Abstract.

The interaction between forest and climate exhibits regional differences due to a variety of biophysical mechanisms. Observational and modelling studies have investigated the impacts of forested and non-forested areas on a single climate variable, but the influences of forest cover change on a combination of temperature and precipitation (e.g., drought) have not been explored owing to the complex relationship between drought conditions and forests. In this study, we use the historical forest and climate datasets to explore the changes in forest fraction and drought from 1992–2018. A set of linear models and an analysis of variance approach are utilized to investigate the effect of various factors on droughts across different time scales and climate zones. Our findings reveal that precipitation is the dominant factor leading to drought in the equatorial, temperate, and snow regions, while temperature controls drought in the arid region. The impact of forest cover on droughts varies under different precipitation and temperature quantiles. Precipitation modulates forest cover's impact on long-term drought in arid and snow regions, while temperature modulates forest cover's impact on both short- and long-term drought in the arid region as well as only on long-term drought in temperate and snow regions. Forest cover can also modulate the impacts of precipitation and temperature on drought. High forest cover leads to a combined effect of precipitation and temperature on long-term drought in equatorial, arid and snow regions, while precipitation is the only dominant factor in low forest cover conditions. In contrast, low forest cover triggers a strong combined effect of precipitation and temperature on drought in the temperate region. Our findings improve the understanding of the interaction between land cover change and the climate system and further assist decision-makers to modulate land management strategies in different regions in light of climate change mitigation and adaptation.

1 Introduction

Forests cover around 4.06 billion hectares, accounting for around 30 % of the global ice-free land surface, and are distributed widely from the tropical to boreal regions (Crowther et al., 2015; Hansen et al., 2013). Global forests have undergone significant changes in the past few decades (Hansen et al., 2013). Most countries have reported a net forest loss due to intensive logging in the tropical region, especially in the 2000s. The tropical forest loss rate increased from -4040 hectares per year in the 1990s to -6535 hectares per year in the 2000s (Kim et al., 2015). At the mid-latitudes, forest cover fraction has increased owing

25 to accelerated afforestation (Hansen et al., 2013). Large deforestation areas have been detected in the boreal regions due to
wildfire occurrence (Hansen et al., 2010). At the national scale, China contributes to the largest afforestation area in the world,
as more than 16 sustainability programs have been launched in the country since the 1970s (Bryan et al., 2018). The area of
planted forest in China has increased by around 1.7 million hectares per year since the 1990s (Peng et al., 2014). Brazil has
been the world leader in tropical deforestation, clearing an average of approximately 1.95 million hectares per year from 1996
30 to 2005 (Nepstad et al., 2009). The global forest areas are predicted to change from about -500 million hectares up to +1000
million hectares by the end of the 21st century under five different Shared Socio-economic Pathways (SSPs) (Popp et al., 2017).

Forests play a vital role in supporting ecosystem services, including local climate regulation via water and heat exchanges
with the atmosphere (known as biophysical effects) (Anderson et al., 2011; Bonan, 2008). Changes in forest cover have the
potential to alter local climate by affecting surface evapotranspiration, albedo and surface roughness (Alkama and Cescatti,
35 2016; Mahmood et al., 2014). The net impact on local climate is highly spatially heterogeneous due to the balance among
these mechanisms (Perugini et al., 2017; Li et al., 2015; Cherubini et al., 2018). In general, afforestation in the tropics results in
regional land surface cooling due to high evapotranspiration, while the effect is warming in the boreal region caused by forests
typically having a low surface albedo, especially in the snow-covered winter (Alkama and Cescatti, 2016; Perugini et al., 2017).
At mid-latitudes, the effects are more uncertain and have more spatial variability, particularly at a local scale (Mahmood et al.,
40 2014; Perugini et al., 2017; Findell et al., 2017). The uncertainties are mainly caused by the regional background conditions
(climate and soil moisture), forest types (coniferous vs. deciduous), types of land used for comparison (cropland vs. grassland),
or analysis methods (observations vs. climate models) (Ge et al., 2019; Li et al., 2016; Pitman et al., 2011; Tian et al., 2022).
For instance, a study using satellite retrieval products shows that the non-radiative (i.e., evapotranspiration) effect dominates
in surface cooling in a typical temperate region (i.e. the Loess Plateau in China) (Ge et al., 2019). Nevertheless, for the same
45 region, a coupled land-atmosphere model finds a net surface warming caused by radiative effects (i.e., changes in surface
albedo and radiation fluxes) (Tian et al., 2022).

Forest change also can influence the hydrologic cycle by altering evapotranspiration, streamflow, precipitation, and soil
moisture (Bonan, 2008; Hoek van Dijke et al., 2022). Deforestation in the tropics can result in a strong decrease in precipitation,
with up to 30 % of annual total precipitation (Snyder et al., 2004; Perugini et al., 2017). This is because more than half of
50 forest evapotranspiration can be recycled and produce rainfall in this region (Salati and Nobre, 1991; Silva Dias et al., 2009).
In the boreal region, tree removal leads to a slight reduction in precipitation, around 15 % of the annual total precipitation
(Snyder et al., 2004; Cherubini et al., 2018). This is likely due to inappreciable differences in the evapotranspiration ratio
between different vegetation covers in boreal region (Beringer et al., 2005). Forests' change impacts on precipitation in the
temperate regions are more complex than in the boreal or tropical region (Bala et al., 2007; Field et al., 2007; Bonan, 2008).
55 It is challenging to detect the signal of forest cover changes on rainfall in the temperate region, owing to the high variability
of synoptic scale meteorological systems, which impact local-to-regional circulation and rainfall patterns (Bala et al., 2007;
Field et al., 2007; Bonan, 2008). Modelling studies suggest that a decline in vegetation cover can lead to a reduction in annual
precipitation in this region, ranging from -73 to -219 mm per year (Perugini et al., 2017).

Changes in temperature and precipitation may affect regional wet and dry conditions, such as drought. Drought is a complex climatic phenomenon characterized by below-normal rainfall over a period from months to years (Dai, 2011). And it is mainly driven by a combined effect of temperature, precipitation, wind speed, and solar radiation (Seneviratne, 2012). Meanwhile, drought is also considered a natural disaster that poses serious threats to ecosystems by changing the forest structure and carbon content (Nepstad et al., 2007). Moreover, several studies have reported changes in drought characteristics in the past few decades (Cook et al., 2014; Trenberth et al., 2014; Naumann et al., 2018; Zhao and Dai, 2015). For example, since the 1950s, the frequency and intensity of droughts have increased in the Mediterranean (Vicente-Serrano et al., 2014) and West Africa (Dai, 2013), while there has been a small increase in central North America (Peterson et al., 2013) and northwest Australia (Jones et al., 2009).

Some studies have indicated that alterations in forest cover are highly likely to have an impact on regional drought conditions. For example, deforestation leads to less water that can be recycled and intensifies the regional dry seasons in the Amazon region (Bagley et al., 2014; Staal et al., 2020). Based on model simulations, the conversion of mid-latitude natural forests to cropland and pastures is accompanied by an increase in the occurrence frequency of hot-dry summers (Findell et al., 2017). To date, no reports have addressed the impact of forest changes on drought conditions in other regions. Additionally, the different time-scale drought responses to forest change have not been explored. Given the significance of forest management decisions for climate adaptation and mitigation targets, it is essential to comprehend how drought responds to alterations in forest cover. In this study, we aim to employ statistical models to explore the connection between forest cover changes and drought, keeping the following questions in mind:

1. How do changes in forest cover affect droughts at different time scales?
2. What is the role of forest cover change in modulating drought across various climatic regions?

The objective of this study is to give a fundamental view of the relationship between observational forest change and drought change to understand how drought responds to forest change across different time scales and climate zones. A brief introduction involving forest change and its climate effect is given in Section 1. Section 2 presents an overview of the data description and source, followed by a discussion on methods used in the paper in Section 3. Section 4 evaluates the effect of forest cover change on drought in different time scales and climate zones. Section 5 concludes the main findings along with the limitation and the possible extension of the work.

