8 **Abstract.** This study evaluates the seasonal and inter-seasonal temperature regime of small tundra ponds ubiquitous to an  
9 extensive low-gradient wetland in the Canadian High Arctic. Pond temperatures can modify evaporation and ground thaw  
10 rates, losses of greenhouse gases, and control the timing and emergence of insects and larvae critical for migratory bird feeding  
11 habits. We focus our study on thaw ponds with a range of hydrologic linkages and sizes across Nanuit Itillinga, formerly  
12 known as Polar Bear Pass (PBP), Bathurst Island, and compare their thermal signals to other Arctic ponds. Pond temperatures  
13 and water levels were evaluated using temperature water level loggers and verified by regular manual measurements. Other  
14 environmental data collected included microclimate, frost table depths, and water conductivity. Our results show that there is  
15 much variability in pond thermal regimes over seasons, years, and space. Cumulative relative pond temperatures were similar  
16 across years, with ponds normally reaching 10-15° C for short to longer periods except in 2013, a cold summer season when  
17 pond temperatures never exceeded 5° C. Pond frost tables and water conductivities respond to variable substrate conditions  
18 and pond thermal patterns. This study contributes to the ongoing discussion of climate warming and its impact on Arctic  
19 landscapes.  
20

## 21 **1 Introduction**

22 Arctic landscapes are warming faster than temperate locations (e.g., Linderholm et al., 2018; Sim et al., 2019; Kreplin et al.,  
23 2021; McCrystall et al., 2021; Webb et al., 2022), specifically, up to four times faster than the global average since 1979  
24 (Rantanen et al., 2022). This rapid warming has implications for thawing of permafrost, the alteration of hydrologic regimes  
25 (snow on/off, ice-free duration, runoff), changes in hydrologic pathways, and a suite of other environmental and ecosystem  
26 impacts (e.g., Webb et al., 2022). There is an expectation that the Arctic will transition from a snow-dominated to a rainfall-  
27 dominated regime, especially with an occurrence of higher rainfall in the fall (McCrystall et al., 2021), and some suggest that  
28 it will occur earlier than initially modelled (McCrystall et al., 2021).

29 Recently, there has also been a suite of studies and literature reviews evaluating the warming of water bodies (e.g.,  
30 ponds, lakes, and streams) across arctic landscapes (e.g., Dranga et al., 2017; Lehnher et al., 2018; McEwen and Butler, 2018;  
31 Saros et al., 2023) and elsewhere (e.g., small ponds in Alaska — Andresen and Lougheed, 2015; wetlands in the high Andes

32 — Dangles et al., 2017; ponds/lakes in W. Greenland — Higgins et al., 2019). Saros et al. (2023) remark that “knowing  
33 temperatures and thermal structure within lakes and flowing waters at present and predicting their changes in the future is  
34 critical for understanding how aquatic ecosystems will undergo future changes”. Other researchers, particularly in the  
35 subarctic, are concerned with deepening talik development (unfrozen ground) and lake expansion due to the interactions of  
36 shoreline erosion, rising lake bottom temperatures and the occurrence of deep snow near lake/pond shorelines (Roy-Leveillee  
37 and Burn, 2017).

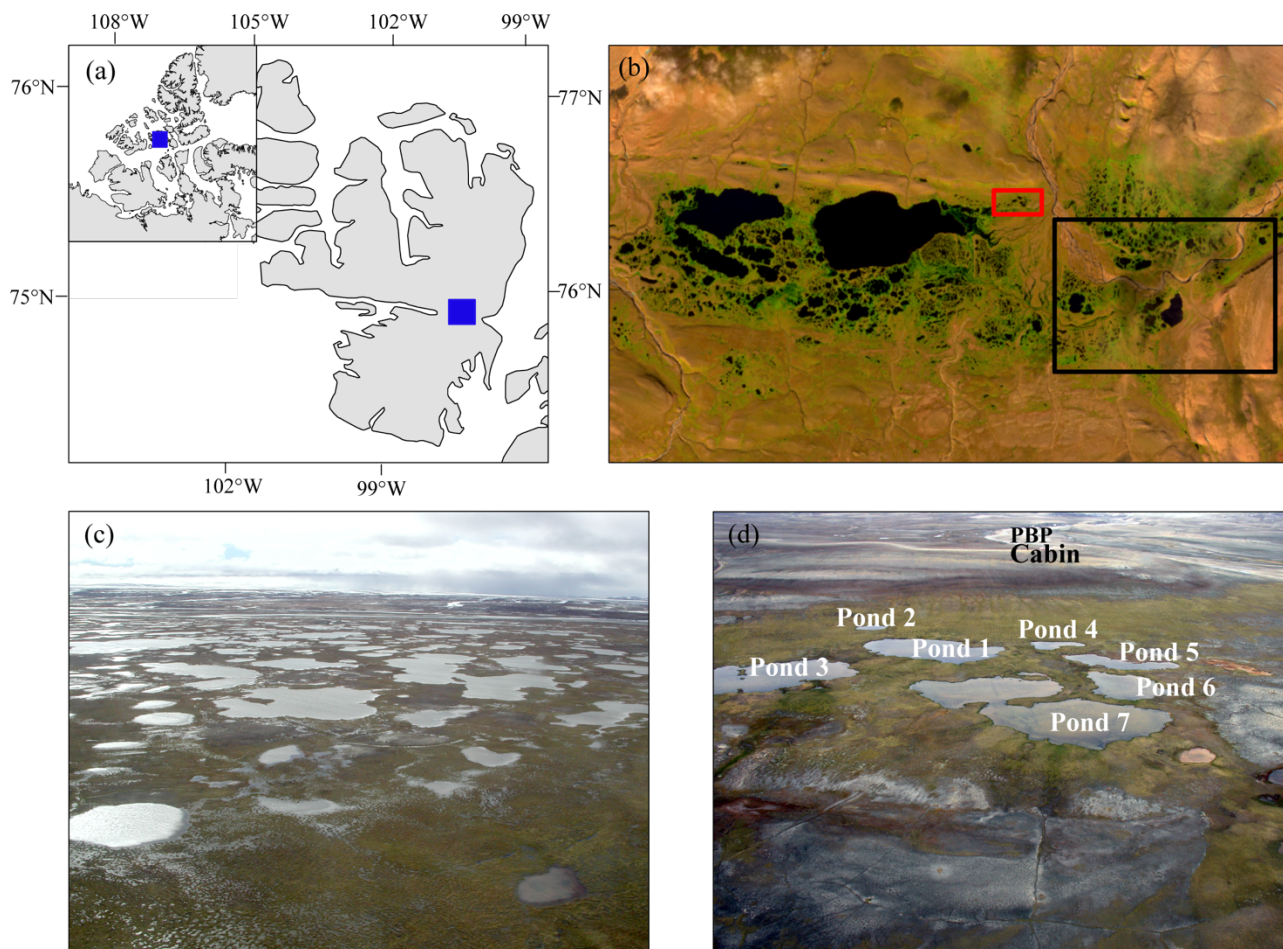

38 In the Eastern Canadian Arctic, warming has been especially prominent since 2000, with growing loss of glacier ice,  
39 permafrost thaw, disappearance of late-lying snowbeds, and the drying of small, patchy wetlands (Woo and Young, 2014).  
40 There has been a growing interest in how climate warming will affect northern wetlands here, because temperature increases  
41 can enhance evaporation rates, thaw permafrost, drain ponds, or initiate the development of new ponds. Warmer substrates can  
42 increase the thaw depth of water bodies and temperature has an impact on vegetation growth and greenhouse gases, including  
43 water vapour, methane and carbon dioxide (Negandhi et al., 2013; Andresen and Lougheed, 2015; Wrona et al., 2016; Zandt  
44 et al., 2020; Kreplin et al., 2021; Dyke and Sladen, 2022, Miner et al., 2022; Rheder et al., 2023). This study of pond thermal  
45 regimes at PBP adds to this body of literature by evaluating the seasonal and inter-seasonal temperature regime of small tundra  
46 ponds ubiquitous to an extensive low-gradient wetland in the Canadian High Arctic spanning warm and cool spring/summers.

