22 **Abstract**

23 A comprehensive understanding of spatiotemporal runoff changes at a sub-basin scale of the
24 Yarlung Zangbo (YZ) basin on the southern Tibetan Plateau (TP), amidst varying climatic and
25 cryospheric conditions, is imperative for effective water resources management. However,
26 spatiotemporal differences of runoff composition, change and the attribution within the YZ
27 basin have not been extensively explored, primarily due to the lack of hydrometeorological
28 observations, especially in the downstream region. In this study, we investigated historical and
29 future evolution of annual and seasonal total water availability, as well as glacier runoff and
30 snowmelt contributions across six sub-basins of the YZ with a particular focus on the
31 comparison between the upstream Nuxia (NX) basin and the downstream Nuxia-Pasighat (NX-
32 BXK) basin, based on a newly generated precipitation dataset and a well-validated model with
33 streamflow, glacier mass, and snow cover observations. Our findings revealed large
34 spatiotemporal differences in changes exist within the YZ basin for 1971–2020. Firstly, runoff
35 generation was dominated by rainfall runoff throughout the YZ basin, with glacier runoff
36 playing more important role in the annual total runoff (19%) in the NX-BXK sub-basin
37 compared to other sub-basins. Notably, glacier runoff contributed 52% of the total runoff at the
38 Pasighat outlet of the YZ basin. Secondly, annual runoff exhibited an increasing trend in the
39 NX basin but a decreasing trend in the NX-BXK, primarily attributed to rainfall runoff changes
40 influenced by atmospheric moisture. Glacier runoff enhanced water supply, by offsetting the
41 decreasing contribution from rainfall. Total runoff will consistently increase (27–100 mm/10yr)

42 across the sub-basins through the 21st century, resulting from increased rainfall runoff and a
43 minor effect of increased snowmelt and glacier runoff.

44

45 **Keywords**

46 Runoff Composition; Runoff Changes; VIC-Glacier Hydrological Model; Yarlung Zangbo;
47 Tibetan Plateau

48

49 **Highlights**

- 50 ● Runoff generation is dominated by rainfall runoff (59%–72%) in the YZ, and the largest
51 glacier runoff contribution is in the downstream sub-basin (16%–19%).
- 52 ● Annual runoff trends indicate an increase in the NX but a decrease in the NX-BXK for
53 1971–2020, due to contrasting precipitation changes.
- 54 ● Total runoff across the sub-basins will consistently increase (27–100 mm/10yr) through the
55 21st century, mostly resulting from increased rainfall runoff.

56

58

59

60

61

62 **1 Introduction**

63 Climatic and cryospheric changes have profoundly affected hydrological processes in high-
64 mountain regions. The Tibetan Plateau (TP), known as the Asian Water Tower, supplying
65 freshwater to nearly 2 billion people. Marked atmospheric warming since the 1980s has
66 changed the balance between liquid and solid states of water, leading to shifts in river runoff,
67 glacier, and snow melt dynamics (Yao et al. 2022). These drastic changes in the upper mountains
68 of the TP pose a threat to the sustainability of the downstream water supply.

69

70 The Yarlung Zangbo (YZ, Figure 1) river basin, located in the southern TP is the largest river
71 basin of the TP and a vital freshwater source for the Tibet Autonomous Region (TAR). It
72 constitutes the main agricultural region in the TAR (Yang et al., 1989; Zhong et al., 2014). Like
73 elsewhere on TP, a rapid ongoing temperature rise (0.3–0.4°C per decade) since the mid-1960s
74 potentially influences runoff processes and water resources availability in the YZ basin (Yao et
75 al., 2012; Li et al., 2018). The YZ basin, spanning approximately 250,000 km², exhibits diverse
76 climatic systems, including the Indian summer monsoon and the westerly system, and varying
77 glacier and snow conditions (Zhang et al., 2013). These factors contribute to spatiotemporal
78 differences in runoff changes within the YZ basin. Therefore, gaining a comprehensive
79 understanding of runoff regimes and flow changes at the sub-basin scale is crucial for informed
80 decision-making in water resources management and social development.

81

82 While numerous studies have investigated runoff regimes and changes using hydrological
83 models in the YZ basin, most have focused solely on the region upstream of the Nuxia (NX)
84 hydrological station (Figure 1, Table 1) (Chen et al., 2017; Cuo et al., 2019; Su et al., 2016;
85 Zhang et al., 2013; Zhao et al., 2019; Cui et al., 2023; Gu et al., 2023). This focus is due to the
86 nearest national hydrological station's proximity to the mainstream outlet, providing long-term
87 daily records (> 50years). Conversely, the glacierized downstream region (about 65% of the
88 total glacier area in the YZ), particularly between NX and Pasighat outlet (NX-BXK, Figure 1)
89 has received less attention. This lack of focus is attributed to limited hydrometeorological and
90 glacier observations in this sub-basin. Remarkably, this region exhibits the largest glacier retreat
91 in the TP, with a length reduction rate of 48.2m yr^{-1} and an area decrease of $0.57\% \text{ yr}^{-1}$ during
92 the 1970s–2000s (Yang et al., 2013; Yao et al., 2012). These changes have the potential to
93 significantly alter the runoff regime, influencing the quantity, timing, and variability of flows
94 across space and time. However, the characteristics and changes in runoff, along with the effect
95 of glacier melt on water supply, remain unclear in the NX-BXK sub-basin.

96

97 The NX basin, with an area of approximately $201,548 \text{ km}^2$, presents divergent glacier and snow
98 conditions (Table 2). For example, the region upstream of the Lhatse hydrological station
99 (Figure 1), the source region of the YZ river, is influenced by both monsoon and westerlies,
100 experiencing higher precipitation in spring and winter compared to other NX sub-basins (Figure
101 S1 in Supporting Information). The Lhasa (LS) and Rikaze (RKZ) sub-basins, vital crop centers

102 for the central Tibet Autonomous Region, play a crucial role in irrigation water resources. The
103 LS sub-basin, with about 23% snow cover contrasts with the RKZ sub-basin, which has little
104 glacier and snow coverage (Table 2). This difference suggests that the water supply in the RKZ
105 sub-basin is more sensitive to climate change. Moreover, runoff in the region between Yangcun
106 and NX hydrological stations (YC-NX, Figure 1) contributes 51% to the total runoff at the NX
107 hydrological station (Sun and Su, 2020), making runoff regimes and changes in this sub-basin
108 influential for the entire NX basin. Therefore, a comprehensive investigation into runoff
109 regimes and changes in different sub-basins is essential for a nuanced understanding of the
110 mechanisms underlying runoff changes in response to climate change.