2 Data

2.1 Climate Classification

The climate classification is based on the latest digital Köppen-Geiger World map dataset (Peel et al., 2007) (<http://www.hydrol-earth-syst-sci.net/11/1633/2007/hess-11-1633-2007-supplement.zip>), which was first formulated by Wladimir Köppen and has been updated for several generations. The philosophy behind the construction of this new version is to rely on

90 observed data rather than experience, wherever this is possible, to minimize the number of subjective decisions. The map
dataset is defined on long-term station records of monthly precipitation sums and monthly mean temperature obtained from the
Global Historical Climatology Network (GHCN) version 2.0 dataset (Peterson and Vose, 1997). In the creation of the climate
classification dataset, 12,396 precipitation stations and 4,844 temperature stations were used, and there are 30 possible climate
types. We aggregate the 30 climate types into five main climate groups, defined as *equatorial*, *arid*, *temperate*, *snow* and *polar*
95 region. These regions are depicted in detail in Fig. 1. In this paper, only the first four regions are considered, as forest cover in
the polar region is negligible.

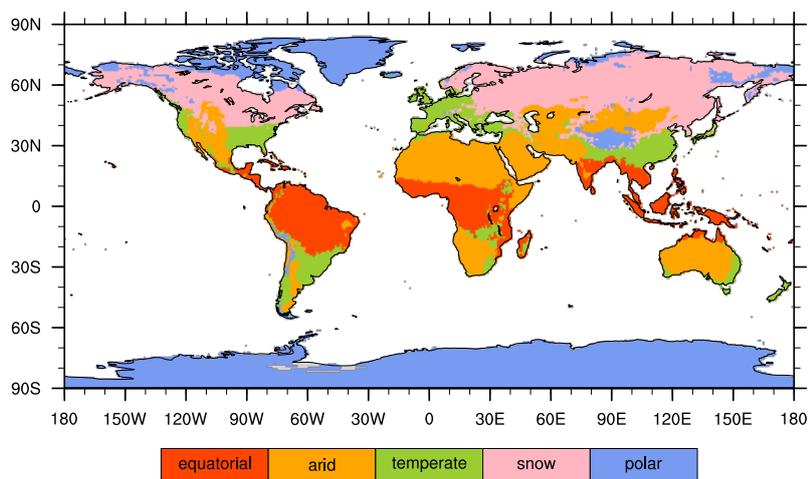

Figure 1. Global distribution of main climate classification, according to Köppen- Geiger World map.

2.2 Drought Indices

To measure, monitor and analyse the drought, multi indices have been developed (Keyantash and Dracup, 2002). Over the past few decades, there are two widely-used drought indices, the *Standardized Precipitation Evapotranspiration Index* (SPEI)

100 (Vicente-Serrano et al., 2010a) and the *self-calibrating Palmer Drought Severity Index* (scPDSI) (Burke et al., 2006). These two indices describe the effect of temperature and precipitation on droughts. Furthermore, the SPEI describes droughts at different time scales, which is important for our first research question. The SPEI focuses more on atmospheric conditions, while scPDSI takes the situation in the soil into account. In order to obtain a more comprehensive picture, both indices are therefore used in this study.

105 **2.2.1 The Standardized Precipitation Evapotranspiration Index (SPEI)**

The SPEI is the extension of the SPI (*Standardized Precipitation Index*), which maps the precipitation intensity on a Gaussian variable and uses precipitation (P) as the only input (McKee et al., 1993). Moreover, the SPEI additionally considers the influence of potential evapotranspiration (PET) and uses the difference between P and PET , and it is a time-scale dependent drought index. For this, we specify an integration time scale τ and a reference month, e.g. SPEI03 for May denotes a drought index obtained for the period from March to May.

The global SPEI dataset used in this study is available as monthly values with a spatial resolution of $0.5^\circ \times 0.5^\circ$. We choose to download various integration time scales τ of the index: 3 months (SPEI03, short-term), 6 months (SPEI06, mid-term), 12 months (SPEI12, mid-term) and 24 months (SPEI24, long-term). The time period considered is 1992-2018. The calculation of PET is based on the FAO-56 Penman-Monteith method (Allen et al., 1998).

115 Data was downloaded from *SPEIbase v.2.6* in March 2020 (Vicente-Serrano et al., 2010b, a) (<http://digital.csic.es/handle/10261/202305>). The dataset is based on the Climatic Research Unit (CRU) TS 4.03 precipitation and potential evapotranspiration data.

Each grid point is then associated with one of the 5 regions given in Fig. 1. Averaging over all grid points in one region yields the $SPEI_\tau$ at monthly resolution for a given region; subsequently averaging over all months of a year yields annual values for each region, e.g., the SPEI03 for the year 2000 is the average over the SPEI03 from January to December of the same year.

2.2.2 The self-calibrating Palmer Drought Severity Index (scPDSI)

The Palmer Drought Severity Index (PDSI) is an old drought indicator, developed in 1965 to assess the soil's moisture available by using precipitation and temperature to estimate moisture supply and demand within a two-layer soil model (Wayne, 1965). In 2004, Wells et al. (2004) developed the PDSI into scPDSI, more effectively improving the comparability of the index at different locations. As with the PDSI, the scPDSI is calculated from time series of precipitation and temperature, together with fixed parameters related to the soil/surface characteristics at each location. The fundamental calculation of PET follows Thornthwaite's method (Thornthwaite, 1948). In 2006, Burke et al. (2006) improved the calculation of PDSI, using the Penman-Montheith approach (Maidment et al., 1993) to establish the evapotranspiration, which is applied to the actual vegetation cover, rather than a reference crop (as is done implicitly in the Thornthwaite's method).

130 The scPDSI dataset is available at a 0.5° resolution at monthly resolution for the time period 1992-2018. It is based on the CRU TS 4.05 dataset and the calculation of PET is based on the Penman-Montheith method. The dataset was downloaded from <https://crudata.uea.ac.uk/cru/data/drought/> in March 2021 (Barichivich et al., 2021; van der Schrier et al., 2013). Each

grid point is associated with one of the 5 regions given in Fig. 1. Averaging the scPDSI over all grid points in a region and subsequently averaging all months of the year yields the annual scPDSI for the region.

135 2.3 Forest Cover

Changes in forest cover fraction are calculated based on the annual European Space Agency (ESA) Climate Change Initiative (CCI) land cover maps from 1992 to 2018 at a spatial resolution of 300 m. Land cover dataset was downloaded from <http://maps.elie.ucl.ac.be/CCI/viewer/download.php> (Santoro et al., 2017) as *Land Cover CCI Climate Research Data Package (CRDP)* in June 2021. The maps describe the earth's terrestrial surface in 37 land cover classes based on the United Nations Land
140 Cover Classification System (UNLCCS), and 14 out of the 37 classes are defined as forest. The dataset was produced after the combination of the global daily surface reflectance of five different satellite observation systems, with the ambition to maintain high levels of consistency over time. It has high accuracy (>70 %) in representing cropland classes, forests, urban areas, bare areas, water bodies and perennial snow and ice (Poulter et al., 2015). This dataset has been widely used in investigating recent land cover change and its climate effect (Huang et al., 2020; Hu et al., 2020). We aggregated the dataset to a $0.5^\circ \times 0.5^\circ$
145 resolution, and at each grid point, the forest fraction can take values between 0 and 1. In the following, we use forest fraction aggregated to the level of regions, centered and scaled the annual values by their standard deviation to unit variance for the sake of visualizing the interannual change and comparing the contribution of forest fraction change in linear models (Sect. 4) to other analogously scaled variables.

Fig. 2 shows the time series of annual forest fraction (centered and scaled to unit variance) for the four regions (equatorial, arid, temperate and snow) as well as the drought indices (scPDSI, SPEI03, SPEI06, SPEI12 and SPEI24) for the period from
150 1992 to 2018.