47 First, we examine the spatial and temporal variability of pond temperatures across PBP, highlighting variations in  
48 pond location, hydrological linkages, and response to climate variability on a seasonal and annual basis. We then evaluate  
49 whether July average pond temperatures vary across ponds at PBP and in relation to other Arctic sites. This study also examines  
50 the air-pond temperature relationship and we explore the impact of pond temperatures on the local environment in terms of  
51 pond ground thaw and water chemistry (i.e., specific conductivity), given that others have reported deeper thaw in warmer  
52 water bodies and higher nutrient loads (e.g., Saros et al., 2023). Finally, we place our results in the context of other studies and  
53 discuss how these ponds are affected by both cool and warm seasons, and what can be expected in the future for these ponds  
54 and the ecosystems that depend on them.

## 55 **2 Study Area**

56 The study took place at the extensive low-lying wetland, Nanuit Itillinga - Polar Bear Pass (PBP) Bathurst Island, Nunavut  
57 (75. 72° N 98.67° W) from 2007 to 2015, with detailed pond studies occurring in 2008 and 2009. PBP is a National Wildlife  
58 Area and a Ramsar wetland site of international importance (Baker et al., 2021). The wetland itself is about 20 km long and 5  
59 km wide and is boarded by low-lying hills ranging upwards of 160 m to the north, and 170 m to the south (Caledonian River,  
60 District of Franklin, NWT, 1985 topographic map (1:50000, 68H/11, edition 1)). The low-lying wetland encompasses two  
61 small lakes and a myriad of ponds (small to large) exhibiting uniform or irregular shapes (Fig. 1). Detailed characteristics of  
62 the PBP watershed and study ponds can be found elsewhere (e.g., Abnizova, 2013; Abnizova et al., 2014; Young et al., 2017),  
63 however we do provide a summary of the study ponds including location, pond area, water, and frost table depths and details

64 on pond substrate where available (Supplementary Table S1, Supplementary Fig. S1). Overall, we had 17 study ponds in 2007,  
65 25 in 2008, 23 ponds in 2009, 25 ponds in 2010, 2 ponds in 2012, and only 1 pond in 2013 and 2015. No pond work was  
66 carried out in 2011 owing to medical issues. Pond surface areas varied from approximately 275 to 31,400 m<sup>2</sup> and water levels  
67 fell between 60 to 359 mm (Table S1). Where available, pond substrates ranged from grey to dark greyish brown and consisted  
68 of fines to coarse sand. Soil tests in 2009 did not fully capture the rocky substrate that existed for some ponds (e.g., Pond 11)  
69 (see Table S1, Fig. S1).

### 76 3 Methods

77 We describe the thermal regime of selected ponds (small to large) across PBP – ones centrally located, and others situated at  
78 the eastern, western, and southern edges of the wetland. Some ponds are isolated (i.e., no apparent water sources feed into  
79 them), whereas other ponds are connected or temporarily connected to small creeks, other ponds, and/or meltwater from nearby  
80 late-lying snowbeds (Abnizova et al., 2014). Ponds at PBP are defined as having a maximum water depth of < 2.0 m (National  
81 Wetland Working Group, 1997; Woo, 2012). Pond substrate type varied: some pond bottoms were firm, light-coloured, while  
82 others had rocky or dark, soft organic beds (see Table S1, Fig. S1). Water levels in the ponds were continuously monitored  
83 with Ecotone water level recorders (Remote Data Systems Inc.,  $\pm 2.54$  mm) or with HOBO water level sensors ( $\pm 3$  mm),  
84 which also measured temperature ( $\pm 0.2^\circ$  C) on an hourly basis. These sensors were typically placed in the centre of the pond  
85 in perforated, screened water wells (5.1 to 7.6 cm dia.) open to the atmosphere and secured into frozen ground. In ponds which  
86 were difficult to access due to a soft substrate, water wells and HOBO sensors were placed near the shoreline and occasionally  
87 these sensors were placed on the pond bed, particularly in remote ponds. HOBO water level sensors were also placed in dry  
88 wells dug into wet meadow areas to monitor the atmospheric pressure. The difference in the pressure determined by HOBO  
89 water level sensors in the ponds and the atmosphere allowed pond water levels (mm) to be derived (see Rosenberry and  
90 Hayashi, 2013). Like other shallow arctic ponds, the study ponds were generally well-mixed negating any concern about  
91 significant differences in temperatures of the bed and the water column (Dyke and Sladen, 2022).

92 Manual measurements of water levels at centrally located ponds were made on a regular basis, usually every one to  
93 two days, with a measuring tape ( $\pm 5$  mm) to verify continuous measurements. Less frequent manual measurements were made  
94 at distant ponds. Small HOBO temperature sensors ( $\pm 0.1^\circ$  C) were also deployed in ponds to track hourly temperatures.  
95 Manual estimates of temperature and conductivity were made with a YSI conductivity meter ( $\pm 0.2^\circ$  C,  $\pm 1$   $\mu$ S/cm), while a  
96 Hanna pH meter provided an additional check on temperature ( $\pm 0.2^\circ$  C) along with water pH ( $\pm 0.2$ ). In 2008, hourly estimates  
97 over several days were made of water chemistry in the selected ponds, including water level (m), temperature ( $\pm 0.15^\circ$  C),  
98 conductivity ( $\pm 1.0$   $\mu$ S/cm), dissolved oxygen (%), and pH ( $\pm 0.2$ ), using a YSI 600 Multiparameter Sonde (Abnizova et al.,  
99 2014). In 2009, the YSI sonde was also used to obtain manual estimates of water chemistry in several centrally located ponds,  
00 and in 2012 pH and conductivity were monitored in Pond 1 on an hourly interval over several days.

01 To examine generalized patterns of spatial and temporal trends between air and pond temperatures, Pearson  
02 correlations ( $r$ ) of pond to air temperatures (2008, 2009) were determined for daily mean temperatures  $\geq 0^\circ$  C (Johnson et al.,  
03 2014). To investigate inter-site correlations, water temperatures at Pond 1 were evaluated in relation to other ponds. A Student-  
04  $t$  test ( $\alpha = 0.05$ ) was used to compare means of pond water temperature ( $T_w$ ) when appropriate in the study (Bluman, 2006).  
05 We also utilize cumulative percentage diagrams and box plots to provide insights into the overall distribution, concentration  
06 and variation of pond thermal data (see <https://www150.statcan.gc.ca/n1/edu/power-pouvoir/ch10/5214864-eng.htm>).

07 Changes in ground thaw can alter drainage patterns and water storage in ponds (Young and Woo, 2003; Rehder et al.,  
08 2023). Thaw depth in ponds was measured by probing the ground with a metal rod ( $\pm 10$  mm) twice a week near water wells

09 early in the season and then weekly once ground thaw slowed, providing a means of assessing active layer development and  
10 re-freeze (i.e., 2008, 2009) (Abnizova et al., 2014). Climate data (e.g., air temperature) were obtained from the main automatic  
11 weather station located near the PBP cabin situated on the plateau above the wetland (see Young and Labine, 2010; Young et  
12 al., 2013; Miller and Young, 2016 for additional details on instrumentation, sensor siting, and frequency of monitoring). These  
13 data allowed us to examine the air temperature-pond response, and to place our results in context of the variable spring and  
14 summer conditions over several years at PBP, and in relation to the nearest government weather station at Resolute Bay  
15 (Qausuittuq), Cornwallis Island, Nunavut (74.72° N 94.97° W) about 146 km to the southwest.

## 16 **4 Results**

### 17 **4.1 Seasonal thermal regime**

18 The seasonal regime of ponds at PBP over several years was explored using the detailed data from Pond 1 (Fig. 2: 2007-2015).  
19 It is a medium-sized pond downslope of a wet meadow and lingering deep snowbed located in the lee of a hillslope (Young et  
20 al., 2017). The diagram also illustrates the range of pond temperatures during two extreme years (2012-warm vs. 2013-cool).  
21 In warm years (e.g., 2010, 2012), pond water temperatures warm rapidly by mid-June with peak pond temperatures reaching  
22 about 15° C for extended periods. There is considerable variability from year-to-year, but the general trend is warming in June,  
23 elevated temperatures in July and then falling temperatures in August. In context of Resolute air temperatures from 1948 to  
24 2015 (Environment Canada (Resolute): weather.gc.ca), the 2012 JJA air temperature (4.6° C) was the 2<sup>nd</sup> highest on record,  
25 while the 2013 JJA average (0.9° C) was one of the coolest (ranked 11<sup>th</sup> coolest, along with three other years) over a period of  
26 68 years.