111

112 While many hydrological studies focus on the region upstream of the NX hydrological station
113 (Zhang et al., 2013; Lutz et al., 2014; Zhao et al., 2019; Sun and Su, 2020; Khanal et al., 2021;
114 Nan et al., 2021; Wang et al., 2021), considerable differences in runoff regimes and change
115 studies exist in the NX basin (Table 1). These differences may arise from variations in forcing
116 inputs for hydrological model simulations. Accurate precipitation inputs play an important role
117 in reliable hydrological model simulations. However, high mountain precipitation in the YZ
118 basin is still inadequately represented in gauge-based, satellite-based, and reanalysis-based
119 estimates, or outputs of regional climate models (Wang and Zeng, 2012; Liu et al., 2020; Sun
120 et al., 2021). The mean annual precipitation ranges from 360–1236 mm in the YZ basin (Qi et
121 al. 2018; Sun; Su 2020; Tong et al. 2014), resulting in significant uncertainties in hydrological

122 simulations. This inconsistency in gridded datasets is often underestimated in hydro-climate
123 studies, especially in glacierized basins with limited data coverage. Even when realistic runoff
124 simulations are achieved at the catchment outlet, they cannot guarantee reasonable results (Zhao
125 et al., 2019) due to the compensation between precipitation-induced runoff and snow/glacier
126 melting. For example, Lutz et al. (2014) simulated glacier runoff in the NX basin with the
127 Spatial Processes in HYdrology (SPHY) model driven by the Asian Precipitation-Highly-
128 Resolved Observational Data Integration Towards Evaluation (APHRODITE) precipitation
129 estimates, suggesting that glacier runoff contributed about 16% to total runoff. In contrast,
130 Khanal et al. (2021) proposed that glacier runoff contributed about 1.8% to total runoff with the
131 same model driven by the newly released fifth-generation reanalysis (ERA5) precipitation of
132 the European Centre for Medium-Range Weather Forecasts (Table 1), primarily due to the
133 overestimation of the ERA5 precipitation estimate. Sun and Su (2020) indicated that the
134 contribution of glacier runoff would increase by 7–10% with a unit decrease in mean annual
135 precipitation. Therefore, an accurate precipitation estimate is crucial as a model input to
136 simulate runoff regimes, and further quantify the effect of glaciers and snowmelt on runoff in
137 the NX basin.

138

139 These uncertainties in the hydrological simulation will be introduced and enlarged on the
140 uncertainty in future projections (Lutz et al. 2016). Existing studies of hydrological responses
141 to future climate changes have been a debate in the NX sub-basin of the YZ basin. For example,

142 Lutz et al. (2014) forced the Spatial Processes in Hydrology (SPHY) model using outputs from
143 4 global climate models (GCMs) and showed that runoff would be increased by 3–13% relative
144 to the reference period 1998–2007 until at least 2050s due to the increasing precipitation in the
145 YZ basin. Zhao et al. (2019) projected the future runoff changes with 5 GCM outputs using an
146 extended Variable Infiltration Capacity (VIC) macroscale hydrological model (VIC-CAS),
147 suggesting that the total runoff will increase by 16–31% by the end of this century relative to
148 the reference period 1970–2010 because of increased rainfall-induced runoff in the YZ basin.
149 Cui et al. (2023) also suggested that total runoff in the YZ basin will increase of $7.3\pm 11\%$ by
150 2070s relative to the 1985–2014 resulted from rainfall runoff. Meanwhile, Su et al. (2016)
151 projected a runoff increase of 6.7–14.4% in the 2041–2070 relative to the reference period
152 1971–2000 in the YZ forced by the VIC-Glacier model with ensemble outputs of 20 GCMs,
153 and attributed the runoff increases to the rising glacier melt runoff. In addition, future flow
154 evolution and the effect of different runoff compositions on total runoff in the NX-BXK are
155 also unclear.

156

157 To address these issues, this study divided the YZ into six sub-basins and collected streamflow
158 observations at three hydrological stations (Yigong, Bomi, and Motuo) and glacier mass
159 balance observations (Parlung No.94) in the NX-BXK sub-basin, filling in the gap of scarce
160 data coverage. Additionally, streamflow observations at five national hydrological stations and
161 glacier mass balance observations at a site (Gurenhekou) in the five sub-basins of the NX

162 (Figure 1), together with hydrological stations in the NX-BXK, constitute a unique observation
163 basis. This basis allows us to validate the glacier-hydrology model and reveal runoff regimes,
164 and changes at the sub-basin scale. Precipitation observations at 280 gauges, were collected,
165 and a high spatiotemporal resolution (10 km; daily) precipitation dataset was generated using a
166 machine learning algorithm based on these gauges (Sun et al., 2022).

167

168 Leveraging this basin-wide observation dataset, this study comprehensively investigates runoff
169 compositions, changes, and attributions across six sub-basins in the YZ for 1971–2020, with a
170 particular focus on the comparison between the NX and NX-BXK. This investigation employs
171 the process-based and well-established Variable Infiltration Capacity (VIC)-Glacier
172 hydrological model. Furthermore, the study assesses the future evolution of annual and seasonal
173 total water availability, glacier runoff, and snowmelt, using an ensemble of multiple global
174 climate models (GCMs) from the latest release of the Coupled Model Intercomparison Project
175 Phase 6 (CMIP6). The objectives are to: (1) use the model framework to identify spatiotemporal
176 characteristics in runoff compositions and changes at the sub-basin scale under heterogeneous
177 climate and glacier/snow conditions. (2) quantify the contributions of three major runoff
178 compositions (glacier, rainfall, and snowmelt runoff) to total runoff among different sub-basins,
179 and investigate their responses to climate changes. (3) assess future water availability under
180 21st-century climate-cryosphere change, assisting policy-makers and water managers in
181 adopting strategies. These findings are anticipated to provide a basic framework for studying

182 cryospheric basin hydrological cycles in the TP and provide adaptation strategies for rational
183 water resource management, and social, and economic development grounded in a robust
184 scientific understanding.

185

186 **2 Study Area**

187 In this study, the YZ basin is divided into six sub-basins based on flow direction and locations
188 of hydrological stations (Figure 1; Table 2). There are five sub-basins located upstream of the
189 Nuxia (NX) hydrological station, collectively termed the NX basin, with an additional sub-
190 basin lying between Nuxia and Pasighat (NX-BXK) hydrological stations. The NX basin
191 comprises the upstream sub-basins of Lhatse (LZ), Shigatse (RKZ), and Lhasa (LS)
192 hydrological stations, along with the sub-basins between Lhatse and Yangcun (LZ-YC)
193 hydrological station and between Yangcun and Nuxia (YC-NX) hydrological station.

194

195 The climate in the YZ is characterized by a wet and warm summer and a cool, dry winter, with
196 precipitation mostly dominated by the summer monsoon, contributing 70–90% of annual totals
197 during June–September (Figure S1). Furthermore, mean annual precipitation increases
198 downstream in the YZ basin, ranging from 283 mm upstream to 1465 mm downstream,
199 averaging about 774 mm for the entire YZ basin (Table 2). All sub-basins exhibit similar
200 seasonal temperature patterns, with peaks mainly occurring in July–August (Figure S1). Glacier
201 coverage varies from 0.9% (LZ-YC) to 10.2% (NX-BXK), averaging 3.3% for the entire YZ

202 basin. The YC-NX (2.8%) and NX-BXK (10.2%) sub-basins host the most extensive glacier
203 coverage (Table 1). The mean annual snow cover fraction (SCF) ranges from 7% (RKZ) to 32%
204 (NX-BXK), with an average of 19% across the YZ basin.

205

206 **3 Data and Method**

207 **3.1 Data**

208 Daily precipitation, maximum and minimum temperature, and wind speed estimates with a
209 spatial resolution of 10×10 km were used as the VIC-Glacier model forcing inputs in this work.
210 Historical meteorological data during 1971–2100 was adopted from Sun et al. (2022). The daily
211 precipitation data with a spatial resolution of 10×10 km for 1961–2020 was reconstructed by
212 correcting gridded estimates from the ERA5 precipitation of the European Centre for Medium-
213 Range Weather Forecasts (ECMWF) based on 580 rain gauges in the monsoon-dominated TP
214 region (290 rain gauges in the YZ basin, Figure 1) and the Random Forest-based (RF) machine
215 learning algorithm (Sun et al., 2022). Inputs of the RF algorithm selected in this study include:
216 1) geographical features (e.g., longitude, latitude, elevation, slope gradient and aspect), which
217 influence precipitation distribution, and 2) climatic features derived from the ERA5 (e.g.,
218 convective available potential energy, lifting condensation level, and total column water vapor),
219 which represent the potential for the generation and development of precipitation. The corrected
220 precipitation data set was evaluated at a point scale by comparing it with gauge observations,
221 and has been inversely evaluated by the hydrological model, which demonstrates its suitability

222 for hydrological simulation (Sun et al., 2022). It was downloaded from the National Tibetan
223 Plateau/Third Pole Environment Data Center (TPDC,
224 <https://doi.org/10.11888/Atmos.tpdc.272885>).