In the equatorial region, the forest fraction declines monotonously until 2013 with the decay being slower since 2004. Since then, it is slightly increasing. From the visual comparison, there is no obvious relation to any of the drought indices. In the arid region, forest fraction declines until 2003 and increases again, interrupted by a few years of decline around 2010. The
155 regeneration to (and even above) values from 1992 happens relatively quickly since 2016. Drought indices are all negative since about 1998 and fluctuate around a relatively constant value since 2010. The temperate zone also show a decline in forest fraction until 2003, followed by slight ups and downs until 2015. In the last years until 2018, the forest fraction has increased again to the average level. Compared to the plots in other regions, the drought indices in the snow zone undulate around zero (coordinate on the right y-axis), and there is little difference between SPEI and scPDSI. The forest fraction bars show an almost
160 opposite behavior as in other regions: an increase until around 2009 followed by a decrease leveling off at around 2016.

2.4 Precipitation and Temperature

Climatic Research Unit (CRU) monthly near-surface temperature and precipitation datasets are downloaded in March 2021 and used in this study. They are gridded datasets with a spatial resolution of $0.5^\circ \times 0.5^\circ$. In the CRU datasets, meteorological station observations were interpolated to grids and given as monthly values by an automated method. It is publicly available

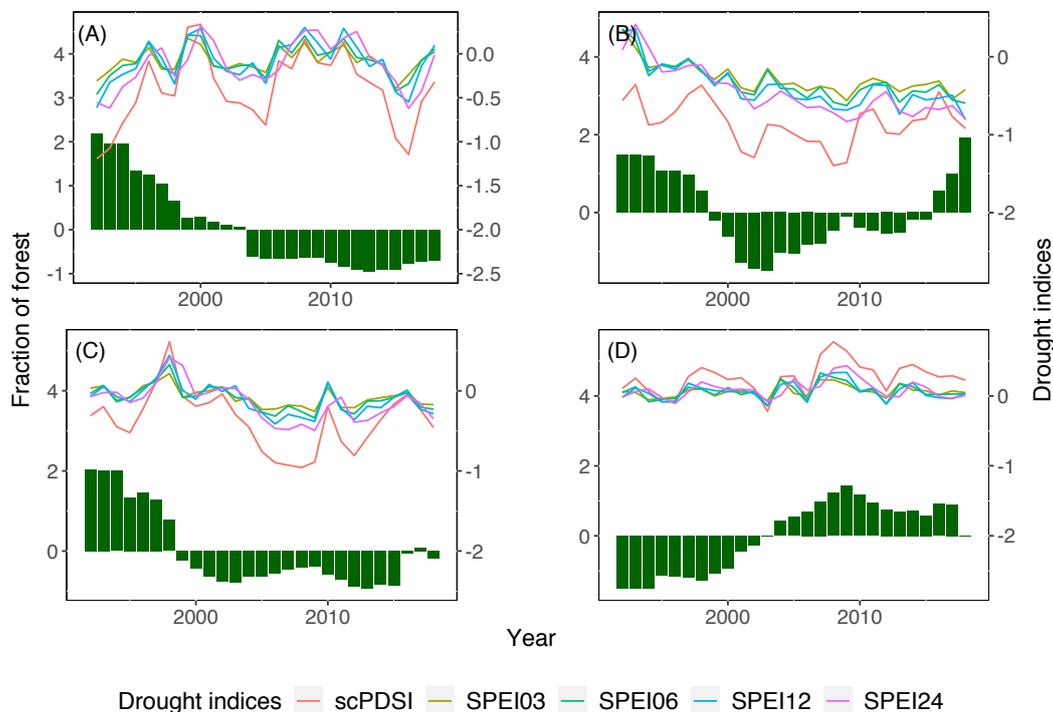

Figure 2. Annual change in forest fraction (centered and scaled to unit variance, green bars) and drought indices (colored lines, see legend) from 1992 to 2018 across 4 regions: (A) equatorial; (B) arid; (C) temperate; (D) snow.

165 (<https://crudata.uea.ac.uk/cru/data/hrg/>) and is referred as CRU TS v. 4.03 (Harris et al., 2014). The datasets are used to analyse the effect of meteorological factors on droughts.

Again, for the sake of easier comparison, the variables in Fig. 3 have been centered and scaled to unit variance. Shown is the annual mean of monthly precipitation as bars and temperature as black dots for the different climate zones (different columns) in Fig. 3 together with the drought indices considered here (different rows). Note that for the SPEI for 3, 6, 12 and 24 months, temperature and precipitation are analogously aggregated to this length. Hence, for SPEI06 in June, we average monthly precipitation and temperature from January to June and for SPEI06 for July, from February to July and so on. Fig. 3 shows the annual means of precipitation and temperature aggregated analogously to the aggregation level of the drought index.

In equatorial and temperate regions, the main influencing factor to droughts is precipitation, which is largely consistent with changes in the drought index; while this relationship is not visible for the arid region, where the temperature has a larger influence. In snow regions, the situation is even more complex. Furthermore, Fig. 3 also gives an idea about the difference between scPDSI and SPEIs. In equatorial, temperate and snow regions, the change of scPDSI and SPEI is similar; but in the arid region, the variation is different. This is probably due to the low precipitation in the arid region, causing a large difference in the water content of the atmosphere and soil.

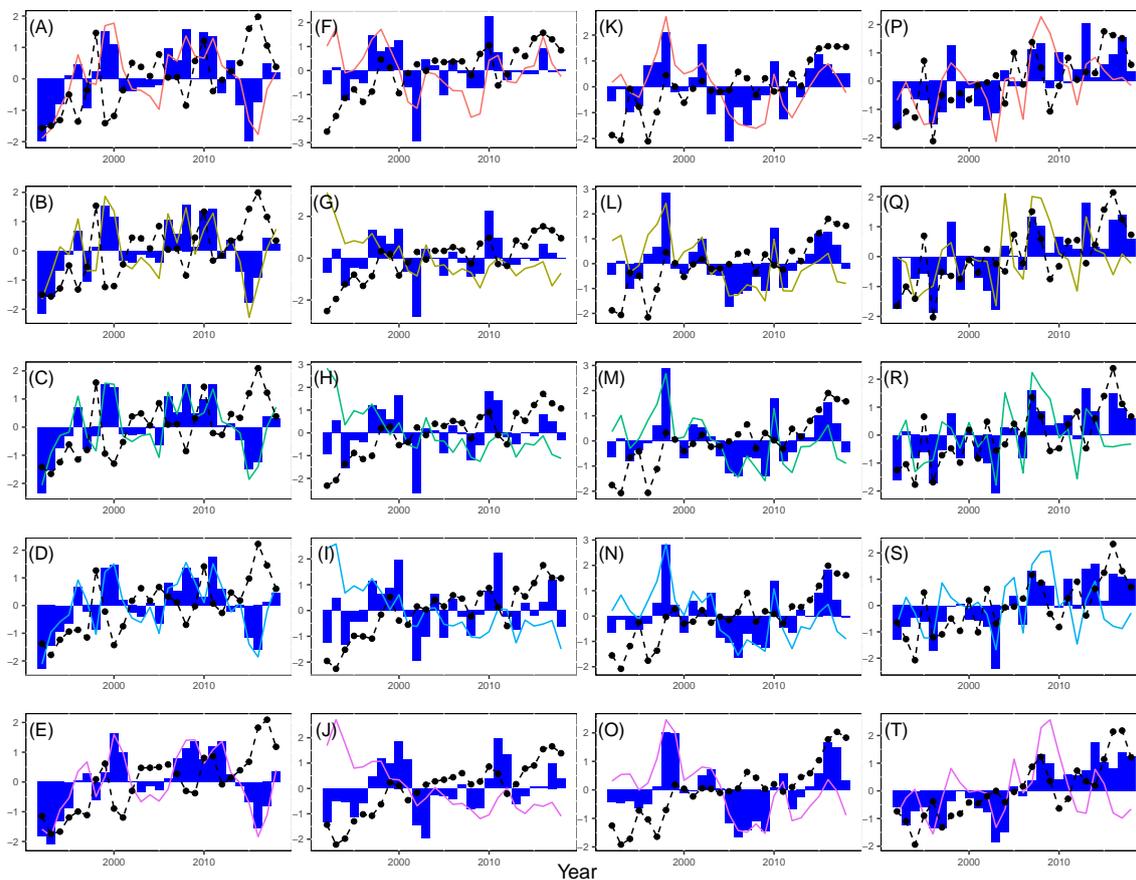

Figure 3. Time series of regional averaged annual precipitation (bar), temperature (dashed line) and Drought indices (lines, the legend is the same with Fig. 2; rows from top to bottom: scPDSI and SPEI τ with $\tau \in \{03, 06, 12, 24\}$) from 1992 to 2018 across different zones (columns from left to right: equatorial, arid, temperate, snow)