27 Figure 3 indicates that Pond 1 and the centrally located ponds show similar seasonal cycles. Pond temperatures ( $T_w$ )  
28 are generally higher than the air temperature during the thaw season when temperatures are  $> 0^\circ \text{C}$ , with most also trending  
29 with the air temperature signal. This pattern suggests well mixed conditions as noted for shallow ponds elsewhere in the Arctic  
30 (Dyke and Sladen, 2022). In 2009, Pond 1  $T_w$  correlated well with all pond temperatures ( $r > 0.8$  to  $> 0.9$ ) including ones at  
31 the periphery of PBP (east, west, and south). In 2008, a similar pattern between Pond 1 and the other ponds across the wetland  
32 emerged ( $r > 0.8$  to  $> 0.9$ ), except for the Meadow Pond ( $r(66) = 0.34$ ,  $p = 0.005$ ). The Meadow Pond is located in a small,  
33 elevated valley, and unlike most ponds, has deep residual snowbeds lying on the adjacent slopes. The nearby Pingo Pond is  
34 not fed by the snowbeds. Meltwater from lingering snowbeds feeding the Meadow Pond ensures that pond temperatures are  
35 dampened in comparison to more exposed and isolated wetland ponds. Others have observed this pattern on northeast  
36 Ellesmere Island (e.g., Smol and Douglas, 2007).

37  
38

39

40  
41

**Figure 2. Seasonal regime of water temperature (Tw) at Pond 1, PBP (2007-2015). Manual measurements for 2007 and daily averages for 2008-2015 are plotted.**

42

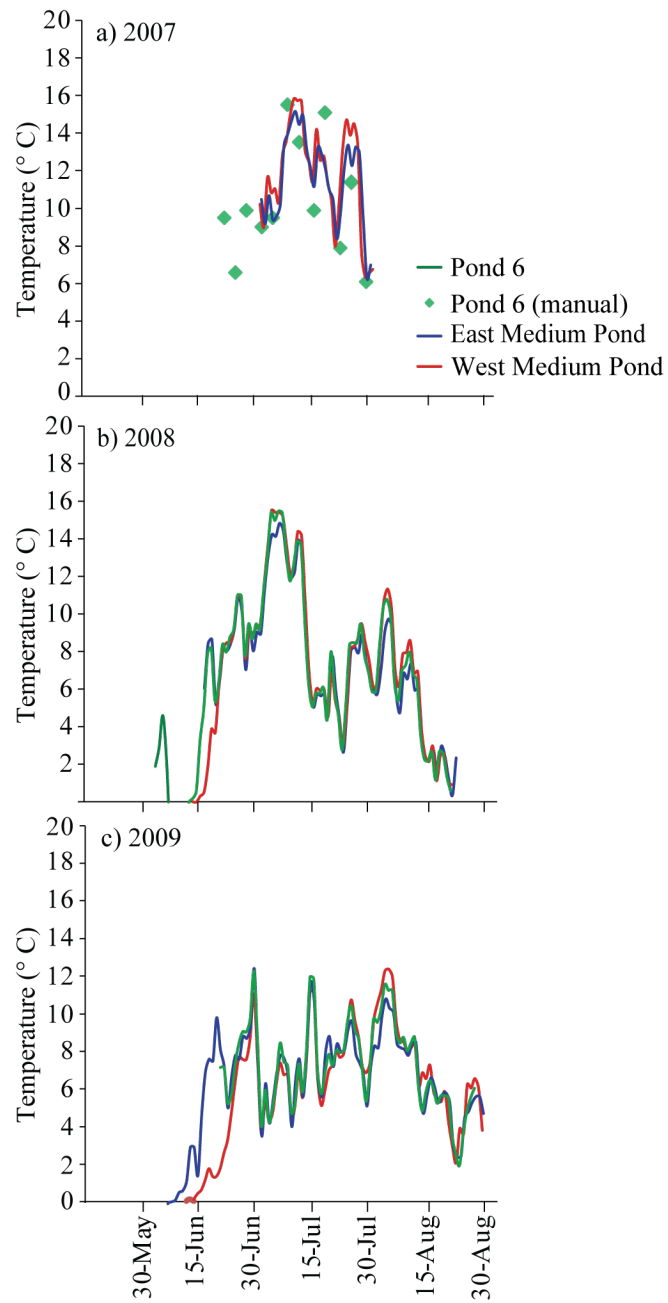

43  
44

**Figure 3. Daily average water temperature of Pond 1 versus other centrally located ponds at PBP, 2009. The daily average air temperature is also plotted.**

45

46 Figure 4 illustrates the seasonal rhythm (2007, 2008, and 2009) of medium-sized ponds across PBP. Here we select Pond 6 in  
47 the central cluster of ponds as representative of a medium-sized pond. In 2007, by July 20, Pond 6 was slightly warmer than  
48 other two ponds, though the rhythms – peaks and troughs of pond Tw remained similar. Warming is comparable to that seen  
49 to Fig. 2, where there is some variation in Tw from year-to-year, though these ponds do not exceed 15° C for prolonged periods.  
50 Young and Labine (2010) found that environmental conditions were slightly cooler in the eastern part of PBP owing to  
51 proximity to the Arctic Ocean, but the largest microclimatic discrepancies across PBP were related to differences in net  
52 radiation (surface albedo) and ground heat flux (substrate, vegetation, etc.) (Young et al., 2010). A Student t-test (2-tailed,  $\alpha$   
53 = 0.05) reveals that in 2008, Pond 6's mean Tw ( $7.3^{\circ} \text{ C} \pm 2.3$ ,  $n = 69$ ) was not significantly different than the East Medium  
54 Pond ( $7.6^{\circ} \text{ C} \pm 3.5$ ,  $n=68$ ) but it was different than West Medium Pond ( $6.6^{\circ} \text{ C} \pm 4.5$ ,  $n = 77$ ). In 2009, both the East Medium  
55 Pond ( $5.7^{\circ} \text{ C} \pm 3.8$ ,  $n=95$ ) and West Medium ( $4.3^{\circ} \text{ C} \pm 5.5$ ,  $n = 94$ ) ponds had significantly different mean water temperatures  
56 than Pond 6 ( $6.6^{\circ} \text{ C} \pm 4.5$ ,  $n=80$ ).

57

58

59 **Figure 4. Seasonal temperature regime of medium-sized ponds across Polar Bear Pass (2007-2009) based on manual (dots) and**  
 60 **continuous data (solid line) from 2007 (a), 2008 (b), and 2009 (c).**

61

## 62 4.2 Mean July temperature

63 Overall, the pond temperatures at PBP fall in the range found by these other Arctic studies, except it was much cooler in 2013  
64 due to a late spring and cold summer. Figure 5 plots the July mean temperatures of the central ponds at PBP, across the years.  
65 In addition, we also include July pond temperature data (11° C, 2005) from Eastwind Lake, Ellesmere Island (Woo and Guan,  
66 2006) and from Cape Bounty, Melville Island (7.2° C, 2009 – Croft, 2011).

