquifer condition. The zonation of BTSs for larger and smaller
 605 river sinusoid wavelengths will be reduced towards the river boundary or further

606 expanded into aquifer, respectively, for both sloping and vertical riverbank conditions.
607 Although the dimensional BTS for various spatial scales are not shown here, similar
608 patterns between Fig. 9-12 and Fig. 15 imply the usability of the mean RTD results (Fig.
609 9-12) to infer on potential biogeochemical reactions.

610 The impact of bank slope on RT is basically controlled by aquifer transmissivity.
611 For higher aquifer transmissivity conditions, the impact of bank slope appears to be
612 more pronounced when the river stage rises during a flood event. For lower aquifer
613 transmissivity conditions, bank slope seems more relevant for mean RTD after the flood
614 event and its impact is more long-lasting. Smaller bank slope angles could extend (near
615 the point bar) or reduce (near the cut bank) pore water travel times throughout the flood
616 event, compared to the non-sloping (vertical) riverbank condition. This indicates that
617 compared with the vertical riverbank condition, point bars with bank slopes are more
618 favorable for removing dissolved organic carbon and for nitrification, while cut banks
619 with bank slope may have adverse effects on the groundwater quality near rivers. The
620 vertical profile modelling study of Derx et al. (2014) suggested for riverbank restoration
621 projects, increasing HEF by reducing the slope angle may have a negative effect on
622 restoration. The mean RTD results of this study also suggest that the impact of bank
623 slope on groundwater quality is determined by the location with respect to the meander
624 (near point bar or cut bank). As such, our analysis of mean RTDs can provide valuable
625 information on whether and where riverbank slope can induce biogeochemical hotspots
626 and hot moments and help guide choices to be made in biogeochemical field surveys
627 regarding location and sampling time under dynamic river stage conditions, especially
628 when the connected aquifers have low hydraulic transmissivity.

629

630 **4.3 Advantages and limitations of using a reduced 2-D model**

631 In this study, we propose a parsimonious reduced-order, idealized horizontal 2-D
632 model that simplifies the variation of the river-aquifer interface by using the moving

633 boundary method to depict the displacement of the SWI along a sloping riverbank. An
634 advantage of this approach is reduced model complexity as compared to a three-
635 dimensional model, which greatly reduces time and data requirements during model
636 building and computational demand during the simulation of HEF and especially
637 residence time distributions. Thus, our reduced-order model acts as a first step to gain
638 insight into the patterns of hyporheic exchange, riverbank storage and mean RTD in
639 settings with more complex riverbank morphology and dynamic forcing. Future efforts
640 should be focused on optimizing the computational method applied here and on
641 including more detailed morphology and hydrodynamic characteristics.

642 In our simulations we assume a constant bank slope angle along the entire
643 meandering river while natural riverbanks often change their slope angle from reach to
644 reach as well as with time. This variability could lead to more complex SWI travel
645 distances and residence time distributions, and new conceptualizations that account for
646 the contribution of bank slope on time-varying RTD and HZ extent are needed. In our
647 simulations we tested the model using a range of aquifer hydraulic conductivities.
648 Although hydraulic conductivity (or transmissivity) is a critical parameter in the
649 quantification of exchange fluxes and RTD between the two systems under varying
650 slope conditions, other parameters such as valley water head fluctuation, water
651 abstraction e.g. for agriculture or drinking water supply, peak flood event characteristics
652 or larger scale groundwater head fluctuation, e.g., due to changing groundwater
653 recharge in the context of changing rainfall patterns have not been considered here but
654 might also impact HZ extent, RTD and river-aquifer exchange flux. For example, valley
655 water head fluctuation and water abstraction in the aquifer will lead to a lower
656 groundwater table, increasing the hydraulic gradient between river and aquifer. This
657 will lead to the formation of a larger HZ area as well as longer travel distances and
658 times of river water in the aquifer. Thus, reducing the slope of the river bank could
659 reduce the infiltration of polluted river water into the riparian aquifer.

