Abstract. Playa-lakes developed in semi-arid regions are sensitive to water input reductions, which may be influenced not only by climate changes and human management but also by changes in the size of the watershed. We accomplished an interdisciplinary study combining structural, geomorphic, sedimentological, mineralogical and hydrological analyses to better understand the Fuente de Piedra (FdP) playa-lake evolution in southern Spain. By using previously published temperature and precipitation reconstructions, we assess the potential evapotranspiration and the runoff to estimate the maximum lake level during the FdP playa-lake lifespan (>35 ka). Our results indicate that the FdP playa-lake level never exceeded 5m, although deposits at its NE margin are up to 15 m above the current lakebed at present. These lacustrine deposits are slightly tilted towards the SW. The electrical conductivity profiles of groundwater in the FdP's shore and surroundings reveal a more pronounced interface between brackish water and brine in the northern part compared to the southern part of the basin. This implies that saline water once occupied the northern playa-lake margin in an area that is hardly ever flooded at present. The presence of reworked gypsum in the sedimentary sequence of the southern margin (down to a depth of 14 m), indicates substantial erosion of prior gypsum deposits, possibly redistributed from northern deposition areas. Altogether, our data suggest a SW displacement of the playa-lake depocenter caused by an uplift of the NE and subsidence of the SW area. This shift is congruent with the combined effect of both the La Nava sinistral-normal fault and the Las Latas dextral-normal fault, respectively at the E and S margins of the FdP playa-lake. Consequently, the FdP flooded surface mostly remained constant and in equilibrium with climate variables and its watershed along its lifespan. The SW-ward displacement of the flooded surface was provoked by the recent tectonic activity.

1 Introduction

Saline playa-lakes develop in semi-arid to arid regions, where precipitation is considerably lower than evapotranspiration, leading to negative water balances. Water inputs are direct precipitation and runoff from the catchment, while water outputs are evapotranspiration and infiltration. Slight changes in the water balance lead to significant seasonal and interannual water level variability.

Under negative water balance conditions, the average flooded surface shrinks, eventually giving rise to complete desiccation and playa-lake disappearance (Moral et al., 2013). Several factors control the change in the water discharge to playa-lakes, such as groundwater extractions for agricultural purposes (Rodríguez-Rodríguez et al., 2015) or climate changes (Schöder et al., 2018; García-Alix et al., 2022). In this regard, variations on temperature and/or precipitation have happened naturally over the Quaternary (e.g., Mann, 2002; Hughes et al., 2013), resulting in changes in evapotranspiration and lake inputs. Besides, recent studies, which modelled the vertical lake evolution, suggest that anthropogenic climate change during the Late Holocene may have provoked additional changes in lake water input and evapotranspiration (e.g. Matthews, 2008). The bathymetry of these wetlands is characterized by planar surfaces and they show low sedimentation rates (e.g. García-Alix et al., 2022). In general, they are ephemeral water bodies, where evaporation leads to the formation of salt crusts during the dry season (e.g. Sánchez-Moral et al., 2002). When these wetlands are dry, they are sensitive to aeolian erosion because of the formation of clay-salt aggregates (Moral, 2016).

Climate changes are recorded in the sedimentary playa-lake register, so playa-lake sediments can provide valuable paleoclimate information (Roberts et al., 2001; Höbig et al., 2016; Schöder et al., 2018, 2020; Cohen et al., 2022; García-Alix et al., 2022, among others). However, accurate interpretations of their sedimentary records require a deep knowledge of the landscape evolution in the surrounding areas, especially those changes related to variations in their catchment size and geometry. Although these changes in both flooded areas and watersheds of playa-lakes have been poorly investigated to date, recent studies have demonstrated that such water bodies are quite dynamic, especially those settled in active orogens (e.g. Berry et al., 2019), where tectonic processes may favour divide migration and watershed capture, leading to variations on the watershed area (Jiménez-Bonilla et al., 2023a).

The Fuente de Piedra (FdP) playa-lake is the largest playa-lake within an endorheic area located at the Atlantic-Mediterranean water divide in southern Spain (Figs.1 and 2). The FdP playa-lake remains completely desiccated during the dry season (May to October), except for exceptionally wet interannual periods, when the lake level can reach more than 2m (Rodríguez-Rodríguez et al., 2016). The FdP watershed developed in a depressed area within the Betics fold-and-thrust belt, which is limited by topographic highs controlled by transpressional shear zones with evidence of moderate Quaternary tectonic activity (Jiménez-Bonilla et al., 2016; 2023a; 2023b). In the past decades, several studies have assessed the modern hydrology and paleohydrological evolution of this endorheic system (e.g. Kohfahl et al., 2008; Höbig et al., 2016; Rodríguez-Rodríguez et al., 2016). These investigations assumed that the FdP playa-lake surface as well as its watershed geometry and extension have remained constant since its origin (at least 35 kyrs BP; Höbig et al., 2016). Consequently, variations in the lake flooded surface

65   had been attributed to paleoclimate changes. Indeed, presumed Pleistocene lake terraces (10 m above the current lake floor) were reported and interpreted as evidence for lake highstands during humid periods (Höbig et al., 2016).