3 Methods

180 3.1 Linear Models

We use linear models to explore the influence of forest cover, as well as temperature and precipitation on the drought indices in various climate zones. Linear models allow the assessment of drought indices for hypothetical situations in a projected climate change scenario. The target variable (drought index) is assumed to be a realization of a normally distributed random variable Y with constant variance σ^2 and varying expectation μ

$$185 \quad Y \sim \mathcal{N}(\mu, \sigma^2). \quad (1)$$

The expectation μ depends on a set of covariates (or independent variables) $X_1, X_2, X_3, \dots, X_p$, which we expect to influence the expectation of the target (drought index) in a linear way,

$$\mu = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \dots + \beta_p X_p. \quad (2)$$

The unknown model parameters β_i are estimated using maximum-likelihood (Wilks, 2019), realized within the environment for statistical computing R (R Core Team, 2018) using the function `lm()` (Chambers and Hastie, 1992; Wilkinson and Rogers, 1973) from the package `stats`.

For ease of communication, we adopt the notation for linear models introduced by McCullagh and Nelder (1989). For example, for a model with covariates X_1, X_2, X_3 which enter all as direct effects and $X_2 X_3$ as interactions, i.e.

$$\mu = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_2 X_3, \quad (3)$$

the model notation reads

$$Y \sim X_1 + X_2 * X_3 = X_1 + X_2 + X_3 + X_2 : X_3, \quad (4)$$

with $X_2 * X_3$ being shorthand for $X_2 + X_3 + X_2 : X_3$, i.e. including X_2 and X_3 as direct effects and as interaction $X_2 : X_3$.

Here, we use

$$D_\tau \sim X_{\text{forest}} + X_{\text{precip}} + X_{\text{temp}} + X_{\text{forest}} : X_{\text{temp}} + X_{\text{forest}} : X_{\text{temp}} + X_{\text{precip}} : X_{\text{temp}}, \quad (5)$$

with D_τ denoting the drought index, i.e. scPDSI or SPEI with integration time τ , X_{forest} the forest cover fraction, X_{precip} the annual mean precipitation and X_{temp} the annual temperature mean. $X_a : X_b$ denote interactions, e.g. $X_{\text{forest}} : X_{\text{temp}}$ describes the influence of temperature depending on forest cover fraction. All variables are standardized to zero mean and unit variance prior to parameter estimation.

The SPEI is a time-scale dependent drought index with integration time τ . Note that the integration time τ also defines the first available data point for D_τ as $\tau - 1$ month after the start of the time series in January 1992. Thus for longer integration times, the SPEI_τ cannot be obtained for the first years of the data set, e.g. for SPEI_{24} , the calculation starts in December of the second year.

Based on Eq. 5, we estimate the impact of forest fraction and meteorological factors on drought. For SPEI_{03} , SPEI_{06} and SPEI_{12} of a specific month, we use the previous 3, 6 or 12 months' data; for SPEI_{24} , we do need the data of the previous 2 years.

Fig. 4 compares annual values for the SPEI_τ obtained as described in Sec. 2.2 (points) to the expectation from the linear models (Eq. 5 using forest fraction X_{forest} , temperature X_{temp} and precipitation X_{precip} as inputs (lines); the rows give the scPDSI and the SPEI_τ for different integration time scales $\tau \in \{03, 06, 12, 24\}$ (from top to bottom) and across various climate zones (columns, equatorial, arid, temperate, snow, from left to right). And in Tab. 1, we also give MSE (Mean Squared Error) and Adjusted R^2 for all models in Fig. 4.

The Mean Squared Error (MSE) quantifies the difference between model estimates and observed values for the drought indices, computed as,

$$MSE = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{Y}_i)^2 = \frac{1}{n} \sum_{i=1}^n (D_{\tau,i} - \widehat{D}_{\tau,i})^2, \quad (6)$$

with y_i representing the observed values for the drought index ($D_{\tau,i}$, scPDSI and SPEIs), \hat{Y}_i denote the model estimates ($\widehat{D}_{\tau,i}$),
 220 n the number of data points, i.e. the number of years. The coefficient of determination R^2 gives the fraction of variability described by the model

$$R^2 = \frac{SS_{\text{reg}}}{SS_{\text{tot}}} = 1 - \frac{SS_{\text{res}}}{SS_{\text{tot}}} \quad (7)$$

with the total sum of squares

$$SS_{\text{tot}} = \sum_{i=1}^n (y_i - \bar{y}_i)^2 = SS_{\text{reg}} + SS_{\text{res}}, \quad (8)$$

225 the sum-of-squares of the regression

$$SS_{\text{reg}} = \sum_{i=1}^n (\hat{Y}_i - \bar{y}_i)^2, \quad (9)$$

the sum-of-squares of the residuals

$$SS_{\text{res}} = \sum_{i=1}^n (y_i - \hat{y}_i)^2, \quad (10)$$

and \bar{y}_i denoting the arithmetic mean of the observations y_i . We use the adjusted R^2

$$230 \quad R_{\text{adj}}^2 = 1 - \frac{SS_{\text{res}}/df_{\text{res}}}{SS_{\text{tot}}/df_{\text{tot}}} = 1 - \frac{\sum_{i=1}^n (y_i - \hat{Y}_i)^2 / (n - 1 - p)}{\sum_{i=1}^n (y_i - \bar{y}_i)^2 / (n - 1)}, \quad (11)$$

with df_{tot} and df_{res} denoting the degrees of freedom for the total and residual sum-of-squares, respectively, n the number of observations and p the number of covariates (independent variables).

The linear model is able to capture the inter-annual variability of the drought indices to a certain extent with performance varying across climate zones. From visual inspection and comparison of R_{adj}^2 , drought indices in the equatorial region can be
 235 described best ($0.84 < R_{\text{adj}}^2 < 0.97$), while for the snow region ($0.23 < R_{\text{adj}}^2 < 0.39$), the model is by far not as performant, cf. Tab. 1. For arid and temperate zones, the models are almost as performant as for the equatorial zone. The MSE in the equatorial region is around 0.1 and smaller, while in the snow region, we find MSE of around 0.5 (Tab. 1). Thus in the equatorial, temperate and arid regions, linear models with two-point interactions of forest cover, temperature and precipitation are well suited to describe the drought indices used here; whereas in the snow region, the factors influencing the drought indices
 240 must be more complex than this.

Furthermore, we see from Fig. 4 and Tab. 1 that the SPEI indices with varying time scale τ are consistently better represented by the model (larger R_{adj}^2) than the scPDSI over all regions, with performance (R_{adj}^2) roughly increasing with τ (except for the snow region). We hypothesize that this is an effect of the calculation of the scPDSI based on a 2-layer soil box model and thus local soil conditions are relevant; the latter are not represented in our model-building process.