660 The current study assumes a perennial stream and unconfined (phreatic) conditions

661 in the connected aquifer as well as changing hydraulic gradients leading to gaining and
662 loosing conditions in the river. Where there is no hydraulic gradient between river and
663 aquifer, no large-scale infiltration of river water into the riverbanks will occur, while
664 local turbulent flow (e.g., due to obstacles in the river channel) might lead to localized
665 infiltration over short distances and short time scales (Sawyer et. al., 2011; Stonedahl
666 et al., 2013; Käser et al., 2013). Where the unconfined layer is small (e.g., in
667 mountainous headwater streams with a rather small sediment layer overlying a hard-
668 rock aquifer with relatively low hydraulic conductivity), the HZ is limited in its
669 maximum extent, and travel times and distances are considerably shorter. However, in
670 mountainous settings, slope angles are often much steeper due to erosion (here rivers
671 incising into the bedrock) and further simulations are required to better understand the
672 feedback between bank slope angle, hydraulic gradient and maximum extent of the
673 unconfined layer allowing for hyporheic exchange processes. These simulations will
674 also help us better understand the impact of bank slope on quantitative and qualitative
675 water supply to abstraction wells, e.g., used for the production of drinking water.

676 While using the Boussinesq equation neglects the influence of the vadose zone,
677 this approach as well as the assumption of a vertically integrated distribution of
678 hydraulic head have been widely used in the literature and proven adequate when
679 simulating sinuosity-driven HEF patterns (Boano et al., 2006; 2010., Cardenas. 2008;
680 2009a, b; Gomez-Velez et al., 2012; 2017, Kruegler et al., 2020). While we found
681 differences in HEF patterns when comparing simple models using the Boussinesq with
682 those using Richard's equation (S4 in SI) these differences exist independent of using
683 the DGM. However, we recommend in future studies to more systematically consider
684 these two different approaches with respect to their advantages and limitations, e.g., in
685 terms of computability or efficiency in predicting HEF under various conditions. While
686 in an ideal scenario a 3-D modeling approach includes vadose zone and riverbank slope
687 angle (both variable in time and space), for the moment the implementation of such
688 detailed models in practice suffers from limited computing capabilities.

689 5. Conclusions

690 The deformed geometry method was applied to characterize the expansion and
691 contraction of hyporheic zones along sloping riverbanks, and to evaluate the impact of
692 bank slope on hyporheic exchange flux, progression of the HZ area and residence
693 (travel) time distributions of the infiltrating water. To achieve this, several unconfined
694 alluvial aquifers with varying slope angles and aquifer transmissivity values were
695 simulated. Our results show that bank slope in a sinuosity-driven river was non-
696 negligible when the aims of numerical/analytical models are the prediction of the
697 progression of the hyporheic zone during and after a flood event (transient flood
698 forcing).

699 The overall findings of our work underline the need for including more realistic
700 riverbank morphological conditions into simulations when studying lateral hyporheic
701 exchange flow responses to dynamic forcings. Furthermore, our results show that more
702 detailed information on bank slope (e.g., through more measurements) can lead to a
703 better understanding of hyporheic flow patterns and potentially result in improved
704 biochemical process understanding for real-world conditions for more complex
705 morphological and depositional environments. Several conclusions can be drawn from
706 our study:

- 707 1. Sloping riverbanks can considerably increase HEF during a flood event, especially
708 when the river is connected to an alluvial aquifer with rather high hydraulic
709 conductivity and small bank slope angles as water can more easily infiltrate the
710 connected aquifer. Smaller bank slope angles can lead to an extended hyporheic
711 zone with river water infiltrating deeper (penetration distance) into the aquifer.
712 However, bank slope has only a minor impact on the hyporheic outflow flux (water
713 re-entering the stream).
- 714 2. During a flood event, the impact of bank slope on mean residence time distributions
715 (RTD) is more pronounced for aquifers with high hydraulic transmissivity, due to

-
- 716 the larger area and deeper penetration distance of the HZ for these conditions. On
717 the contrary, the impact of bank slope on mean RTD for lower transmissivity
718 aquifers is minor during the flood event, but bank slope can have a significant and
719 long-lasting effect post-flood.
- 720 3. River sinuosity should be considered when assessing the impact of bank slope on
721 mean RTD. Variable bank slope can lead to both longer and shorter residence times
722 when compared to vertical riverbank conditions.
- 723 4. Bank slope has a greater impact on the residence time of hyporheic water in lower-
724 transmissivity aquifers, thereby delaying the time of younger water discharge
725 downstream of a meander bend, which also delays the outflow of older water
726 upstream of that bend.