225

226 Using the newly generated daily meteorological data for 1961–2020, Sun et al. (2024) applied
227 the Bias Corrected Spatial Disaggregation (BCSD) statistical downscaling approach (Wood
228 2002; Wood et al. 2004) to downscale and bias-correct daily transient meteorological data,
229 including precipitation, maximum and minimum temperature, and wind speed, with a spatial
230 resolution of 10×10 km through the 21st century from 10 GCMs from the CMIP6 under the
231 Shared Socioeconomic Pathways (SSPs)2-4.5 and SSP5-8.5 scenario. Daily transient climate
232 estimates, at a spatial resolution of 10×10 km for 1971–2100 under 20 scenarios (10 GCMs ×
233 2 SSPs) from Sun et al. (2024) were directly employed to drive the VIC-Glacier model to
234 continuous runoff production in the YZ basin.

235

236 Observed streamflow, observed glacier mass balance, satellite-based glacier area and snow
237 cover fraction estimates were applied to calibrate and validate the model in this study. Monthly
238 streamflow since 1971 were collected at eight hydrological stations (Lhatse, Shigatse, Lhasa,
239 Yangcun, Nuxia, Yigong, Bomi, and Motuo from the Ministry of Water Resources, China
240 (Figure 1, Table S1).

241

242 Two shapefiles of glacier inventory, the first Glacier Inventory of China (CGI) from the
243 “Environment & Ecological Science Data Center for west China”
244 (<http://westdc.westgis.ac.cn/glacier>) and Randolph Glacier Inventory (RGI) 6.0
245 (https://www.glims.org/RGI/rgi60_dl.html), were used to describe the glacier information of
246 the YZ in the VIC-Glacier model. Observed annual glacier mass balance data from Gurenhekou
247 and Parlung No.94 glacier sites since 2005 were used to validate the performance of glacier
248 model (<http://www.tpdc.ac.cn>, Figure 1, Table S1). The Moderate Resolution Imaging
249 Spectroradiometer (MODIS) 10CM reporting the maximum percentage of snow cover during
250 an 8-day period in 0.05° resolution grid ([https://nsidc.org/ data](https://nsidc.org/data)) during 2006–2018 was used to
251 calculate the snow cover fraction (SCF) and to compare with VIC-Glacier model simulations
252 in the YZ basin.

253

254 The model required land surface characteristics, including soil texture and vegetation types,
255 were adopted from Sun and Su (2020). These data were used as initial model inputs, and
256 remained unchanged in simulation period.

257

258 **3.2 VIC-Glacier Hydrological Model**

259 The present study employed the physically-based and distributed VIC hydrological model
260 (Liang et al., 1994; Liang et al., 1996) linked with a simple degree-day glacier melt algorithm
261 (Hock, 2003), referred to as VIC-Glacier. This modeling framework facilitates the

262 comprehensive simulation of the physical exchange of water and energy within a grid mesh
263 encompassing soil, vegetation, and the atmosphere. The VIC-Glacier effectively models surface
264 water balance compositions, including evapotranspiration, surface runoff, baseflow (subsurface
265 drainage into the local stream channel network, as opposed to groundwater recharge), and total
266 soil moisture, including liquid and ice content in each soil layer. The model integrates a two-
267 layer energy-balance snow model (Cherkauer and Lettenmaier, 1999) and a frozen
268 soil/permafrost algorithm (Cherkauer and Lettenmaier, 1999; 2003). These components account
269 for ground snowpack, snow within the vegetation canopy, snow atop lake ice, and sublimation
270 of snow. In each time step, the model calculates the rain or snow fraction contributing to the
271 snowpack. Subsequently, all energy fluxes are computed, triggering melt if the energy balance
272 is positive. The VIC-Glacier model has demonstrated its effectiveness in hydrological
273 simulations for various high-mountainous TP basins (Meng et al., 2019; Su et al., 2016; Sun
274 and Su, 2020; Tong et al., 2016; Zhang et al., 2013; Zhao et al., 2019).

275

276 Here, the modeling framework at a 10 km ×10 km spatial resolution and a three-hourly time
277 step was adopted from Sun and Su (2020). To categorize the total runoff sources in this study,
278 we partitioned it into three components: rainfall runoff, snowmelt runoff, and glacier runoff.
279 Glacier runoff was defined as all water generated in the glacierized area, including rainfall,
280 snow melt, and ice melt in the glacierized area.

281

282 $Total\ runoff\ (TR) = Rainfall\ runoff\ (RR) + Snowmelt\ runoff\ (SR) +$
 283 $Glacier\ runoff\ (GR)$ (1)

284 $Rainfall\ runoff\ contribution = \frac{RR}{TR} \times 100\%$ (2)

285 $Snowmelt\ runoff\ contribution = \frac{SR}{TR} \times 100\%$ (3)

286

287 Recognizing the influence of glacier melt at different elevations, each glacierized grid cell
 288 underwent division into various elevation bands with an interval of 100 m (Kan et al., 2018).
 289 The simulated total runoff of each grid is from both the glacierized and non-glacierized areas,
 290 that is,

291 $R_i = f \times R_{glac} + (1 - f) \times R_{vic}$ (4)

292 Where, R_i is the total runoff (mm) in grid I , f is the percentage of glacier area, and glacier area
 293 is updated every year, R_{glac} is the runoff (mm) from the glacier area calculated by the glacier
 294 model, and R_{vic} is the sum of surface runoff and baseflow runoff (mm) for non-glacierized areas
 295 calculated by the VIC model, including both rainfall and seasonal snowmelt runoff. R_{glac} can
 296 be calculated as:

297 $M_i = \begin{cases} DDF \times (T - T_{base}); & T > T_{base} \\ 0; & T \leq T_{base} \end{cases}$ (5)

298 $R_{glac} = M_1 + M_2 + \dots + M_i; i = 1, 2, 3, \dots, n$ (6)

299 where, M_i is the meltwater (mm) from elevation band j and n is the total number of elevation
 300 bands in grid i ; DDF is the degree-day factors of glacier or snow melt ($\text{mm } ^\circ\text{C}^{-1} \text{ day}^{-1}$); T ($^\circ\text{C}$)
 301 is the daily average air temperature above the glacier surface; T_{base} ($^\circ\text{C}$) is the temperature
 302 threshold for glacier and snow melt ($0\ ^\circ\text{C}$). In a precipitation event, rainfall occurs when the air

303 temperature is above 0°C; otherwise, it snows. In the presence of a snowpack on the glacier,
304 the snow melts first before glacier melting starts, following the same degree-day approach but
305 different degree-day factors.

306

307 The calculated glacier area and volume were updated every year in the model by the volume-
308 area scaling approach (Bahr et al., 1997). An exponential form (equation 7), derived from
309 glacier observations in western China (Liu et al., 2003), converts glacier area to volume for a
310 basin:

$$311 \quad V = 0.04S^{1.35} \quad (7)$$

312 Where, V is glacier volume (km³) and S is glacier area (km²). Initial glacier volume was
313 determined using glacier area data from the first Glacier Inventory of China (CGI V1.0,
314 <http://westdc.westgis.ac.cn/glacier>) dataset, which presented glacier area for period
315 1970s–1990s. The Randolph Glacier Inventory (RGI V6.0) dataset presented glacier area for
316 period 2000s–2010s. Therefore, glacier area was simulated by glacier model since 1971, and
317 then it was updated every year with the snowfall accumulation and simulated ice melt from all
318 the glacier cells in the glacier model based on volume-area scaling approach. The simulated
319 mean annual glacier area during 2000–2010 was compared with the Randolph Glacier
320 Inventory (RGI V6.0) dataset in the YZ basin and its six sub-basins.