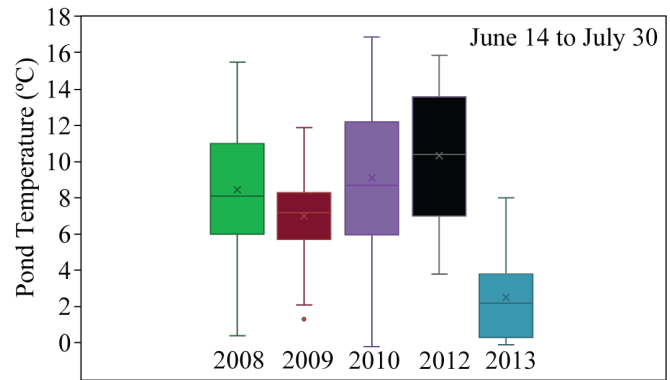

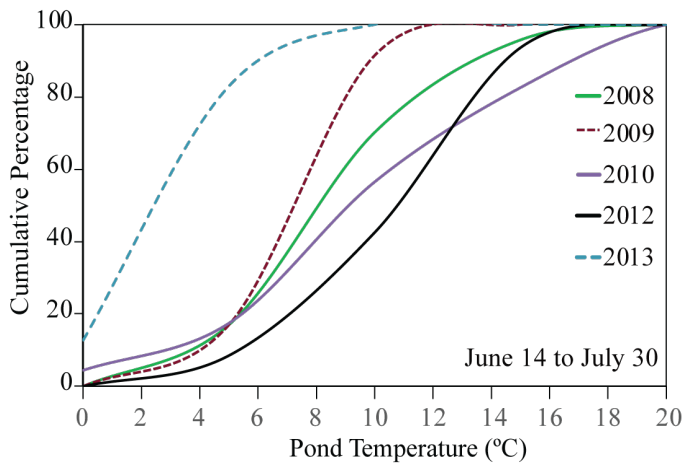

67

68 **Figure 5. Average July pond temperatures at PBP ponds. Pond data from other Arctic studies are included here for comparison.**  
69 **Illness in 2011 prevented pond temperatures from being obtained at PBP.**

## 70 4.3 Cumulative percentages and box plots of pond water temperatures

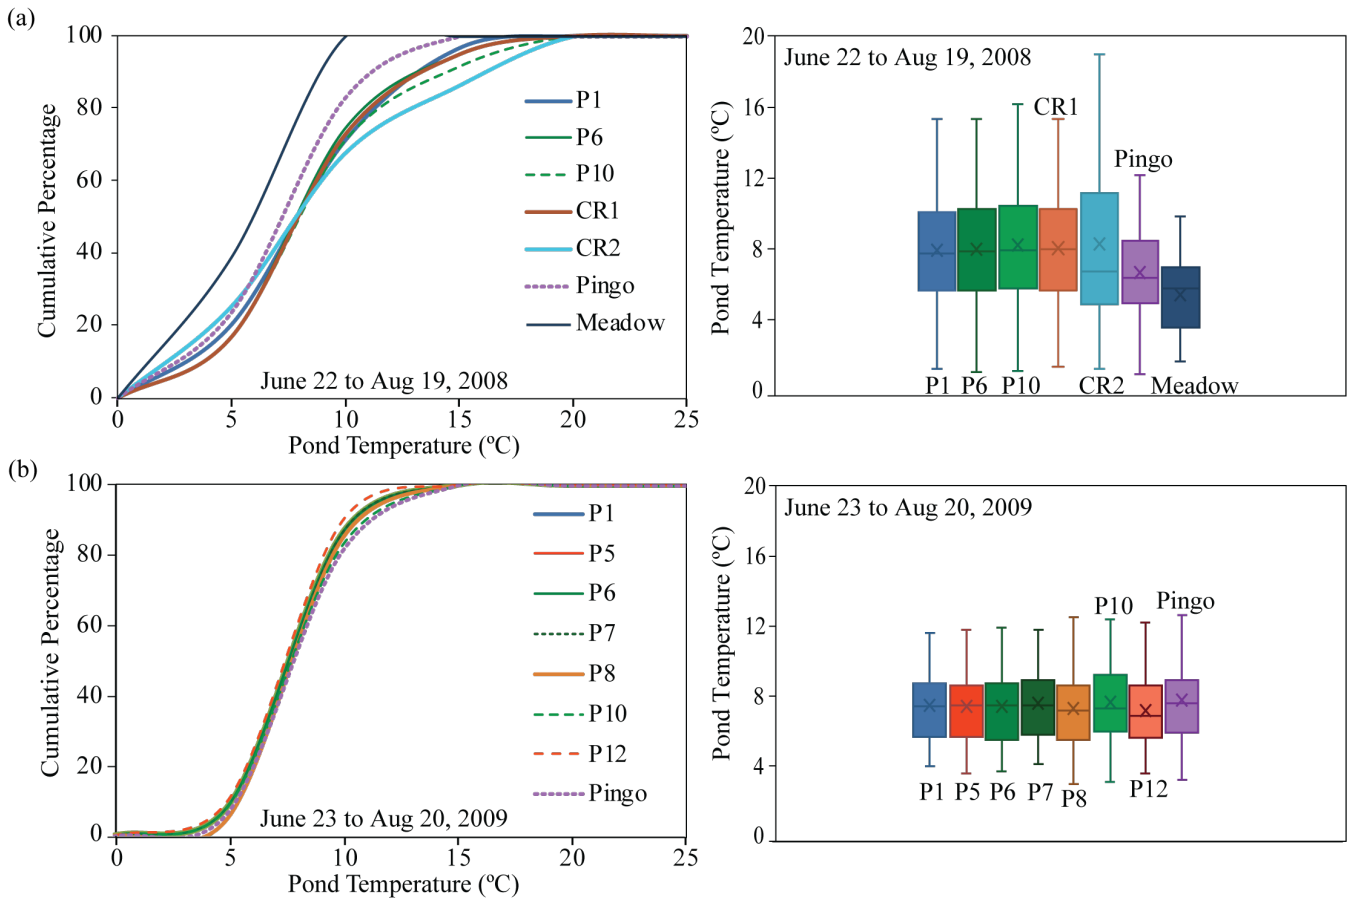

71 The cumulative percentages of Pond 1 from 2008 to 2013 (June 14 to July 30) based on continuous water temperature  
72 measurements is plotted in Figure 6 along with box plots. Comparable to Fig. 2, there is considerable variability from year-to-  
73 year. In 2012, a warm season, pond Tw exceeded 11° C about 50% of the time and 14° C about 15% of the time, but in 2013,  
74 a cool year, pond Tw only exceeds 2.5° C about 50% of the time and remains below 10 °C. Amongst the three years (2008,  
75 2009, 2010), Pond 1 was the warmest in 2010 but showed the greatest variation according to the box plots (see Fig. 6).

76  
77  
78  
79  
80

**Figure 6. Cumulative percentages (left) and box plots of water temperatures ( $T_w$ ) (right) in Pond 1, 2008 to 2013. The time frame selected for comparison is June 14 to July 30. Box plots show median (line in box), and x indicates the average temperature.**

81 Figure 7, based on continuous daily mean data in 2008 (June 22 to Aug. 19) and 2009 (June 23 to Aug. 20), shows the  
82 cumulative percentages of water temperature of the central ponds and box plots. The pattern of ponds in a year are similar to  
83 Pond 1 (see Fig. 6), but variability from year-to-year and occasionally from pond-to-pond does exist (e.g., Ponds 2, 6).  
84 Differences in pond water depth, and water sources can impact water temperatures not just air temperature. For instance, the  
85 Meadow Pond plot varies from the others, as it remains cooler for a longer duration. About 80% of the time the  $T_w$  here never  
86 exceeds 10°C. As mentioned earlier, this is due to its location nestled in a small valley with adjacent late-lying snowbeds that  
87 supply cool meltwater to it for a protracted time (see Figures 8a, b). The Meadow Pond  $T_w$  does not increase until after the  
88 late-lying snowbed disappears. Median temperatures capture this effect as well.

89

90

91

**Figure 7. Cumulative percentages and box plots of temperatures ( $T_w$ ) of Central ponds, 2008 (June 22 to Aug. 19) (a) and 2009 (June 23 to Aug. 20) (b) using continuous pond water temperatures.**

92

93 **Figure 8. Photo of the Meadow Pond taken June 15, 2008, and air temperature versus pond water Tw (Meadow Pond) in 2008. Note**  
 94 **the late-lying snowbeds adjacent to Meadow Pond.**