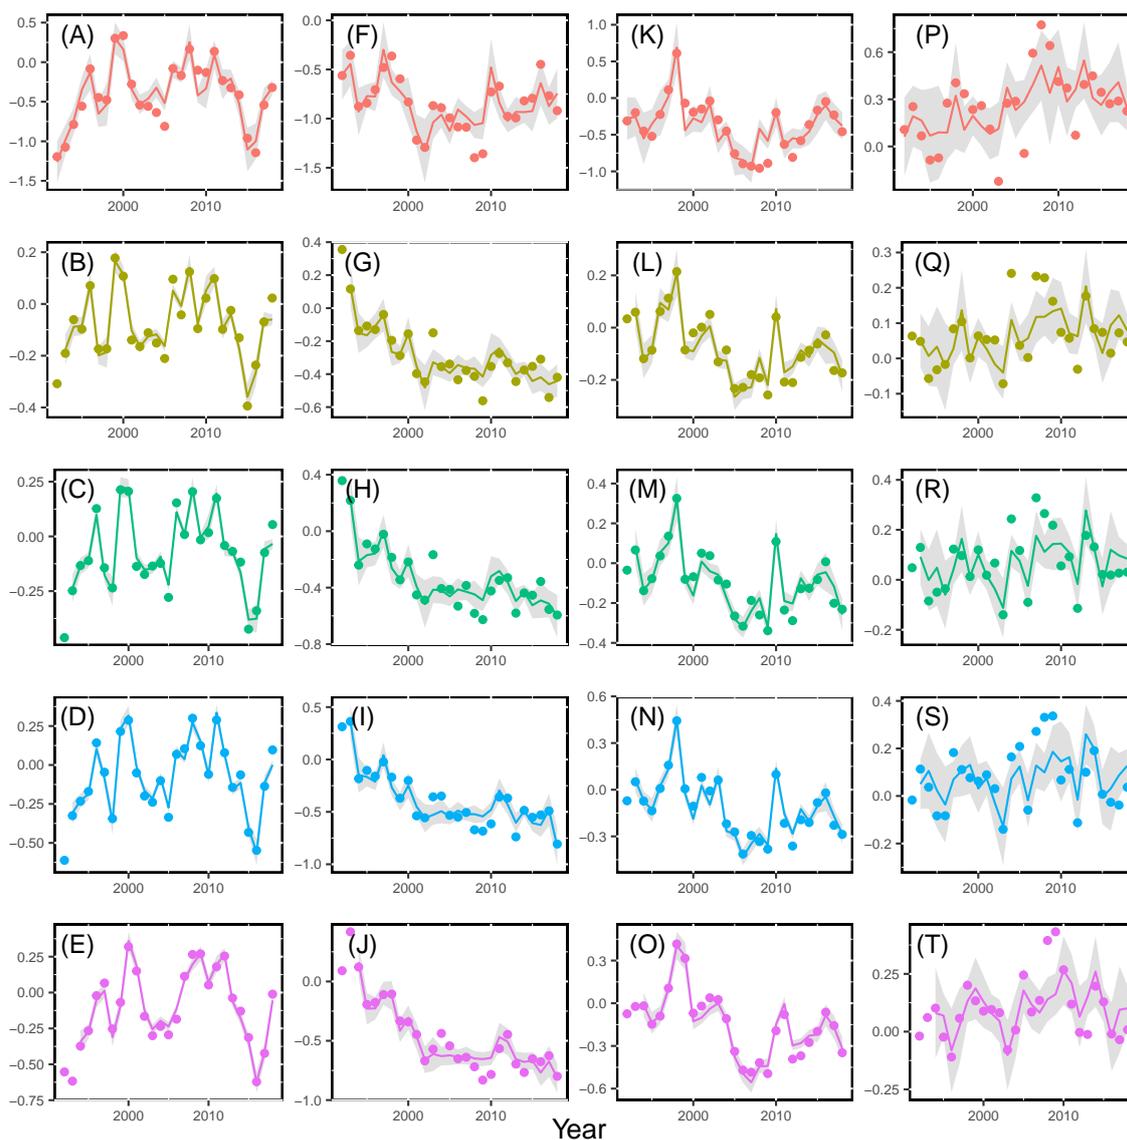

Figure 4. Time series of drought indices (colors as same as in Fig. 2); annual point estimates (points) and estimates from the linear model (Eq. 5, lines) across different climate zones (columns from left to right: equatorial, arid, temperate, snow) and for the scPDSI and $SPEI_{\tau}$ with different integration times (rows from top to bottom: scPDSI and $SPEI_{\tau}$ with $\tau \in \{03, 06, 12, 24\}$). The shade signifies the range lies at a 95% level of confidence. Note that $SPEI_{03}$, $SPEI_{06}$ and $SPEI_{12}$ cannot be obtained for the first year and $SPEI_{24}$ can not be obtained for the first 2 years.

Table 1. MSE (Mean Squared Error) and Adjusted R^2 (R_{adj}^2) for all models in Fig. 4.

	Equatorial region		Arid region		Temperate region		Snow region	
	MSE	R_{adj}^2	MSE	R_{adj}^2	MSE	R_{adj}^2	MSE	R_{adj}^2
scPDSI	0.12	0.84	0.31	0.59	0.23	0.70	0.57	0.23
SPEI03	0.05	0.93	0.17	0.77	0.10	0.86	0.49	0.32
SPEI06	0.03	0.95	0.17	0.76	0.09	0.88	0.45	0.39
SPEI12	0.03	0.97	0.11	0.85	0.05	0.94	0.53	0.27
SPEI24	0.02	0.97	0.09	0.87	0.04	0.94	0.53	0.27

245 3.2 Analysis of Variance

Analysis of variance (ANOVA Anscombe, 1948) gives a quantitative estimate of the relative strength of these factors, which is used to quantify the effect of the various covariates X . We use it to describe the drought indices with, i.e. forest fraction, precipitation and temperature, cf. Eq. 5. We denote the full model for a drought index D as D_{full} as given in Eq. 5. The model without the information on the forest is denoted as

$$250 \quad D_{\text{-forest}} \sim X_{\text{precip}} * X_{\text{temp}}, \quad (12)$$

analogously, we denote models without information on temperature or precipitation as $D_{\text{-temp}}$ and $D_{\text{-precip}}$, respectively. With

$$SS_{\text{forest}} = SS_{\text{reg}}(D_{\text{full}}) - SS_{\text{reg}}(D_{\text{-forest}}), \quad (13)$$

we assess the improvement in model performance in terms of regression sum-of-squares due to including the forest fraction as a covariate, with the F -test giving significance to that. Note that the difference in degrees of freedom used in the F -test for the full and the reduced model is $\delta p = 3$ as all terms in Eq. 5 involving forest fraction X_{forest} are taken out. Analogously, we define SS_{temp} and SS_{precip} for quantifying the influence of temperature and precipitation.

The fraction of variance contributed to the regression by forest fraction is given as

$$\Delta SS_{\text{forest}} = \frac{SS_{\text{forest}}}{SS_{\text{reg}}(D_{\text{full}})}, \quad (14)$$

analogously for precipitation ($\Delta SS_{\text{precip}}$) and temperature (ΔSS_{temp}).

260 4 Results

The gridded monthly data have been averaged to annual regional mean values according to the climate classification in Fig. 1. In the following, we analyze four regions: equatorial, arid, temperate and snow. For each region, linear models for scPDSI, SPEI03, SPEI06, SPEI12 and SPEI24 are built to describe the relationship between the drought indices (D_{τ}) and 3 covariates

(factors) (X_{forest} , X_{precip} , X_{temp}). The annual values for forest fraction X_{forest} and the SPEI τ have a time delay, as discussed
 265 in Sec. 3: the model for SPEI03, SPEI06 and SPEI12 uses meteorological data from 1993 to 2018 while the values for forest
 fraction are from 1992 to 2017; the model for SPEI24 uses meteorological data from 1994 to 2018, while values for forest
 fraction are from 1992 to 2016; for scPDSI, all values for the covariates are from 1992 to 2018. Here, the results in terms of
 the proportion of variance added to the models by forest cover change and other meteorological factors across different regions
 are displayed first. Subsequently, we investigate the interaction of the three factors on droughts in four regions. Key insights
 270 emerging from the results are discussed and we also give some possible explanations.

4.1 The proportion of variance described by forest cover change

Based on the linear models for all variants of drought indices and across climate zones, we estimate the contribution of the 3
 covariates to the regression according to the procedure described in Sec. 3.2. The bars in Fig. 5 show the proportion of variance
 contributed by forest cover fraction (X_{forest} , green), precipitation (X_{precip} , blue), and temperature (X_{temp} , red) to the regression.