321

322 **3.3 Model Calibration and Validation**

323 The VIC-Glacier model requires the calibration of two sets of parameters: (1) the degree day
324 factor (DDF), related to glacier runoff simulation; and (2) VIC model parameters related to

325 runoff simulation in non-glacierized regions. The latter includes parameters (Table 3) such as
326 the depth of the first and second soil layers (D1 and D2), the infiltration shape parameter (B_{inf}),
327 and three base flow parameters, including the maximum velocity of baseflow (D_{smax}), a
328 fraction of D_{smax} where non-linear baseflow begins (D_s), and a fraction of maximum soil
329 moisture where non-linear baseflow occurs (W_s).

330

331 To adjust the internal stores of energy and water from the initial state to equilibrium, the VIC-
332 Glacier model underwent a spin-up from 1961–1970, with subsequent simulation for the years
333 1971–2020. In addition, 1971–2000 was selected as the calibration period and 2001–2015 the
334 validation period based on the observed monthly streamflow for 1971–2015. Calibration and
335 validation of the VIC-Glacier hydrological model followed a systematic two-step approach,
336 employing observed streamflow, glacier mass balance, and satellite-based estimates of glacier
337 area and snow cover fraction (Table S1). Model performance was assessed using metrics such
338 as Nash-Sutcliffe efficiency (NSE), relative bias (RB, %), and correlation coefficient (CC). The
339 optimization process utilized a trial-and-error method to minimize bias against predefined
340 criteria. Linear regression was employed to calculate annual and seasonal trends of precipitation,
341 temperature, and runoff.

342

343 The model calibration and validation were conducted using a two-step approach to overcome
344 equifinality problems. First, initial values of DDF parameters in the glacier model related to

345 glacier and snowmelt were adopted from Sun and Su (2020). The glacier model was calibrated
346 to match the glacier area observations from RGI V6 for 2000s–2010s in the YZ and six sub-
347 basins, and validated by observed mass balance data from the Gurenhekou site in the NX basin
348 and the Parlung No.94 glacier site in the NX-BXK sub-basin (Figure S2). Given the good
349 performance in simulating glacier area (with RB of mostly < 7%, Figure 2c) and good
350 consistency (CCs of 0.65–0.96) in annual variations between observed glacier mass balance
351 and simulation, final DDF values ($6.5\text{--}11.0 \text{ mm}^\circ\text{C}^{-1} \text{ day}^{-1}$) were determined across six sub-
352 basins (Table 3).

353

354 Second, the VIC-related parameters were validated against observed streamflow and satellite-
355 based snow cover fraction (SCF) data. The infiltration parameter (B_{inf}) and the second soil
356 layer depth (D2) have been identified as the most sensitive parameters (Zhang et al., 2013). The
357 B_{inf} which defines the shape of the variable infiltration capacity curve has a common range
358 of 0–0.4, while the D2 mainly determines the moisture storage capacity of the VIC model, with
359 a range of 0.5–1.0 (Liang et al., 1996; Shi et al., 2008). The simulated monthly streamflow
360 captured well the magnitudes and patterns of observation at eight hydrological stations, with
361 NSEs of 0.71 to 0.86 and RBs of within $\pm 8\%$ for the calibration and validation period across
362 the sub-basins (Table 3, Figure S3). To further validate the model, monthly satellite-based SCF
363 data for the years 2001–2019 in the YZ basin were compared with the model simulations
364 (Figure S4). The simulated SCF closely mirrors the monthly variations observed in the satellite-

365 based data, exhibiting a CC of 0.60–0.82 ($p < 0.05$) and RB within $\pm 12\%$ across sub-basins.
366 This alignment suggests the VIC-Glacier model's satisfactory performance in simulating snow
367 cover dynamics in the YZ basin.

368

369 **4 Result**

370 **4.1 Hydrological Response to Historical Climate Changes**

371 **4.1.1 Runoff Composition**

372 The credibility of our model allows for a reasonable interpretation of the current runoff
373 composition and change, and their responses to climate change. Examining simulated
374 streamflow across sub-basins reveals significant differences in each sub-basin contribution to
375 the total runoff at the Pasighat outlet of the YZ basin (Figure 1b). The NX-BXK emerges as the
376 most critical runoff-generating area, contributing approximately 52% to the total runoff in the
377 YZ basin, followed by YC-NX (25%), LS (10%), and other sub-basins with contributions
378 ranging from 3% to 6%.

379

380 According to the source of runoff generation, total runoff is partitioned into three compositions
381 in this study: rainfall runoff, snowmelt runoff, and glacier runoff. In this study, glacier runoff is
382 defined as all water generated in the glacierized area, including rainfall, snow melt, and ice melt
383 in the glacierized area. Rainfall and snowmelt runoff are originating from the non-glacierized
384 area. Different runoff regimes of rainfall runoff, snowmelt, and glacier runoff influence their
385 contributions to total runoff across the six sub-basins of the YZ with heterogeneous surface

386 characteristics (Figure 2). Rainfall runoff dominates the mean annual total runoff in the YZ and
387 all its sub-basins from 1971 to 2020, contributing 59%–78% to annual total runoff, with an
388 average of 62% in the entire YZ basin. Snowmelt contributes 22% to annual total runoff in the
389 YZ basin, varying from 14% to 36% across six sub-basins, with the LS sub-basin having the
390 largest contribution at 36%. Glacier runoff contributes 16% to the annual total runoff in the YZ
391 basin, ranging from 5% to 19% across six sub-basins for 1971–2020. The highest contributions
392 are in the NX-BXK (19%) and YC-NX (16%) sub-basins, which have the largest glacier
393 coverage in the YZ basin (Table 2).

394

395 Figure 3 shows the spatial pattern of average annual rainfall runoff, snowmelt, and glacier
396 runoff for 1971–2020, along with their percentages at different elevation bands in the YZ basin.
397 The spatial pattern of average annual rainfall runoff (Figure 3a) is similar to that of total runoff
398 (Figure 1b) and precipitation (Figure 3b), decreasing from east to west, with the NX-BXK sub-
399 basin exhibiting the largest runoff. Similarly, the largest snowmelt and glacier runoff occur in
400 the NX-BXK sub-basin, consistent with the spatial distribution of glacier and snow cover area,
401 constituting about 65% of total glacier area and 34% of total snow coverage in the YZ (Figure
402 3c–f). Approximately 84% of the YZ basin runoff originates from middle altitudes (3500–5500
403 m), with 62% from 4500–5500 m and 22% from above 3500–4500 m, primarily contributed by
404 rainfall and seasonal snow (80%–83%, Figure 3g). About 8% of the basin runoff is generated
405 from high altitudes (>5500 m), where 29% of the flow is from glacier runoff, and the remainder

406 is from rainfall (50%) and snowmelt (21%). In low altitudes (<3500 m), 8% of the basin runoff
407 is primarily from rainfall (82%) and snowmelt (11%), with only 7% attributed to glacier runoff.