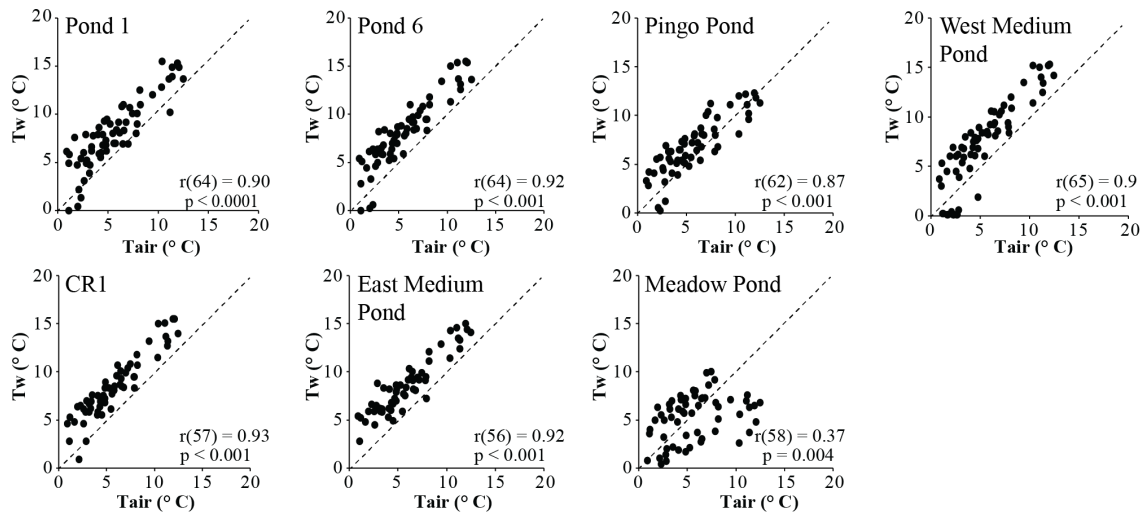

95

96 **4.4 Air temperature and pond water temperature response**

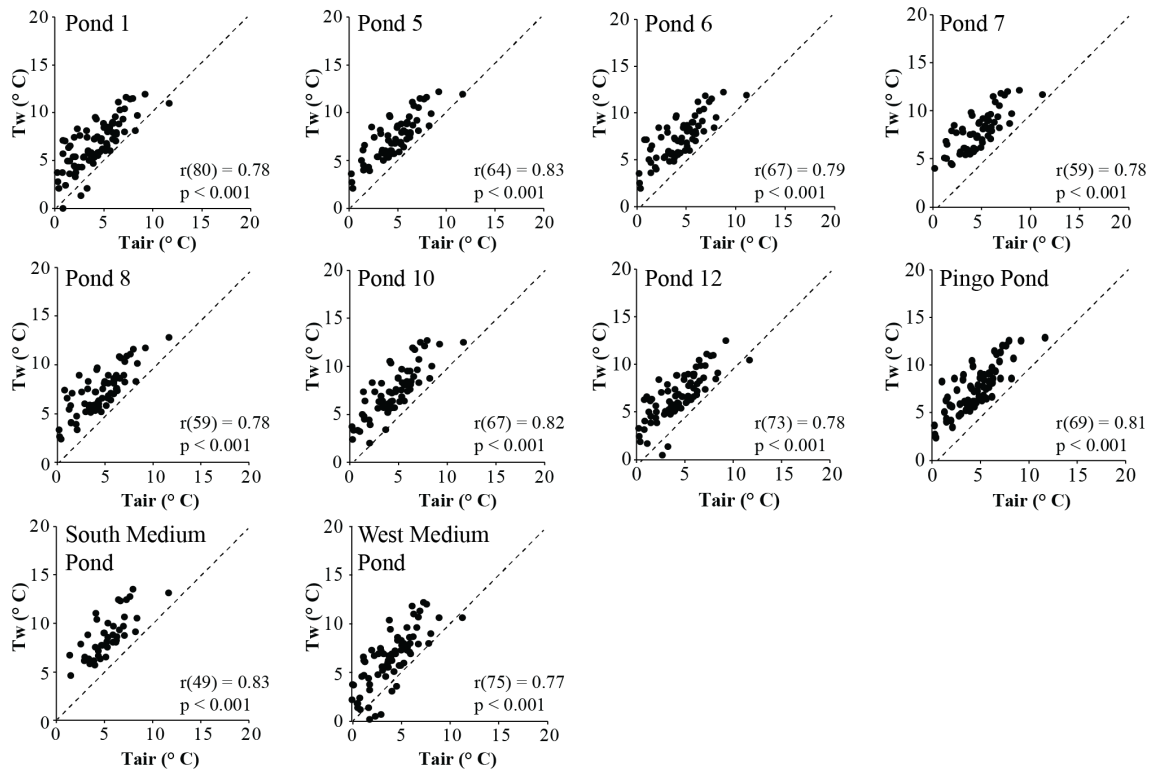

97 Figure 9 shows the correlations between Plateau air temperatures and pond water temperatures in 2008 (a) and 2009 (b); the  
 98 two years when continuous measurements were made until the end of August (International Polar Year). In 2008, the

99 relationship between air temperature and pond water temperature is strong, when temperatures are  $> 0^{\circ}$  C. Here most ponds  
00 show a correlation  $r > 0.8$  or  $> 0.9$ . When points fall below the 1:1 line, it signals there was an initial lag in pond warming due  
01 to ice-off (see Fig. 3). As mentioned earlier, the water temperature of Meadow Pond has a much weaker relationship with air  
02 temperature. This is due to its location near melting late-lying snowbeds, which help to delay pond warming (see Figure 8).

a) 2008

b) 2009

 05 **2009 (b), using continuous water temperature data. The black dashed line in the plots is the 1:1 line.**

06

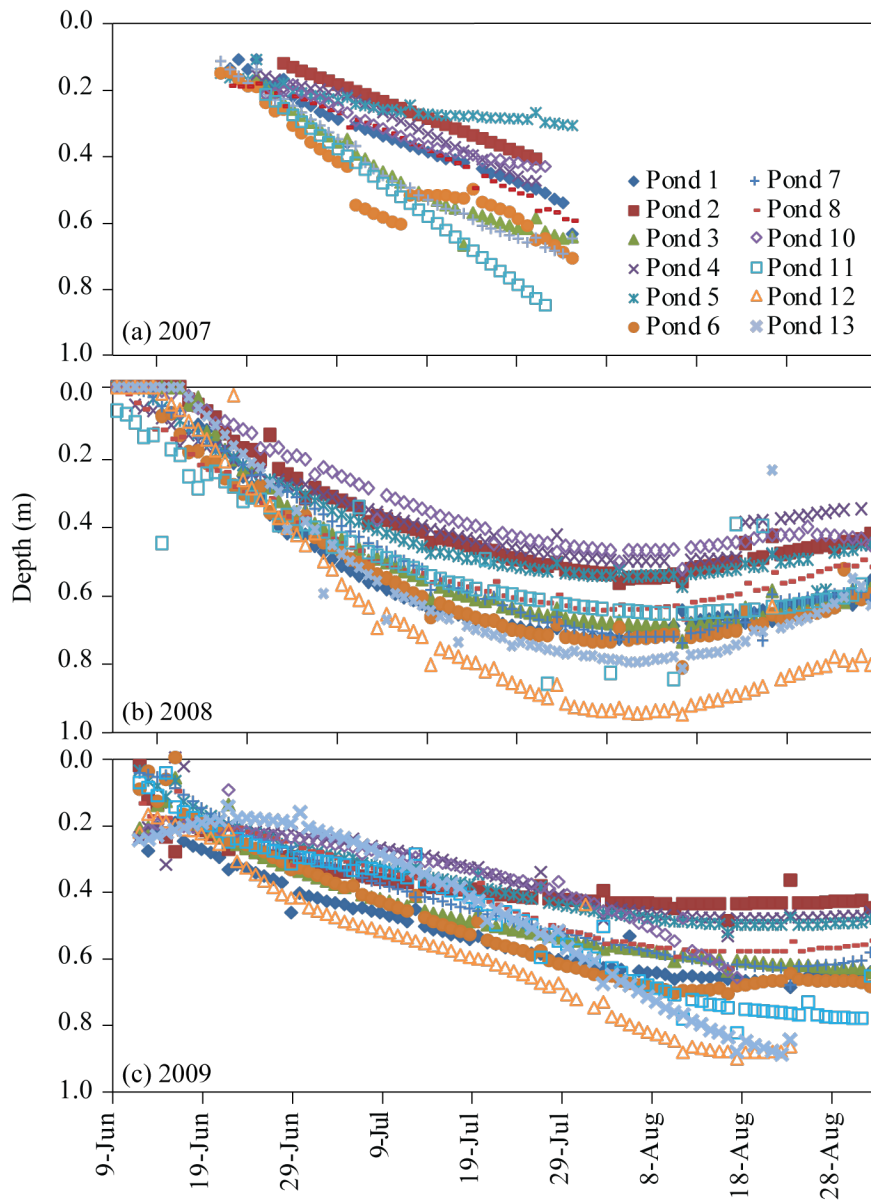

## 07 **4.4 Other environmental responses**

### 08 **4.4.1 Ground thaw**

09 In 2007, it can be observed that there is considerable variation in pond thaw depth (0.3 m to > 0.7 m) (Figure 10a). Pond 5 had  
10 a mucky organic bottom, which might be indicative of high ice content that restrains ground thaw. Pond 10 exhibited a deep  
11 thaw > 0.6 m. It was a shallow pond with a rocky, blue-green algae (dark colour substrate) (see Table S1), which would be  
12 effective in absorbing incoming radiation and accelerating ground thaw (Young and Woo, 2003; Young and Abnizova, 2011).  
13 Rapid thawing in the month of July can also be attributed to warm air temperatures (average  $T_a = 7.4^\circ \text{C}$ ).