Here, we develop an evolution model for the FdP playa-lake based on structural, hydrological and sedimentological information. The general aims of this paper are i) to re-examine the role of late Quaternary tectonic activity in the FdP playa-lake, ii) to propose an integrated chronology of FdP playa-lake sediments after careful characterization of its sediments and

70   tectonic setting and iii) to investigate potential impact of climate changes on the lake by modelling the water level over the past 35 kyrs upon both lithological and mineralogical variations in the FdP sedimentary sequence and changes in the geometry of the flooded area.

2 Geological setting

The Betic Cordillera, which is the northern branch of the Gibraltar arc, is built up by the Neogene collision between the Alboran

75   domain (hinterland) and the South Iberian paleomargin (Vera, 2004; Fig. 1A). During the westward migration of the Alboran domain, Flysch units were deposited and later sandwiched between both domains. The South Iberian paleomargin was deformed into the Betics fold-and-thrust belt, which registers a main, lower to middle Miocene deformation and a late post-Serravallian deformation event, responsible for the main current relief. This late deformation is still active along the belt (e.g., Balanyá et al., 2012; Jiménez-Bonilla et al., 2015).

85

2.2 The Antequera Depressed Zone (ADZ)

The study area is the FdP endorheic watershed, which lies in an E-W elongated depressed area in the Betics fold-and-thrust belt. This basinal area, hereafter referred to as the Antequera depressed Zone (ADZ, Figs. 1 and 2), is limited by mountain ranges which are mainly controlled by two post-Serravallian, dextral transpressive zones: the Algodonales-Badolatosa Shear

90   Zone (ABSZ; Jiménez-Bonilla et al., 2015) to the NW, and the Torcal Shear Zone (TSZ, Díaz-Azpiroz et al., 2014; Barcos et al., 2015) to the S and SW (Figs. 1 and 2). Both the ABSZ and TSZ show evidence of upper Miocene to recent tectonic activity (Barcos et al., 2015; Díaz-Azpiroz et al., 2020; Jiménez-Bonilla et al., 2023). Both shear zones produce topographic highs located at 600-800 and > 1,000 m a.s.l. for the ABSZ and TSZ, respectively (Fig. 2), which sharply drops to the ADZ. The ADZ is characterized by a mostly flat topography at approx. 450 m a.s.l. It includes some scattered reliefs, as the Humilladero

95   range (Fig. 2), generated by a compressive bridge that links two left-lateral shear zones of the post-Tortonian Humilladero Transverse Zone (HTZ, Fig. 2). Some studies suggest that the ADZ nucleated as an endorheic area since the emersion of this