408

409 The seasonal pattern of total runoff remains consistent across the six sub-basins within the YZ
410 for 1971–2020, with more than 60% of the annual total runoff occurring in June–September
411 and 10%–15% in November–February (Figure 2a–h). This seasonal pattern aligns with the
412 rainfall runoff, which peaks in July–August, reflecting the peak in total runoff in the YZ and its
413 sub-basins (Figure 2 a–h). Snowmelt predominantly takes place from April–October, with peak
414 months varying across sub-basins. In LZ, RKZ, LS, and LZ-YC sub-basins, the peak is in July–
415 September (Figure 2a–d), attributed to the melting of fresh snowfall in the warm season.
416 Conversely, in the YC-NX (Figure 2e) and NX-BXK (Figure 2f) sub-basins, the peak is in May–
417 June, possibly due to snowfall accumulation during October–March. Simulated glacier runoff
418 occurs mainly from June to September for all basins, peaking in July–August, coinciding with
419 the co-occurrences of peak precipitation and temperature.

420

421 **4.1.2 Runoff Changes and the Response to Climate Changes**

422 **(a) Annual Scales**

423 Figure 4 illustrates annual trends in precipitation, temperature, total runoff, and three runoff
424 compositions (rainfall, glacier, and snowmelt runoff) across the six sub-basins for 1971–2020,
425 respectively. Annual variations for precipitation, temperature, and simulated runoff in each sub-

426 basin are presented in Figure S5–S10. All sub-basins exhibit significant warming trends (0.3–
427 0.5 °C/10yr, $p < 0.05$), with precipitation tending to increase (6–15 mm/10yr) in the LZ, LZ-YC,
428 LS, RKZ, and YC-NX sub-basins (Figure 4a–e) upstream of the NX hydrological station (NX
429 basin). Conversely, the NX-BXK sub-basin experiences a significant decrease in precipitation
430 (-35 mm/10yr, $p < 0.05$, Figure 4f).

431

432 Simulated annual total runoff demonstrates increasing trends of 8.1–18.8 mm/10yr for 1971–
433 2020 across all sub-basins within the NX basin, except for the RKZ sub-basin with an
434 insignificant change (-1.1 mm/10yr), resulting in a significantly increasing trend of 9.4
435 mm/10yr ($p < 0.05$) over the entire NX basin (Table 4). Strong correlations between annual
436 variation of total runoff, precipitation, and rainfall runoff exist in these sub-basins (CC of 0.90–
437 0.99, $p < 0.05$), while total runoff shows weak relationships with temperature and glacier runoff.
438 This suggests the predominant role of rainfall runoff from nonglacierized areas, with minor
439 impacts from glacier runoff on annual runoff, along with significant increases in precipitation
440 and temperature (Figure 4a). In contrast, the NX-BXK sub-basin exhibits a significantly
441 decreasing trend of 9.4 mm/10yr ($p < 0.05$) for 1971–2020 (Figure 4f), resulting from significant
442 decreases in rainfall runoff (-22 mm/10yr) and seasonal snowmelt (-5.5 mm/10yr) from non-
443 glacierized areas. Glacier runoff, however, exhibits a significantly increasing trend (6.0
444 mm/10yr, $p < 0.05$, Table 3) in NX-BXK during the same period, partially compensating for the
445 decreasing trend of total runoff in this sub-basin. The integrated result is a weakly increasing

446 trend of 3.1 mm/10yr in total runoff for the entire YZ basin (Table 4), primarily attributed to
447 increases in rainfall (3.0 mm/10yr) and glacier runoff (2.1 mm/10yr). Snowmelt tends to
448 decrease (-1 to -6 mm/10yr) in the YZ and its sub-basins during 1971–2020, associated with a
449 reduction in solid precipitation and an increase in liquid precipitation (Figure S12), along with
450 significant temperature increases.

451

452 Cuo et al. (2019) investigated precipitation and streamflow mutations in the YZ basin using
453 Mann-Kendall analysis, identifying a streamflow mutation in 1997 at the NX hydrological
454 station. This abrupt change is consistent with our long-term runoff observations. This abrupt
455 change is consistent with our long-term runoff observations. Total runoff trends are opposite
456 before and after the year 1998 in the YZ, and its NX and NX-BXK sub-basins (Table 4). During
457 1971–1997, annual total runoff shows increasing trends (8.9–48.1 mm/10yr) in the basins
458 during 1971–1997, mainly due to an increasing trend in rainfall and glacier runoff (Table 4).
459 However, during 1998–2020, total runoff showed insignificant decreasing trends (-0.3 to -3.3
460 mm/10yr), attributed to a decreasing trend in rain runoff induced by the weakening Indian
461 monsoon from 1998–2000 (Table 4). It is noteworthy that the rate of decrease in precipitation
462 is faster in NX-BXK (-16.0 mm/10yr) than in NX (-7.0 mm/10yr, Table 4). However, the decline
463 in total runoff is less pronounced in NX-BXK (-0.3 mm/10yr) compared to NX (-3.3 mm/10yr,
464 Table 3) during 1998–2000. This discrepancy arises from different influences of glacier runoff
465 on total runoff between NX and NX-BXK sub-basins. A more rapid increase in glacier runoff

466 in NX-BXK (16 mm/10yr) than in NX (0.7 mm/10yr, Table 4) partly compensates for the
467 quicker decline in rainfall-runoff, resulting in a slower overall decrease in total runoff in NX-
468 BXK.

469

470 Figure 5 illustrates the mean monthly vertical integral of atmospheric moisture budget in June,
471 July, August, and September from ERA5 data across the YZ basin for 1971–2020. It
472 demonstrates an increasing trend in the NX basin but a decreasing trend in the NX-BXK. This
473 pattern corresponds with precipitation trends in the NX and NX-BXK sub-basins, influencing
474 rainfall runoff in these areas. Additionally, teleconnection indices can modulate circulation
475 patterns over a region, thereby affecting precipitation and its induced runoff. Among the 10
476 teleconnection indices (Text S1), Pacific Decadal Oscillation (PDO) and El Niño/Southern
477 Oscillation (ENSO) exhibit significantly negative consistency with precipitation, while Atlantic
478 Multidecadal Oscillation (AMO) shows significantly positive consistency ($CC=0.43$, $p<0.05$)
479 with precipitation for 1971–2020 in the NX basin (Figure S13a, d). The change in runoff
480 induced by precipitation is mostly influenced by EASM with significantly positive consistency
481 ($CC=0.38$, $p<0.05$) for 1971–2020 in the NX-BXK sub-basin (Figure S13a, e). The streamflow
482 mutation in 1997, associated with the precipitation mutation, is also influenced by NAO and
483 ENSO in the NX and EASM in the NX-BXK.

484

485 **(b) Seasonal Scales**

486 Because of the similarity in annual runoff regimes and changes across five sub-basins within
487 the NX basin, here, we particularly focus on comparing the NX and NX-BXK sub-basins at
488 seasonal scales for 1971–2020. The high-altitude NX basin exhibits faster warming trends (0.2–
489 0.5 °C/10yr) in each season compared to the low-altitude NX-BXK basin (0.16–0.23 °C/10yr,
490 Figure 6d) for 1971–2020. Seasonal precipitation trends increase (2–9 mm/10yr) for 1971–2020
491 in the NX basin (Figure 6a), particularly in summer, influenced mainly by the AMO and PDO
492 (Figure S14). Conversely, in the NX-BXK, precipitation decreased (-18 to -2 mm/10yr) for
493 1971–2020, influenced by the EASM in summer and the AMO in autumn. Consequently, total
494 runoff during 1971–2020 reflects similar trends to precipitation, affected by increased rainfall
495 (1–6 mm/10yr) and glacier runoff (1 mm/10yr) in the NX (Figure 6a), and decreased rainfall (-
496 10 to -3 mm/10yr) and snowmelt (-2 mm/10yr), along with increased glacier runoff (1–5
497 mm/10yr) in the NX-BXK (Figure 6b). Due to these different trends in the two sub-basins, total
498 runoff shows an increasing trend in summer (5 mm/10yr) but decreasing trends (-1 mm/10yr)
499 in other seasons for 1971–2020 in the YZ basin (Figure 6c), attributed to the dominance of
500 rainfall runoff.