14 Frost table measurements continued until the end of August in both 2008 and 2009 (see Figures 10b, c). Maximum  
15 frost table depths occurred around July 28 in 2008 and slightly later in 2009 (Aug 23). In 2008, the maximum depth reached  
16 in the ponds ranged from about 0.45 to 0.95 m, and in 2009, it was similar (0.42 to 0.95 m), with Pond 12 exhibiting the deepest  
17 thaw in both years. The rate of frost table decline amongst ponds is similar in the early part of the 2008 season but then a wider  
18 range in thaw develops with the maximum spread emerging around July 18 – 23<sup>rd</sup>. The thaw pattern of ponds is similar in  
19 early 2009, but then pond thaw show variable depths by July 29, which continues for the rest of the thaw period.

20 The well-defined freeze-back pattern is not as clear in 2009 as in 2008. While the rate and maximum frost table thaw  
21 in ponds might be different between the years owing to varying meteorological conditions, the thaw pattern of ponds is  
22 consistent; typically, Pond 5 exhibits a shallow thaw versus Pond 11, which can reach deep thaw, particularly in 2007 and  
23 2009, and sporadically in 2008. This regular pattern in frost table depths amongst the ponds was replicated in 2010 as well  
24 (data not shown here).

25

26 **Figure 10. Frost table development in ponds at PBP in 2007 (a) 2008 (b), and 2009 (c).**

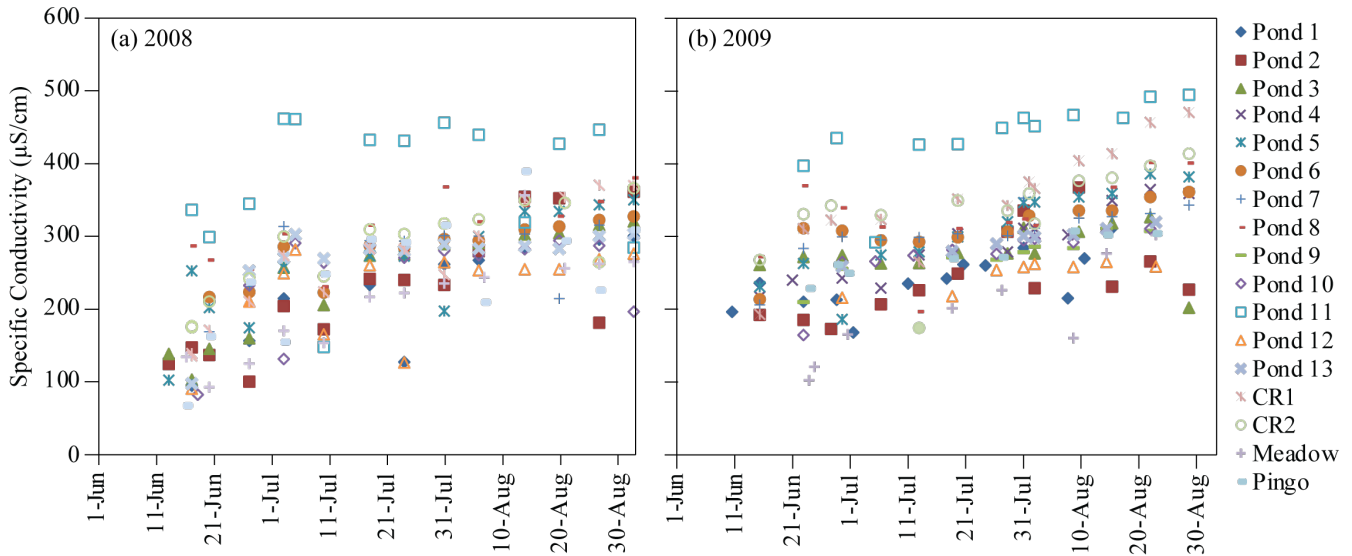

27 **4.4.2 Pond water conductivity ( $\mu\text{S}/\text{cm}$ )**

28 There is considerable variation between ponds throughout the 2008 season and the conductivity levels rise from  $\sim 100 \mu\text{S}/\text{cm}$   
 29 to most ponds exceeding  $250 \mu\text{S}/\text{cm}$  (Figure 11a). Like water temperatures, meltwater from the nearby late-lying snowbed  
 30 adjacent to the Meadow Pond causes dilution so the water conductivities are generally lower than other ponds. Pond 11, due  
 31 to its rocky, blue-green substrate and deep ground thaw exhibits the highest water conductivity, maintaining levels  $> 400$   
 32  $\mu\text{S}/\text{cm}$  by early July 2008 (Fig. 11a). A similar pattern emerges in 2009. Pond 11's water conductivity reaches  $> 400 \mu\text{S}/\text{cm}$

33 near the end of June and about 500  $\mu\text{S}/\text{cm}$  at the end of August. Pond 11 is an irregular shaped pond with a dark substrate. It  
 34 was prone to drying as was Pond 8. Like 2008, the Meadow Pond in early 2009 has a lower water conductivity signal than  
 35 other ponds. Later in the season, water conductivity levels start to rise at the Meadow Pond arising from the loss of meltwater  
 36 from the nearby late-lying snowbed (Fig. 11b).

37

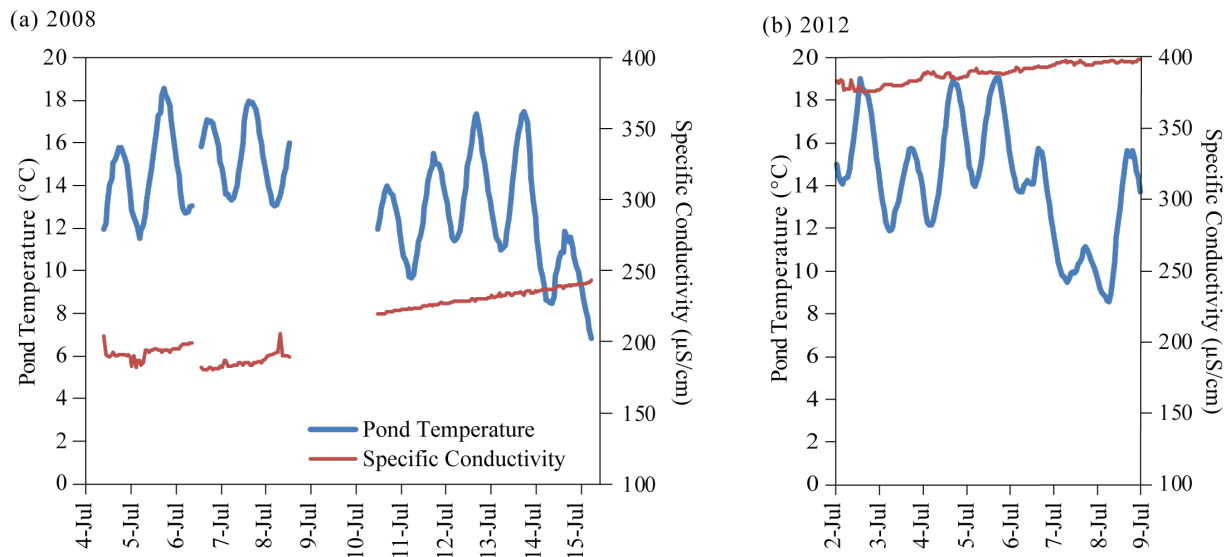

38

39 **Figure 11. Spot measurements of specific conductivity ( $\mu\text{S}/\text{cm}$ ) of ponds at PBP in (a) 2008 and (b) 2009.**