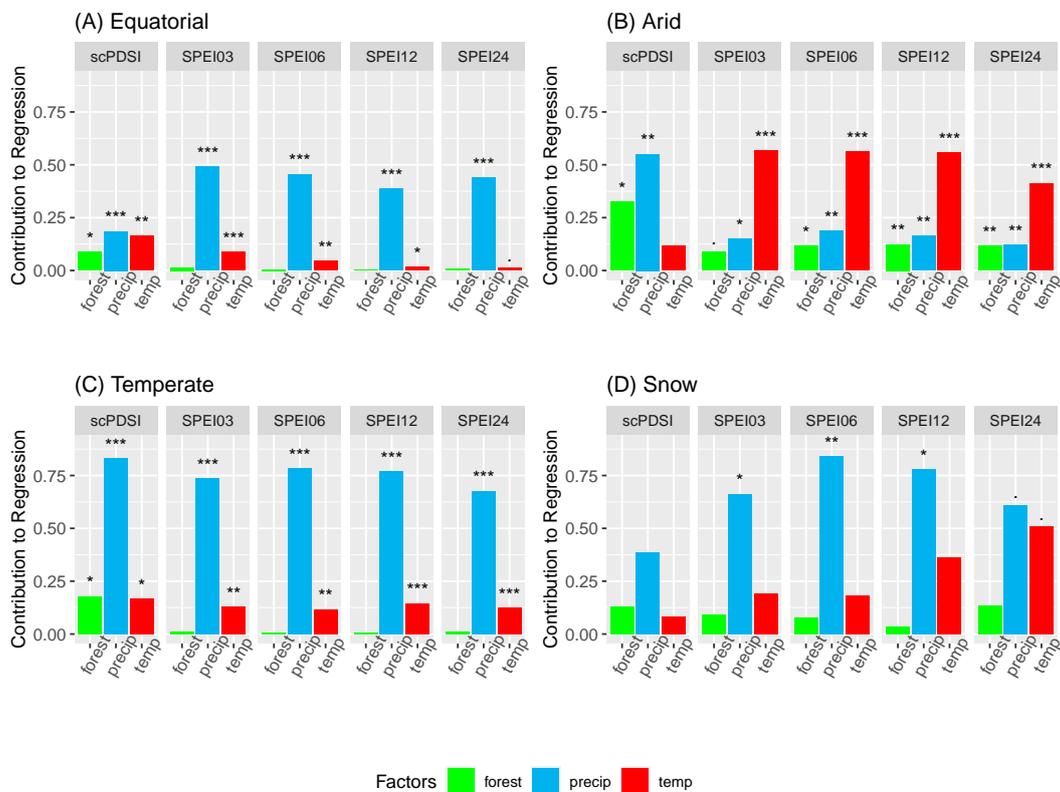

Figure 5. Proportion of variance contributed by forest fraction, precipitation, and temperature to the full model that describes drought indices at different time scales across 4 climate regions. (confidence significant level at '***' 0.001, '**' 0.01, '*' 0.05, '.' 0.1.)

275 The contribution of precipitation to variability omimates for drought indices in equatorial, temperate, and snow regions. For the arid region, precipitation only dominates scPDSI, while for SPEI-based drought indices, temperature dominates its variability here. For the temperate region, precipitation contributes the largest fraction of variance compared to other regions, followed by the snow region.

Across all regions, the forest fraction describes a more significant fraction of the regression variance for scPDSI than for
280 the SPEI-based drought indices. As scPDSI is the only drought index used here which involves soil properties, we hypothesize that forest fraction is linked to these and thus has some potential to describe more about the variability of scPDSI. However, we still should note that the linear models better represent SPEI-based indices (higher R_{adj}^2 in Tab. 1) than scPDSI.

For the equatorial and temperate regions, forest fraction does not contribute to describing the variability of the SPEI-based indices (non-significant). In the arid region, however, the proportion of variance contributed by forest cover to SPEI-based
285 indices is around 0.1 and at least significant on the 0.05 level (SPEI03 only on 0.1 level). While for the snow region, the contributing fraction of variance is comparably large but not statistically significant on any reasonable level. Here, the contribution of precipitation is particularly large for SPEI06 and the influence of temperature seems to increase with time scale τ , however, the latter is not significant on the normal levels. Thus for the snow region, precipitation seems to have a larger impact on short-term drought indices while temperature affects more long-term indices. Note that the linear models for the snow region
290 show adjusted R^2 values of around 0.3 and hence are a lot less capable of describing the index variability than that in other regions ($R_{adj}^2 \geq 0.7$), cf. Tab. 1. Processes in the snow region seem to be more complex than what can be represented with the approach here.

Proportions of contribution do vary across regions and drought indices: precipitation has a large influence in all regions except the arid region; the temperature has a larger influence on SPEI-based drought indices in the arid region; forest fraction
295 describes a larger fraction of the regression variance for scPDSI than for the SPEI-based indices. Thus in the arid region, where the ecosystems are fragile and highly vulnerable to climate change, the forest fraction has a stronger impact on changes in drought indices.

4.2 Variations in droughts response to forest fraction according to different precipitation and temperature quantiles

Fig. 6 explores the effect of forest cover fraction on SPEI24 and SPEI03 conditioned on precipitation and temperature. Again,
300 this analysis is based on the previously discussed models. The first two rows show the effect of forest cover on SPEIs for different levels of precipitation (dark green lines) with temperature held fixed at its median. For the bottom two rows, precipitation has been held fixed at its median and the forest cover effect for various levels of temperature (dark yellow lines) is explored. The strength of the colored bands is associated with the quantiles of precipitation/temperature. The dark green/dark yellow part of the band covers the central part of the precipitation /temperature (0.4 to 0.6-quantile). For each successive outer band the
305 quantile level for temperature/precipitation changes by 0.05.

The first row of Fig. 6 (SPEI03) shows only a minor influence of forest fraction for various levels of precipitation (lines are close to horizontal) indicating that precipitation does not modulate the influence of forest cover on the short-term drought index. This is different for the second row (SPEI24), where a strong influence of precipitation on the forest fraction effect for