501

502 Relative to the period 1971–1997, divergent seasonal changes in total runoff are apparent in the
503 YZ basin during 1998–2020 (Figure 7). In the NX basin, total runoff tends to increase by about
504 5%–22% in all seasons, with the largest increases during May–August (11%–22%), mainly due

505 to increases in rain-induced and glacier runoff. The smallest increases occur during December–
506 February (5%–6%), mostly due to increased rainfall runoff (3%–5%) in the NX (Figure 7a, d;
507 Table S2). Snowmelt significantly increases during March–May (24%–50%) due to early snow
508 melting (Figure 7d; Table S2), potentially benefiting agricultural water supplies. Conversely,
509 total runoff in the NX-BXK sub-basin decreases by about 3%–20% in all seasons (Figure 7b;
510 Table S2) due to declines in rainfall runoff (3%–23%) and seasonal snowmelt (4%–28%). This
511 indicates a trend toward drier conditions, although increased glacier runoff (2%–12%)
512 somewhat compensates for the loss of total runoff in July–August (Figure 7e). The integrated
513 result of seasonal runoff changes in NX and NX-BXK shows total runoff in the YZ increases
514 by 2%–4% in June–September, mostly due to increases in rain-induced (3%–7%) and glacier
515 runoff (2%–6%), while it decreases in other months due to decreased rain-induced runoff (2%–
516 8%) and seasonal snowmelt (3%–10%, Figure 7c, f, Table S2).

517

518 The distinct seasonal changes in rainfall, snowmelt, and glacier runoff largely play a crucial
519 role in determining the seasonal shifts in their contributions to total runoff across the entire YZ
520 basin and its NX and NX-BXK sub-basins. Compared to the period 1971–1997, the contribution
521 of rainfall increases by 5%–8% from May to October in the NX for 1998–2020, whereas glacier
522 and snowmelt contributions decline by -0.3% to -2% and -5% to -7%, respectively (Figure 7g,
523 Table S2). Conversely, in the NX-BXK, contributions from rainfall runoff and snowmelt
524 decrease by -2% to -6% during May–October, while glacier contribution increases by 2%–7%

525 in these months (Figure 7h, Table S2), underscoring the growing significance of this season in
526 sustaining summer water supplies in the NX-BXK. Taken together, for the entire YZ basin
527 (Figure 7i), glacier contribution increases by 0.5%–2% (Table S2) during June–October, and
528 the seasonal changes in rainfall and snowmelt contributions to total runoff closely mirror those
529 observed in the NX basin.

530

531 **4.2 Hydrological Response to Future Climate Changes**

532 Historical differences in total runoff changes in the NX and NX-BXK sub-basins are projected
533 to weaken in the future. The YZ basin is projected to experience increased precipitation (7–33
534 mm/10yr) and higher temperatures (0.3–0.8 °C/10yr) under the SSP2-4.5 and SSP5-8.5
535 scenarios throughout the 21st century (Table 5). Predictions indicate an increase in total runoff
536 for the NX (7–27 mm/10yr) and BXK (34–100 mm/10yr) for 2021–2100 under both SSPs,
537 with significant increases (36–142 mm/10yr) anticipated in the latter half of the century (2071–
538 2100) under SSP5-8.5 (Table 5). The changes in total runoff are projected to be primarily
539 influenced by increased rainfall runoff, with minor contributions from increased snowmelt and
540 glacier runoff under both SSPs scenario through the 21st century (Table 5). However, in
541 comparison to the 1971–2000 mean, a reduction of approximately -6% to -14% is projected in
542 the first half of the 21st century (2021–2050) in the YZ and its NX and NX-BXK sub-basins
543 under the SSP2-4.5 and SSP5-8.5 scenario (Figure 8). This reduction is attributed to decreased
544 rainfall (-9% to -19%) and snowmelt (-5% to -6%), which may result in the decline of

545 freshwater supply. Conversely, there is a broadly consistent increase (6%–32%) in total runoff
546 in the second half of the 21st century (2071–2100), mainly driven by increased rainfall (4%–
547 52%) and glacier runoff (9%–78%), suggesting that the YZ basin will not face a water supply
548 crisis in the end of 21st century.

549

550 Changes in meltwater from glaciers and seasonal snow significantly impact total runoff,
551 influencing both quantity and timing and are particularly important for water availability during
552 warm and dry seasons (Barnett et al., 2005). Relative to the 1971–2000 mean, the future annual
553 hydrograph appears relatively stable across all sub-basins (Figure 9), with 60%–80% of mean
554 annual runoff occurring from June to September. However, a decline of about -18% to -3% is
555 projected in each month during 2021–2050 under the two SSPs due to decreased monthly
556 precipitation and precipitation-induced rainfall and snowmelt runoff (Table S3 and S4). In
557 contrast, there is an anticipated increase of about 6%–40% in each month, particularly in
558 summer (25%–40%), during 2071–2100 under the two SSPs. The increased total runoff in the
559 NX basin is primarily attributed to increased rainfall runoff and spring snowmelt, indicating an
560 earlier spring snow melt and delayed fall freeze-up (Figure 9a, b). Similarly, the increased total
561 runoff in the NX-BXK basin is mostly a result of increased rainfall and glacier runoff, coupled
562 with decreased snowmelt (Figure 9c, d), primarily due to reduced snowfall with ongoing
563 warming in each month (Figure S4 and S5). Future changes in seasonal runoff across the entire
564 YZ basin closely align with those in the NX-BXK sub-basin (Figure 9e, f) due to its significant

565 contribution to the overall runoff of the YZ basin.

566

567 **5 Discussion**

568 Forcing inputs, parameters, and representation of physical processes are major sources of
569 uncertainty in hydrological model simulations.

570

571 Precipitation is the most important atmospheric input for land surface hydrology models, but
572 none of the multiple precipitation datasets proves equally suitable for all basins in the TP due
573 to the high spatiotemporal variability in their performance at the sub-basin scale (Dahri et al.
574 2021). The variation in precipitation datasets for high mountains can lead to significant
575 differences in meltwater contribution (Lutz et al., 2014; Zhao et al., 2019; Sun and Su, 2020;
576 Khanal et al., 2021; Nan et al., 2021; Wang et al., 2021). Duethmann et al. (2014) applied a
577 multi-objective genetic algorithm to characterize the trade-off curve between model
578 performance in terms of discharge and snow cover area in Central Asia, suggesting that good
579 discharge simulations at the catchment outlet cannot guarantee good internal functioning of the
580 model, as different forcing inputs may result in error compensation among different runoff
581 compositions. Jost et al. (2012) simulated glacier runoff of 25 large glacierized basins
582 (>50,000 km²) in North and South America, Europe, Asia, and New Zealand, suggesting that
583 the runoff differences ranged from 0.07 % for weakly glacier-influenced basins to 252 % for
584 strongly glacier-influenced basins. They also suggested that hydrologic model calibration in

585 glacier-fed catchments was difficult, because errors in modelling snow accumulation can be
586 offset by compensating errors in glacier melt. Zhang et al. (2013) simulated glacier runoff by
587 the VIC-Glacier model with the APHRODITE precipitation estimates in the upper Indus (UI)
588 river basin of the TP during 1961–2009, and suggested that contribution of glacier runoff to total
589 runoff was about 48.2. However, Meng et al. (2023) simulated glacier runoff by the VIC-
590 Glacier model with the corrected MERRA-2 precipitation estimates in the UI basin, suggested
591 that glacier runoff contributed of 24% to total runoff. The difference between Zhang et al. (2013)
592 and Mengand (2023) mostly resulted from the higher amount of corrected MERRA-2 than
593 APHRODITE precipitation estimates in the UI basin, because the underestimation of
594 precipitation-induced runoff would be compensated by glacier runoff.