40

41 Figure 12 provides an illustration of the impact of a warm season on the conductivity of pond water as measured by  
 42 a YSI 600 multiparameter sonde. Fig. 12a, shows the hourly water temperature and conductivity of Pond 1 in the early summer  
 43 of 2008 versus the early summer in 2012. Pond temperatures do not vary that much in these two years during this time.  
 44 Conductivity only reaches about 250  $\mu\text{S}/\text{cm}$  in 2008 (mean  $T_{\text{air}} = 4.39^\circ\text{C}$ , June 1- July 31) but exceeds 400  $\mu\text{S}/\text{cm}$  in 2012, a  
 45 warmer season (mean  $T_{\text{air}} = 6.43^\circ\text{C}$ , June 1-July 31). Due to the warmer air temperatures in 2012, frost tables reached upwards  
 46 of -0.45 m in the wet meadow upslope of Pond 1 by June 27, 2012 (field notes). In 2008, on June 27, frost table of the wet  
 47 meadow well adjacent to Pond 1 was only -0.172 m while the pond's frost table depth was 0.369 m. It was also drier in 2012,  
 48 only 10.8 mm of rainfall was received by the end of June at PBP, while in 2008  $\sim 19.5$  mm was recorded by then, followed by  
 49 44.1 mm in July. Rainfall measured at Resolute in July 2012 was 30.7 mm.

50

51

52 **Figure 12. Hourly estimates of pond temperature (blue line) and specific conductivity (µS/cm) (red line) of Pond 1 in 2008 (a) and**  
 53 **in 2012 (b).**

54 **5 Discussion**

55 **5.1 Pond temperatures**

56 Benyahya et al. (2007) and others (e.g., Dranga et al. 2017; Morison et al., 2023) indicate that water temperature is one of the  
 57 most important parameters in ecosystem studies as it can influence both chemical and biological processes. At PBP, limited  
 58 monitoring of the thermal regime of ponds indicates that most ponds show a rapid warming in the spring following snowmelt  
 59 with most peaking in July. Then, pond water starts to cool in August. Average July temperatures are consistent with other pond  
 60 studies across the Canadian High Arctic including polar oasis regions (Woo and Guan, 2006). Like McEwan and Butler's  
 61 (2018) study in northern Alaska, temperatures in central ponds all correlate well with each other and, for the most part, with  
 62 ponds across PBP. This indicates that these ponds are all responding to similar climatic conditions (warming temperatures),  
 63 which is also supported by strong correlations of pond temperatures with air temperature ( $> 0^\circ \text{C}$ ). In this study, 2008  
 64 correlations (pond Tw vs. Tair) were slightly higher than in 2009 (see Fig. 9). We do not have a good explanation for this  
 65 difference. In addition, there are still slight differences in the ponds owing to their unique settings. The Meadow Pond remains  
 66 cooler than the other ponds owing to lingering meltwater from late-lying snowbeds, a pattern noted by others (e.g., Northern  
 67 Ellesmere Island — Smol and Douglas, 2007; Somerset Island — Young and Abnizova, 2011). The South Ponds are delayed  
 68 in warming relative to other ponds due to a regular and persistent snowpack - the southern part of the PBP has a north-facing  
 69 aspect ensuring later snowmelt and pond opening than the northern part of the PBP (Young et al., 2013; Young et al., 2018;  
 70 Young, 2019) but once ice free, their pond temperatures quickly catch up to others (Fig. 9).

71 McEwan and Butler (2018) examined air temperature and water temperatures in an arctic pond over 40 years in  
72 Alaska's Arctic Coastal plain. They documented a 2.2° C increase over a 42-year period or roughly 0.5° C per decade. They  
73 found that the average thaw temperature of the pond increased during the first 30 days of the growing season from 1971 to  
74 2012. Figure 2 indicates that there is still much variability in climate and pond temperature response at PBP from year-to-year  
75 (e.g. 2012-warm vs. 2013-cold). The anomalously warm summer 2012 and cool summer 2013 were a result of opposing NAO  
76 phases. The summer of 2012 had a very negative NAO (resulting in warm temperatures and substantial snow and sea ice melt)  
77 (Overland et al., 2013), while the summer of 2013 had a positive NAO with anomalously low spring and summer temperatures  
78 through the Canadian North, dipping 1-3°C cooler in the High Arctic relative to 2007 – 2012 (Overland et al., 2014).  
79

## 80 **5.2 Environmental response to pond warming**

81 The effects of warming and permafrost thaw on Arctic freshwater ecosystems remain poorly understood (Lougheed et al.,  
82 2011). Generally, permafrost and the seasonal frost table maintain water levels in wetlands and ponds near the surface but with  
83 an increase in thaw the water level can drop. As the permafrost thaws to deeper soil layers or is completely thawed, the perched  
84 water table may be lowered, resulting in drier surface soils, and then this can lead to substantial carbon loss. But in other areas,  
85 ground collapse can fill with water to form ponds and wetlands enhancing methane losses (Moonmaw et al., 2018; Rehder et  
86 al., 2023).

87 Pond sediments at PBP have varying ice contents (small to large) depending on their texture and porosity  
88 characteristics (see Table S1, Fig. S1). This can influence pond thawing rates and maximum thaw depths. Permafrost  
89 degradation can also cause expansion or shrinkage of wetland areas and warming associated with permafrost thaw could also  
90 turn wetlands into sources of carbon that increases greenhouse gas emissions to the atmosphere (Moonmaw et al., 2018;  
91 Kreplin et al., 2021; Rehder et al., 2023). Wrona et al. (2016) argue that while temperature is a key driver in ecological  
92 processes in tundra ecosystems, it is hydrological interactions that mediate the climate responses of tundra ecosystems.

93 While pond temperatures are generally similar across PBP but vary due to climatic conditions (cool versus warm  
94 years), there are considerable differences in the ground thaw rates, which can be attributed to the physical characteristics of  
95 the sediments (coarser vs. finer) and colour. Some ponds have darker substrates than others, which can lead to greater  
96 absorption of incoming solar radiation due to a lower albedo (Young and Abnizova, 2011). Warmer summers (e.g., 2007)  
97 versus cooler ones (e.g., 2008) did lead to higher rates of pond evaporation (Young and Labine, 2010) but deeper thaw in  
98 warm, dry years also contributed to enhanced vertical pond seepage due to an increase in the active layer storage capacity.  
99 This process most likely contributed to drying and pond shrinkage (Young and Abnizova, 2011). Pond thaw rates differ from  
00 pond-to-pond, but they are consistent from one year to the next confirming the critical role played by the pond sediments (see  
01 Table S1, Fig. S1).

02 A similar pattern emerges when evaluating pond water conductivity. Ponds that are shallow and subject to drying  
03 tend to have the greatest water conductivities in both cool and warm years. Here, shallow pond waters are in greater contact

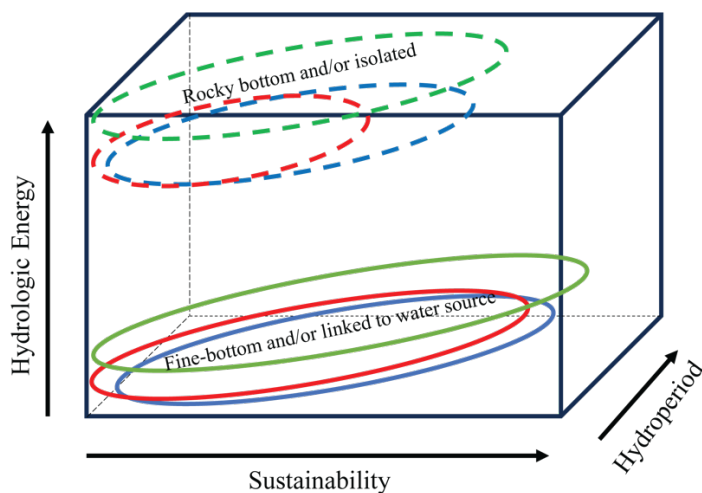

04 with thawing soil materials. Figure 12 also confirms that pond conductivities can rise substantially in the same pond from one  
05 year to another in response to warmer air temperatures and deeper ground thaw.