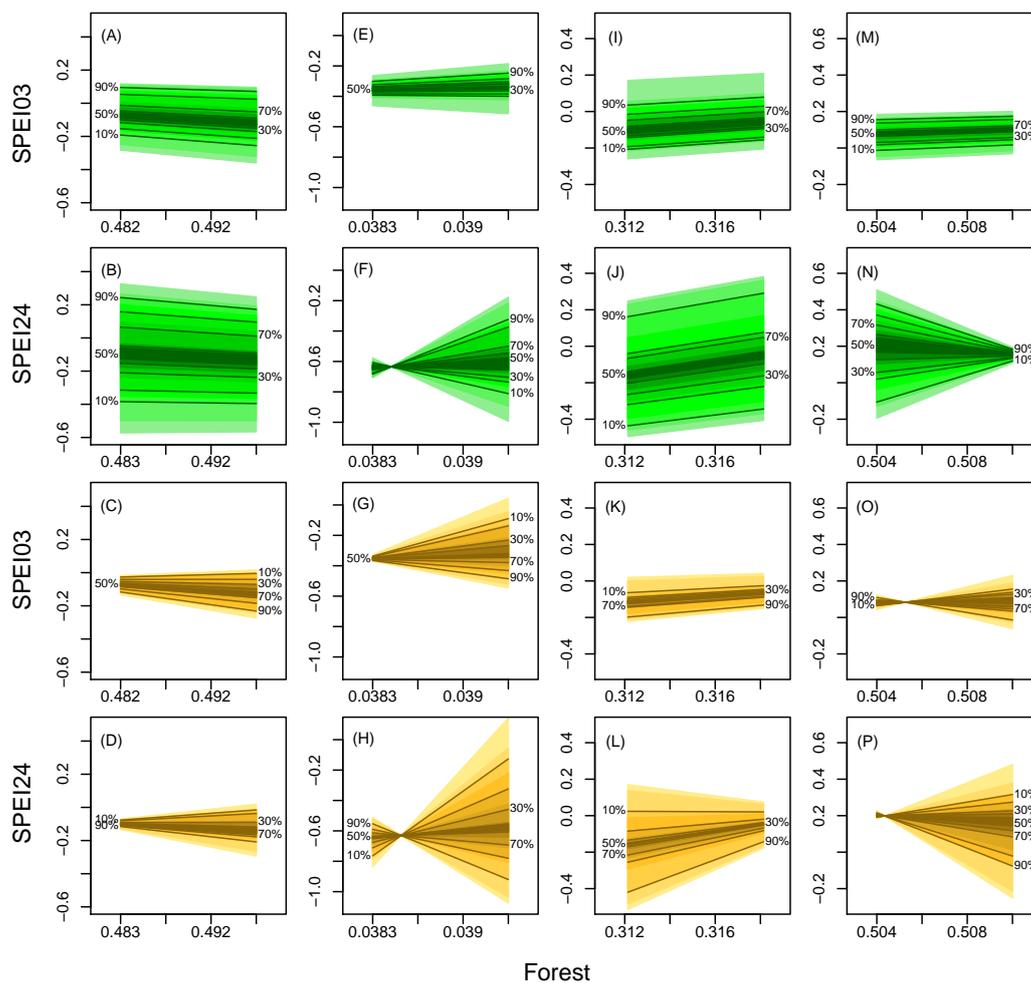

Figure 6. The effect of forest fraction on droughts for SPEI03 in the first and third rows; for SPEI24 in the second and fourth rows for different levels of precipitation (blue lines) and temperature (red lines) using the model from Sec. 3 across different climate zones (from left to right: equatorial, arid, temperate, snow). For the first two rows, the temperature is held constant at its 0.5 quantiles and the forest cover effect is explored under different quantiles of precipitation. For the bottom two rows, precipitation is held constant and the effect is shown under different temperature quantiles.

the arid region (Fig. 6F) is noted: for precipitation more than about median, the drought index increases with forest cover and
310 decreases if precipitation is less than the median. If precipitation is low and forest cover high, a low SPEI24 may be the result
of a small amount of water being transpired into the atmosphere due to a high fraction of available trees. For high precipitation
amounts instead, a larger forest cover would hold the water vapor, and make the SPEI24 high. The opposite effect can be
observed for the snow region (Fig. 6N): for little forest cover, precipitation directly affects the SPEI24 leading to a more humid
situation with more precipitation. For a higher forest cover, this effect vanishes. Recall, that for the snow region, the model
315 captures less than 30% of the total variability.

The modulation of forest cover by temperature (Fig. 6, two bottom rows) is more diverse. In the equatorial region (Fig. 6C
and D), the temperature influence is a lot weaker than precipitation (cf. Fig. 5), hence precipitation dominates the drought
index in the equatorial region. However, for the higher temperature, we see a slight decrease in SPEI24 (Fig. 6D) with forest
cover, while for the low temperature, SPEI24 increases with forest cover. This modulating effect of the forest cover effect on
320 the drought index is a lot stronger for the arid region. For the short-term index (SPEI03, Fig. 6G), high/low temperatures lead
to a notable decrease/increase in forest cover, while the same effect is even stronger for the long-term index (SPEI24, Fig. 6H).
A possible explanation is that rising temperature leads to increasing transpiration from trees, and if there are more trees, more
water will be taken away, and the drought indices will decrease. For low temperatures, the forest transpiration will be weak
and if there are more trees, exposed surface area decreases, and less water will be taken away (Shaxson and Barber, 2003).
325 A simulation about soil evaporation has been carried out in Kenya (in an arid region), which found that trees could reduce
annual soil evaporation directly beneath their canopy by an average of 35% (compared to completely bare soil), equivalent
to 21% of rainfall over there (Wallace et al., 1999). For the temperate zone, high temperatures lead to an increase in drought
index with forest cover, possibly because precipitation is always sufficient in this location and the types of trees here can adapt
their leaves and roots to absorb all of the excess water, with the effect being stronger for SPEI24 (Fig. 6L) than for SPEI03
330 (Fig. 6K). For the snow region, we see a notable effect of high temperatures: SEPI24 decreases with forest cover. Trees in
mostly snow-covered regions change the albedo and the transpiration. Again, for the snow region, the model captures only a
little part of the variability, which limits its interpretability.

The combined forest fraction and meteorological effect on drought indices varies across regions and time scales τ in mag-
nitude and direction. In equatorial and temperate regions, the long-term drought index (SPEI24) is primarily influenced by
335 precipitation, rather than forest cover. Similarly, the short-term drought index (SPEI03) in 4 regions is also more dependent
on precipitation than on forest cover. However, in the arid region, temperature plays a significant role in modulating the short-
term drought index (SPEI03), as well as the long-term drought index (SPEI24). Additionally, in temperate and snow regions,
temperature also has a notable modulating effect on the long-term drought index (SPEI24).

4.3 Response of drought to precipitation and temperature under extreme forest fraction(minimum and maximum) 340 conditions

We studied the effect of precipitation and temperature on short-term (SPEI03) and long-term (SPEI24) drought indices for
observed minimum ($\min(X_{\text{forest,region}})$) and maximum forest cover fractions ($\max(X_{\text{forest,region}})$). We generate a grid with $100 \times$

100 points based on the variables of precipitation and temperature used in the linear models across different climate regions, and then, use the precipitation, temperature, and forest extremes (maximum and minimum) to calculate the drought indices (SPEI03 and SPEI24) based on the models from Eq. 5. The first two rows in Fig. 7 depict the short-term drought index (SPEI03) obtained for the minimum (first row) and maximum forest cover (second row); the last two rows depict the long-term drought index (SPEI24) for minimum (third row) and maximum forest cover (fourth row).

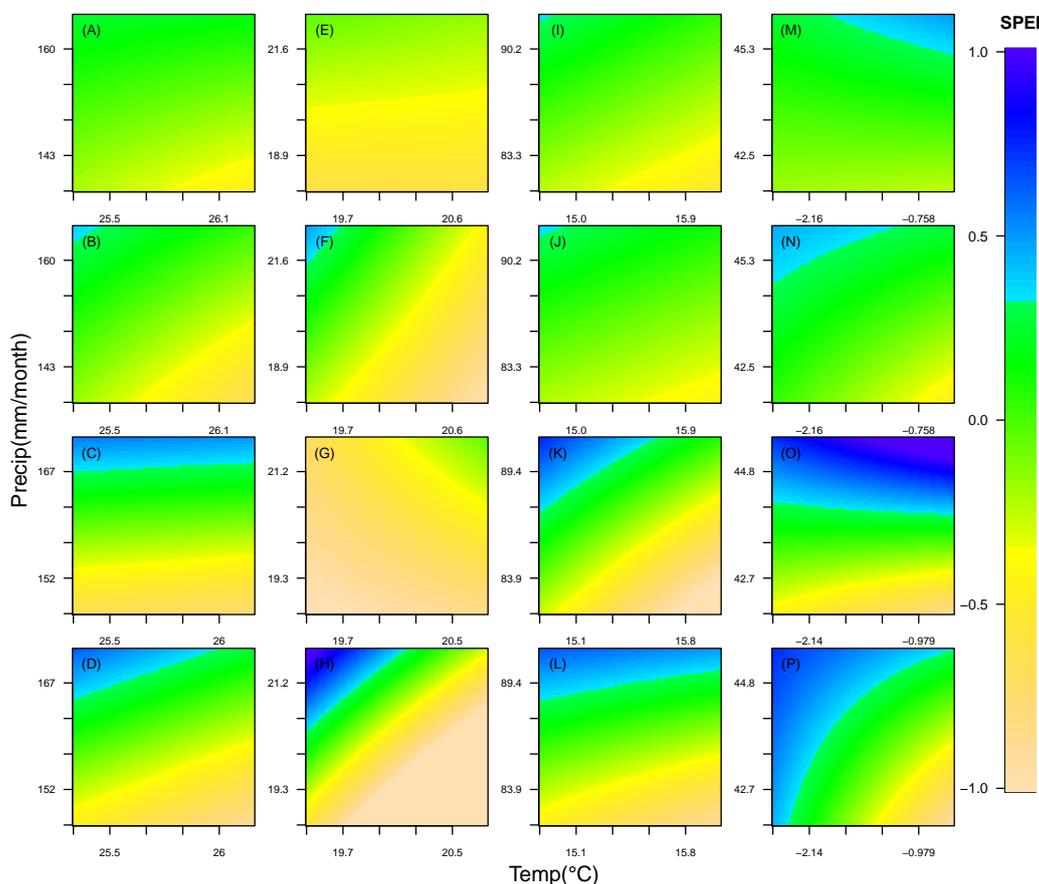

Figure 7. The variation of droughts (SPEI03: the first and second rows; SPEI24: the third and fourth rows) under the effect of minimal (the first and third rows) and maximal (the second and fourth rows) forest cover across four regions (from the left to right: equatorial, arid, temperate and snow regions)