595

596 Like elsewhere on earth, the aforementioned issues are typical of the YZ basin. In the case of
597 the NX basin, glacier melt contributed approximately 2–18% to the total runoff in existing
598 research (Table 1), mostly resulting from differences in forcing inputs used in hydrological
599 models. The YZ basin received less attention regarding glacier runoff contributions in the NX-
600 BXK, with significant inconsistencies in glacier contributions evident in these studies (Table
601 1). Sun and Su (2020) suggested that mean annual glacier runoff contributed about 45% to total
602 runoff in the NX-BXK sub-basin for 1980–2000, using a hydrological model without
603 calibration and validation due to a lack of hydrometeorological observations in the sub-basin.
604 In this study, we utilized newly acquired rain gauge data, and streamflow, glacier mass balance,

605 and glacier and snow cover observations in the NX-BXK sub-basin, glacier runoff was
606 simulated using the well-validated VIC-Glacier model, forced by a comprehensively
607 reconstructed long-term precipitation dataset in this study. The updated contribution of glacier
608 runoff to total runoff during 1971–2020 in the NX-BXK sub-basin was determined to be 19%.
609 Furthermore, accurate historical precipitation estimates have the potential to reduce uncertainty
610 in future projections with the large spread in the GCMs, forming the basis for correcting future
611 GCM estimates. Different study period also results in the difference of hydrological model
612 simulation. For example, streamflow also mutates in 1997 at the RKZ sub-basin of the YZ
613 (Figure S15). Increased precipitation and evaporation caused an insignificant runoff change
614 during 1971–1997. However, due to significant decrease of precipitation and increase of
615 evaporation, runoff decreased during 1998–2000, resulting in the insignificant decrease for
616 1971–2000 (Figure S15).

617

618

619 Hydrological model themselves have their own uncertainties, such as model parameters and
620 structure of physical processes, which are ideally all taken into account. Reliable parameters
621 play a crucial role in accurate runoff simulation by hydrological models. The DDF emerges as
622 the most sensitive parameter for the degree-day glacier model (Hock 2003; Radić; Hock 2010).
623 Zhang et al. (2013) examined the sensitivity of glacier melt runoff to DDF parameters,
624 suggesting that average annual glacier runoff could change by about 10% with each one unit

625 change in DDF ($\text{mm } ^\circ\text{C}^{-1} \text{ day}^{-1}$). In this study, the DDF parameters are derived based on
626 observed glacier mass balance data, with intensive validations on glacier melt, including
627 observed glacier mass balance and satellite-based glacier area estimates. The uncertainty
628 associated with VIC model parameters is generally lower than the uncertainties from
629 precipitation inputs. Su et al. (2022) indicated that changes in the RB are within 8% when B_{inf}
630 ranges from 0.05 to 0.4, D2 ranges from 0.5 to 3.0 m, and the changes in NSE are generally
631 within 0.1. Therefore, high-density hydrometeorological observations are expected to better
632 constrain the model and further improve the description of hydrological responses to climate
633 and spatiotemporal changes in glacier/snow.

634

635 Uncertainties are introduced by different representation of physical processes in hydrological
636 model, especially the snow and glacier melt simulation in high-mountainous basins. Existing
637 studies used different definitions of runoff composition. For example, Lutz et al. (2014) and
638 Khanal et al. (2021) divided total runoff into four compositions: rainfall runoff, snow melt,
639 glacier melt and baseflow. Some studies also further divided the glacier melt into ice melt and
640 supraglacial snowmelt (Armstrong et al. 2018; Wang et al. 2021). In this study, we divided total
641 runoff into rainfall runoff, snow melt and glacier runoff. Baseflow is a relatively stable
642 streamflow composition, and it plays an important role in sustaining surface water flow,
643 especially for the winter half-year when surface water availability is limited. The VIC model
644 accounts for baseflow (<https://vic.readthedocs.io/en/master/>), which is comprised of three soil

645 layers to represent the rapid dynamics of soil moisture movement during storm events (surface
646 runoff) and the slower deep inter-storm response in the bottom layer (baseflow). Figure S16
647 shows mean annual contribution and annual variation contribution of rainfall runoff, snowmelt,
648 glacier runoff and baseflow to total runoff. The baseflow contribution was relatively stable, and
649 it only contributed of 4% to total runoff in the NX basin since 1971. Wang et al. (2022)
650 quantified the contribution of baseflow by the water and energy budget-based distributed
651 hydrological model (WEB-DHM), and suggested mean annual baseflow contributed of 3.3%
652 to total runoff. However, different model structures to represent baseflow processes may also
653 result in uncertainties. In addition, the effect of climate change on the baseflow in the YZ basin
654 remains uncertain mainly due to the generally poor understanding of mountain aquifers.
655 Detailed study of infiltration and recharge processes, aquifer characteristics, and flow pathways
656 needs to be a focus of future research to predict how baseflow will respond to the changes in
657 climate and cryosphere.

658

659 The representation of glacier melting processes introduces substantial uncertainties in model
660 simulations. The accuracy of distinguishing between debris-free and debris-covered glacier
661 extents at the basin scale critically influences the simulated contribution of glacier runoff.
662 Currently, the differentiation between these two glacier surface types relies on elevation
663 constraints. However, due to the observation in these two glacier surface types, the DDFs were
664 set to the same value in the debris-free and debris-covered glacier. To address this pivotal issue,

665 additional glacier observations encompassing both surface types, coupled with high-quality
666 remote sensing mapping, would solve this key issue. This approach holds the potential to refine
667 distinctions between debris-free and debris-covered glaciers, thereby enhancing the precision
668 of model simulations concerning glacier melting processes.

669

670 Another key issue is the restricted comprehension of the effect of snow and ice sublimation on
671 glacier runoff. Sublimation can potentially be an important component of the high-altitude
672 water balance in the Himalayan region (Lutz et al., 2016). Sublimation was mostly calculated
673 based on gauge measurement and estimated using an elevation-dependent potential sublimation
674 function (Lutz et al., 2016; Khanal et al., 2021; Stigter et al. 2018). Stigter et al. (2018)
675 suggested that the fraction of snowfall sublimation may be much higher than 21% at wind-
676 exposed locations in the Himalayan region. Lutz et al. (2016) and Khanal et al. (2021) proposed
677 that snow sublimation accounts for approximately 10% in the UI basin and 2%–3% in the YZ
678 basin. Furthermore, the impact of snow sublimation diminished as a result of a smaller fraction
679 of precipitation falling as snow with ongoing warming (Khanal et al., 2021). Yang et al. (2013)
680 investigated mass balance of a maritime glacier on the YZ basin of the southeast TP during
681 2005–2010, and indicated that the mass loss by way of sublimation/evaporation was quite
682 negligible (about -0.07 m/yr).

683

684 Runoff change is also influenced by land cover and land use. Liu et al. (2023) studied the effect

685 of vegetation growth induced by climate change to runoff variation during 1981–2010 in the
686 YZ basin with the Variable Infiltration Capacity (VIC) model, suggesting that implanting
687 grassland effectively reduces flash flood runoff in the short term and balances groundwater
688 runoff in the long term. Broad-leaved and coniferous forests, with their longer growth cycles,
689 also play a key role in adjusting soil moisture. Ji et al. (2023) explored the effect of vegetation
690 growth on runoff changes in the YZ basin by computing the functional equation for the
691 Normalized Difference Vegetation Index (NDVI) and Budyko parameter, suggesting that the
692 NDVI and discharge both presented an increasing trend, and the contributions of NDVI on
693 streamflow change in the 1998–2015 were about 43.04%.