06 In the Old Crow Flats, Yukon, Roy-Leveille and Burn (2017) found that near-shore taliks could develop in shallow  
07 (often less than 20 cm) lake pond water when warm summers increased the thawing degree days. Deep and early snowpacks  
08 near the shoreline also helped to keep lake bed temperatures above 0° C, preventing permafrost aggradation.

### 09 5.3 Climate warming: What can we expect for PBP ponds?

10 Climate warming over the last century has been greatest in the Arctic and is projected to continue in the 21<sup>st</sup> century at a rate  
11 above the global average (Sim et al., 2019; Miner et al. 2022). Future hydrological changes, vegetation shifts and degradation  
12 of permafrost have been identified as key areas of uncertainty in the prediction of permafrost carbon dynamics (Sim et al.,  
13 2019). So what can we expect for PBP? We will likely see continued warming, and if 2012 (a warm/dry season) is any  
14 indication of future climate warming, we can expect early snowmelt, an earlier opening of ponds, a prolonged thaw season,  
15 and extended periods of time when pond temperatures exceed 15° C. We can expect pond substrates to thaw earlier in the  
16 season and frost tables to deepen, and that together with increases in evaporation loss, we may see pond water levels dropping  
17 below ground with some ponds drying out (see Figure 13 - general schematic of pond response at PBP). This conclusion is  
18 supported by Dyke and Sladen (2022), whose modelling efforts notes deeper talik development under shallow ponds dotted  
19 on subarctic peat plateau landscapes.

20

21

22

23 **Figure 13. Schematic showing the functional integrity of PBP ponds. Blue lines (solid/dashed) represent ‘present’ conditions; red**  
24 **lines (solid/dashed) represent pond response to ‘future warm/dry’ conditions and green lines (solid/dashed) represent response to**  
25 **future ‘warm/wet’ conditions. Hydrologic energy refers to the degree of fluctuations in water level, hydroperiod refers to the length**  
26 **of time that the pond contains water over the season (diagram adapted after Young and Abnizova, 2011).**

27

28 It is likely that hillslope streams, which now provide some ponds with a source of water for an extended time during  
29 the thaw season may not do so for as long (Young, 2019) and that ponds buffered now from elevated Tw and higher  
30 conductivities by lingering meltwater contributions from late-lying snowbeds will cease to do so (Woo and Young, 2014). In  
31 the high Andes, ponds and wet meadows are now being sustained by meltwaters from melting glaciers but they are predicted  
32 to diminish and disappear by the end of the century. These ponds and wet meadows will then dry out and ultimately disappear  
33 (Dangle et al., 2017). Moonmaw et al. (2018) also indicate that permafrost thaw can dramatically affect hydrology and that  
34 fen-like systems are vulnerable as they rely on terrestrial water inputs (e.g., groundwater and streamflow). As these external  
35 water sources change or cease to exist like the rapid loss of late-lying snowbeds at PBP and elsewhere across the Arctic islands  
36 (Woo and Young, 2014), wetlands will be impacted. At PBP, many irregular shaped and shallow ponds (e.g., Ponds 8, 11)  
37 have already been observed to dry out over summer seasons with vascular plants encroaching, suggesting that in the long-term  
38 certain ponds may transition into wet or dry meadow features (see Fig. 14), which may eventually alter greenhouse gas  
39 emissions (Rehder et al., 2023), snowcover receipt, and evapotranspiration rates as shifts in vegetation have done elsewhere  
40 (Morison et al. 2023).

41 Strong correlations between air temperature and pond Tw will persist but departures will grow as pond water become  
42 warmer than the air temperatures, especially shallow ponds with dark, rocky substrates (e.g., Pond 11). Lougheed et al. (2011)  
43 observed that establishing a direct relationship between air and water temperatures is complicated by wind, water depth, ice  
44 cover, and other physical processes that determine temperature in small tundra ponds < 0.5 m at the International Biological  
45 Program (IBP) site, Barrow, Alaska. They noted that variability in temperature is higher in both the early and late part of the  
46 season, a pattern emerging for PBP ponds as well (see Figs. 2, 3).

47

48 **Figure 14. Desiccated pond (Pond 8) July 23, 2007 (left) and Pond 8, August 19, 2010 (right), showing how *Eriophorum scheuchzeri***  
49 **-White Cottongrass are encroaching.**

50

51 Linderholm et al. (2018) indicate that reanalysis data show an increasing trend in Arctic precipitation over the 20<sup>th</sup>  
52 century, but changes are not homogeneous across seasons or space. Possible increases in 21<sup>st</sup> century Arctic late autumn and  
53 winter precipitation counter increased pond evaporation losses to some extent. However, large uncertainties remain in  
54 predicting future precipitation patterns (Sim et al., 2019). If there are a series of years where fall rainfall fails to replenish pond  
55 storage deficits, and little spring snowmelt occurs, then it is likely that these ponds, especially the irregular shaped and shallow  
56 ones will dry out permanently, and vascular plants will encroach as has happened to patchy wetlands on Cornwallis Island  
57 (Woo and Young, 2014) (see Fig. 14).

## 58 **6 Conclusions**

59 The thermal regime of High Arctic ponds was monitored over several years at Polar Bear Pass, a Ramsar wetland of  
60 international importance. Variability in pond temperatures occurs on a seasonal and inter-seasonal basis with ponds responding  
61 to warm and cool springs and summer seasons. There is little variation in pond temperatures across the PBP but linkages to  
62 other terrestrial sources besides rainfall and seasonal snowmelt remain important (e.g., Meadow Pond). Prolonged inputs of  
63 meltwater from late-lying snowpacks into adjacent ponds serves to dilute and dampen water temperatures for extended periods  
64 in the summer.

65 Ground thaw is variable in ponds owing to substrate type, water depth and ground ice content. In the future, an earlier  
66 start to ground thaw and deepening of frost tables may drain some shallow ponds, while others due to deep waters and abundant  
67 ground ice will be sustained. Like frost table patterns, the water chemistry (i.e., specific conductivity), which reflects evapo-  
68 concentration processes, groundwater flow varied amongst these ponds. The rapid and sizeable increases in water conductivity  
69 at Pond 1 in an extremely warm season (2012) highlight the large shifts in environmental responses that these ponds are now  
70 undergoing. Uncertainties about fall precipitation exist for High Arctic regions. If pond storage deficits persist for several years  
71 and cannot be augmented by seasonal snowmelt or linkages to other water sources (i.e., late-lying snowbeds and streams),  
72 more ponds will disappear at PBP and may be replaced by larger wet/dry meadows. This will potentially have an impact on  
73 greenhouse gases and the feeding patterns of migratory birds. Finally, future research efforts should focus on the response of  
74 other large wetland areas in the Canadian High Arctic including Alison Inlet (southwest coast of Bathurst) and Truelove  
75 Lowland, Devon Island in order to investigate the response of ponds to future fluctuations in climate.

76 **Data Availability**

77 The data that support the findings of this study are available at <https://doi.org/10.5683/SP3/KGRQDO>.

78 **Author Contributions**

79 Young carried out field work, analyzed the field data, and wrote the manuscript. Brown carried out field work, finalized  
80 diagrams, and helped to edit the manuscript.

81 **Competing interests**

82 Some authors are members of the guest editing team of the special issue in HESS.

83 **Acknowledgments**

84 First, we would like to thank the anonymous reviewers who took the time to read our paper and provided valuable advice  
85 and insight. You have all greatly improved the paper. Secondly, we would like to acknowledge sabbatical funding from York  
86 University to K. Young in 2021, which allowed these data to be analysed and a paper to be prepared. Since 2006 to 2015, the  
87 Canadian Government Agency, Polar Continental Shelf Program (PCSP) has provided exceptional logistical support for our  
88 work at Polar Bear Pass. We are also grateful to the many undergraduate and graduate students who have worked at Polar  
89 Bear Pass to help obtain these environmental data. Jennifer Rausch, a wildlife ecologist with Environment Canada, kindly  
90 retrieved pond water temperature data in 2015. John R. Siferd, kindly corrected the grammar. Finally, K. Young presented  
91 some of these findings at the 23<sup>rd</sup> Northern Research Basins Symposium and Workshop held in Northern Sweden, August  
92 20-25, 2023.