Blue colors indicate the situations wetter than the median (positive indices), green represents situations close to the median (indices around 0), and yellow indicates conditions drier than the median conditions (negative indices). For the equatorial region, precipitation influences the short and long-term drought indices (vertical color change); for maximum forest cover (Fig. 7B), the dependence on temperature (horizontal color change) becomes visible, even more so for the long-term index (Fig. 7D). The long-term index in the arid region shows a somewhat stronger temperature dependence for maximum forest

cover (Fig. 7H) than that in the equatorial region (Fig. 7D). For minimum forest cover (Fig. 7G), the temperature dependence is very weak (and reversed). For SPEI03 (Fig. 7E and F), the dependence also changes from precipitation to temperature if
355 there are more trees. In the temperate region, the SPEI24 for minimum forest cover (Fig. 7K) shows the strongest temperature and precipitation dependence; increasing forest cover to maximum (Fig. 7L) significantly reduces the temperature dependence, leaving the long-term drought index for the temperate region dominated by precipitation. The short-term index (Fig. 7I and J) is less dependent on both, and the influence from precipitation and temperature is almost unaffected by the change in forest cover. In the snow region, the relationship between temperature, precipitation, and long-term droughts is closely linked to the extent
360 of forest cover. Maintaining maximum forest cover is crucial in strengthening the effects of temperature and precipitation on droughts (Fig. 7P). Minimizing the forest cover (Fig. 7O) eliminates the temperature dependence. For SPEI03 (Fig. 7M and N), the dependence on both variables is a lot weaker, with temperature dependence being reversed by reducing the forest from maximum (Fig. 7N) to the minimum (Fig. 7M).

Comparing all panels in Fig. 7, forest cover has a greater influence on the long-term drought index in the snow region.
365 Increasing the forest cover increases the dependence on temperature in snow, arid and equatorial regions, and it reduces the dependence on temperature for the temperate region.

Fig. 5 presents that the droughts indices are greatly affected by precipitation (except arid regions). In most cases, the color change in Fig. 7 should be more vertical. Transpiration from the forest is essentially the evaporation of water vapors from plant leaves and stems, which is an important part of the water cycle (39% of terrestrial precipitation and 61% of evapotranspiration globally) (Schlesinger and Jasechko, 2014). within the cycle, temperature plays a major role in the rate of transpiration
370 (Kimball, 1999), especially during the growing season. Using forests as a medium, the temperature effect would be more pronounced in the water cycle in most cases, as shown in snow, arid and equatorial regions. In the temperate region, the drought indices are dominated by precipitation and the forest only affects the influence of temperature to SPEI24, and when there are fewer trees, the influence of temperature will be amplified (shown in Fig. 6L). And this is consistent in Fig. 7K and L. Note:
375 simultaneously with afforestation or deforestation the global climate is changing. Therefore, local changes in climate may also be additionally influenced by global climate change and not only afforestation or deforestation rates.

5 Conclusions

The scientific community has dedicated significant efforts to quantify the influence of land cover changes on climate. In this study, linear models were employed to evaluate the impacts of forest cover and climatic factors on droughts at various temporal
380 scales in four distinct climate regions (excluding the polar region, which has negligible forest cover). The study findings are summarized as follows:

1. Linear models incorporating forest fraction, precipitation, and temperature yield the most accurate results for explaining drought indicators in the equatorial region, but are less effective in the snow region. These three variables provide a better fit for changes in SPEIs compared to scPDSI, which may be due to scPDSI's consideration of soil conditions.

385 Precipitation is the primary factor explaining a significant proportion of the regression variance in all regions, except for the arid region where temperature is the dominant factor.

2. It is conceivable that changes in precipitation and temperature can impact the relationship between forest cover changes and drought occurrence. Specifically, precipitation alters the influence of forest cover on long-term drought (SPEI24) in arid and snow regions, while temperature significantly modifies the effect of forest cover on both short- and long-
390 term droughts (SPEI03 and SPEI24) in the arid region and on long-term drought (SPEI24) only in temperate and snow regions.

3. Forest cover has differing effects on drought occurrence (especially long-term drought) depending on the maximum and minimum levels of forest fraction in different climate regions. Specifically, in equatorial, arid, and snow regions, higher forest cover intensifies the combined influence of precipitation and temperature for long-term drought. Conversely, in
395 regions with lower forest cover, precipitation is the dominant factor for drought occurrence. The opposite pattern is observed in the temperate region, where lower forest cover promotes a combined effect of precipitation and temperature for long-term drought.

Despite the substantial progress made in understanding the factors that influence drought occurrence, uncertainties remain that have not always been fully acknowledged. One source of uncertainty is the use of different drought indices, which can
400 produce divergent results. In this study, we focused on two indices, scPDSI and SPEI. However, the calculation of drought indices, particularly scPDSI, is subject to various uncertainties. For example, scPDSI requires information on temperature, precipitation, and soil conditions. Obtaining detailed soil information for each location can be challenging, leading to potential inaccuracies in the calculation of the index. In addition, human activities like irrigation are not accounted for in the index calculation, which can affect its accuracy. Meanwhile, each of the drought indices has its own niche where it excels. Different
405 drought indices should be used when assessing different types of droughts (Mishra and Singh, 2010). Secondly, this study used a relatively short-term dataset of 25-26 years, and future studies can use longer-term data to obtain a more robust understanding of the relationship between forest cover and drought. Finally, this study utilized linear models with a limited number of predictors, and future studies can investigate more complex models to explore other potential effects of forest cover change on drought. These gaps in knowledge present opportunities for future research and can help in developing a broader framework
410 for understanding natural hazards, including droughts.

Possible extensions of this study include broadening the scope of land cover analysis to include other types of land cover, such as agricultural land, grasslands, wetlands, and settlements. Additionally, conducting more specific research in particular locations, such as Europe, could provide more definitive recommendations. Future model inter-comparison studies, such as the Land-Use Model Intercomparison Project simulations (LUMIP; Lawrence et al., 2016) under the CMIP phase 6 (CMIP6), could
415 further investigate the impact of land use on climate and examine the effect of land cover change on the onset and evolution of drought under various forcing conditions. These extensions could significantly expand our understanding of the relationship between land cover change and drought and inform the development of more effective land use policies to mitigate the impacts of climate change. Expanding our understanding of the regional and global climate impact of land cover changes, including

their scale effects, can help to inform the development of land use policies that prioritize climate objectives. This is particularly
420 important given that decisions regarding land use are frequently made at the subnational level by regional authorities.

This study enhances our comprehension of the connection between forest cover and drought across various temporal scales and climatic regions. Additionally, it elucidates the combined impact of forest cover, temperature, and precipitation on drought variability. The findings of this study can offer a theoretical framework for the creation of regional land use policies that prioritize climate concerns, as well as deepen our insight into the impact of land surface changes on climate change.

425 *Code and data availability.* All the datasets in the article can be downloaded from the website for free. The links have been given in Sec. 2. The statistical analysis is finished by R. All the packages used in the paper are free and the information is given in Sec. 3.

Author contributions. YL and HWR conceived and designed the research. YL built the models with the primary processing data from BH, and conducted the statistical analysis under the supervision of HWR. YL made the figures. All authors interpreted the results and wrote the paper.