694

695

696 **6 Conclusions**

697 This study comprehensively investigates runoff composition, flow changes, and their
698 attribution across six sub-basins in the YZ for 1971–2020, with a particular focus on the
699 comparison between the NX and NX-BXK using a newly generated precipitation dataset and a
700 well-validated large-scale VIC-Glacier model with observed streamflow at eight hydrological
701 stations, glacier mass balance data at two sites, and satellite-based glacier and snow cover
702 estimates. The study also assesses the future evolution of annual and seasonal total water
703 availability, as well as glacier runoff and snowmelt contributions, using an ensemble of multiple
704 GCMs from CMIP6 under two SSPs. The key findings are summarized as follows:

705

706 1. Large regional differences in runoff regimes were observed in the YZ basin for 1971–2020.
707 The NX-BXK contributed 52% to total runoff at the Pasighat outlet of the YZ basin, followed
708 by the YC-NX (25%), LS (10%), and other sub-basins. While rain-induced runoff dominated
709 the entire YZ (59%–72%), glacier runoff played a more important role in annual total runoff in
710 downstream sub-basins (16%–19%), particularly in summer (23%–35%).

711

712 2. Regional differences in runoff changes were identified in the YZ basin. Annual runoff
713 generally increased (8–19 mm/10yr) during 1971–2020 in all sub-basins of the NX basin, but a
714 significant decrease is noted in the NX-BXK sub-basin (-9.4 mm/10yr). Total runoff trends
715 reversed after 1998 for all sub-basins of the YZ, with increasing trends during 1971–1997 and
716 decreasing trends during 1998–2020, influenced by changes in summer rainfall runoff due to
717 atmospheric moisture and teleconnection indices (PDO, ENSO, and AMO). Glacier runoff
718 mitigated the decreasing contribution from rainfall since 1998, exhibiting an increased effect
719 on water supply.

720

721 3. Total runoff will consistently increase (27–100 mm/10yr) across the sub-basins through the
722 21st century, with increases of 7–27 mm/10yr in NX and 34–100 mm/10yr in NX-BXK under
723 two SSPs, resulting from increased rainfall runoff and minor effect of increased snowmelt and
724 glacier runoff. Relative to the 1971–2000 mean, a decrease of about -6% to -14% is expected

725 in the first half of the 21st century (2021–2050), followed by a consistent increase (6%–32%)
726 in the second half (2071–2100).

730 (42201140), a project funded by the China Postdoctoral Science Foundation (2022M723256),
731 and the Second Tibetan Plateau Scientific Expedition and Research (STEP) Program
732 (2019QZKK0201). We extend our gratitude to Daqing Yang, Ying Li, Qikai Sun and Tinghai
733 Ou for their constructive suggestions.

734

735 **Data availability**

736 Daily precipitation, maximum and minimum temperature, and wind speed estimates with a
737 spatial resolution of 10×10 km during 1971–2100 were adopted from Sun et al. (2022), and
738 were downloaded from the National Tibetan Plateau/Third Pole Environment Data Center
739 (TPDC, <https://doi.org/10.11888/Atmos.tpdc.272885>). Daily transient climate estimates, at a
740 spatial resolution of 10×10 km for 1971–2100 under 20 scenarios (10 GCMs × 2 SSPs) used in
741 this study were from Sun et al. (2024). Observed streamflow was from the Ministry of Water
742 Resources, China. Two shapefiles of glacier inventory were downloaded from the
743 “Environment & Ecological Science Data Center for west China”
744 (<http://westdc.westgis.ac.cn/glacier>) and Randolph Glacier Inventory (RGI) 6.0

745 (https://www.glims.org/RGI/rgi60_dl.html). Observed annual glacier mass balance data from
746 Gurenhekou and Parlung No.94 glacier sites since 2005 were downloaded from the TPDC. The
747 snow cover fraction (SCF) estimates during 2006–2018 were form the Moderate Resolution
748 Imaging Spectroradiometer (MODIS) 10CM (<https://nsidc.org/> data).

Figure 1. (a) Location and topography of the Yarlung Zangbo (YZ) river basin. Sub-basins, numbered 1 to 6, represent Lhatse (LZ), Lhatse-Yangcun (LZ-YC), Shigatse (RKZ), Lhasa (LS), Yangcun-Nuxia (YC-NX), and Nuxia-Pasighat (NX-BXK), respectively. (b) Spatial pattern of average annual streamflow for 1971–2020 in the YZ basin. The lower histogram shows the mean annual streamflow contribution from each sub-basin to the Pasighat outlet for 1971–2020 in the YZ..... 39

Figure 2. Mean monthly simulated rainfall, snowmelt, and glacier runoff, along with their contribution to total annual runoff in the YZ and its sub-basins for 1971–2020. 40

Figure 3. Spatial pattern of average annual rainfall runoff (a), snowmelt (c), glacier runoff (e), and precipitation (b) for 1971–2020 in the YZ basin. The spatial pattern of average annual snow cover fraction (SCF, d) for 2001–2019 and glacier distribution in the YZ basin. Percentage (%) of three runoff components (rainfall, snowmelt, and glacier runoff) at four elevation bands in the YZ basin, with the number in parentheses indicating the number of 10-km grids in each elevation band. 41

Figure 4. Annual trends in precipitation (mm/10yr), temperature (°C/10yr), total runoff (mm/10yr), and three runoff components (rainfall, glacier, and snowmelt runoff, mm/10yr) in the six sub-basins for 1971–2020, respectively. Asterisks indicate the 95% significance level. 37

Figure 5. Mean monthly vertical integral of atmospheric moisture budget (mm) in June, July, August, and September from the ERA5 data across the Yarlung Zangbo river basin for 1971–2020 (indicated by colors). Arrows represent the directions of the vertical integral of water vapor flux ($\text{kg}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$)..... 38

Figure 6. Seasonal trends in precipitation (mm/10yr), temperature (°C/10yr), total runoff (mm/10yr), and three runoff components (rainfall, glacier, and snowmelt runoff, mm/10yr) in the YZ and its sub-basins for 1971–2020, respectively. 39

Table 5. Trends of projected annual precipitation (mm/10 yr), temperature (°C/10 yr), and total runoff and runoff components (mm per decade) from 10 GCMs for 1971–2000, 2021–2050, and 2071–2100 under the two SSPs in the YZ and its two sub-basins (The uncertainties are indicated with one standard deviation).

| | | NX | NX-BXK | YZ |
|-----------------------|-----------------|-------------|-------------|-------------|
| SSP2-4.5 2021–2050 | Total runoff | 6.84±4.9 | 52.65±22.41 | 16.15±7.37 |
| | Rainfall runoff | 5.53±3.97 | 29.99±15.43 | 10.54±5.73 |
| | Snowmelt | -0.43±1.0 | 9.24±6.88 | 1.54±1.71 |
| | Glacier runoff | 1.68±1.32 | 13.41±6.91 | 4.07±2.38 |
| | Precipitation | 4.98±8.96 | 31.87±27.85 | 10.4±11.59 |
| | Temperature | 0.43±0.16 | 0.42±0.12 | 0.43±0.15 |
| SSP5-8.5 2021–2050 | Total runoff | 16.22±6.78 | 59.34±28.23 | 24.99±10.59 |
| | Rainfall runoff | 11.9±5.75 | 31.2±22.06 | 15.82±8.69 |
| | Snowmelt | 1.35±1.05 | 9.53±5.65 | 3.01±1.88 |
| | Glacier runoff | 2.98±0.54 | 18.61±3.77 | 6.16±1.06 |
| | Precipitation | 18.02±11.86 | 32.73±36.08 | 21.01±16.29 |
| | Temperature | 0.66±0.1 | 0.6±0.09 | 0.64±0.09 |