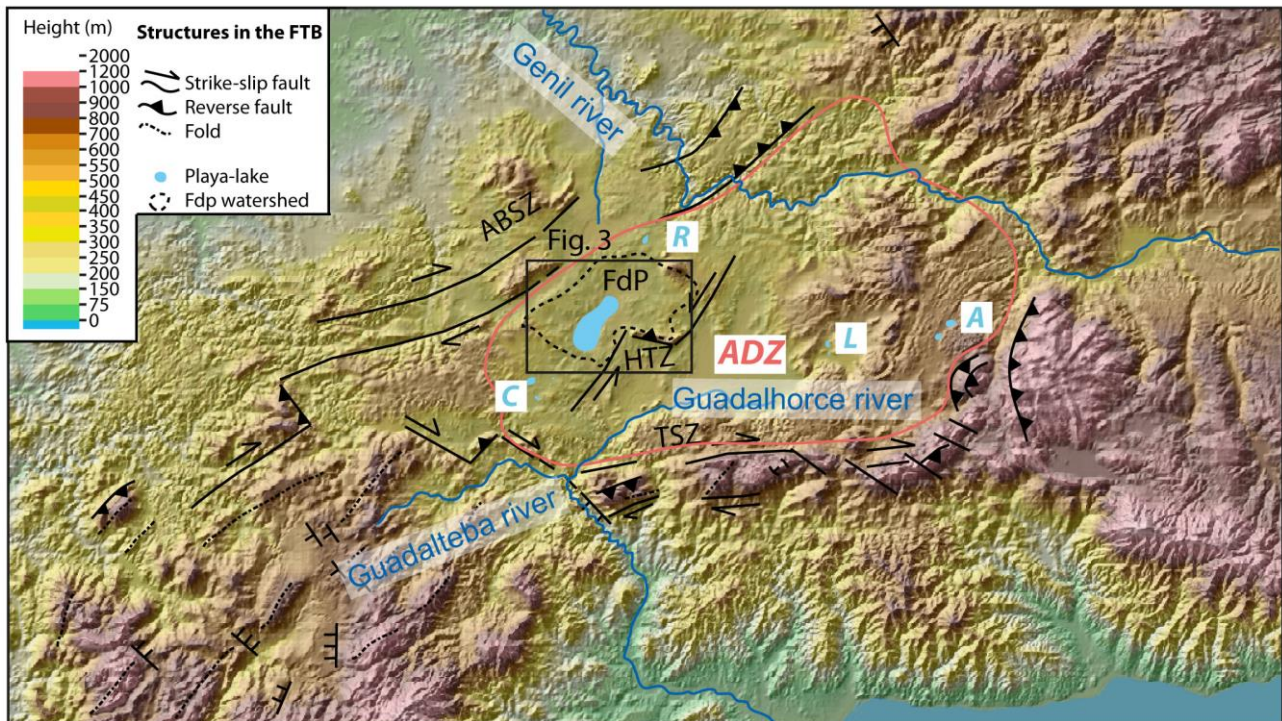
Betics segment in Pliocene to Pleistocene times (Elez et al., 2018; 2020). The ADZ was later captured and partially drained by Guadalhorce and Guadalteba rivers to the Mediterranean and by the Guadalquivir network to the Atlantic (Figs. 1 and 2). Thus, the main Quaternary Atlantic-Mediterranean water divide is located in the western Betics, but it is not a sharp feature. In fact, it is a km-wide diffuse area presenting several endorheic basins (Rodríguez-Rodríguez et al., 2010): the FdP watershed, which includes the FdP and La Nava playa-lakes, the Campillos (C) endorheic basin, made up by more than 10 playa-lakes, the Archidona (A) playa-lakes, the Ratosa (R) endorheic basin and Lomas (L) playa-lakes (Fig. 2).


Figure 2: Topographic map and hillshade of the Antequera Depressed Zone (ADZ) showing the main playa-lakes: FdP (Fuente de Piedra), R (Ratosa), C (Campillos), L (Lomas) and A (Archidona), and the main structures grouped into three main shear zones: TSZ (Torcal Shear Zone), ABSZ (Algodonales-Badolatosa Shear Zone) and HTZ (Humilladero Transverse Zone).

2.3 FdP watershed rocks

The lithological formations that crop out in the FdP watershed (Figs. 1 and 2) belong to the Subbetic units. These Subbetic units derive from the most internal position of the South Iberian paleo margin and are made up of Tortonian to Messinian shallow-marine deposits and Pleistocene to Holocene continental deposits (Vera et al., 2000). Subbetic units are composed of: (1) Triassic clays, gypsum and marls that include isolated dam- to hm-scale dolostone bodies; (2) Jurassic dolostones and

limestones that constitute the main mountain ranges (Sierra de los Caballos in the ABSZ and Sierra de Humilladero in the HTZ; Fig. 3) and (3) Cretaceous to Paleogene marls and marly-limestones. Recent works have interpreted the Triassic rocks

115   outcropping in this area as an allochthonous canopy and the main mountain ranges made up of Jurassic limestones as tectonic windows (Flinch and Soto, 2017; 2022). Upper Miocene shallow-marine deposits testify to the progressive shallowing of the ADZ. They are Tortonian to Messinian calcarenites and marls (Cruz-Sanjulián, 1991), probably deposited in small-size basins (Flinch and Soto, 2017). Previous geological maps show that these sediments are deformed by open folds and faults and often lie unconformably over Subbetic units (Flinch and Soto, 2017;2022). Pliocene sediments vary from polygenic sandstones

120   associated with beach-like environments to continental conglomerates related to alluvial fans. The source of these conglomerates and sandstones is located immediately to the south of the TSZ and includes Alborán domain-related clasts of schists, marbles and gneisses, together with sandstones and limestones clasts coming from Flysch and Subbetic units.

Pleistocene to Holocene sedimentary sequences are stream-related sediments such as alluvial terraces, alluvial fans and playa-lake-related deposits (e.g., sandy aeolian lunettes and other lacustrine deposits, Fig. 3).

pediment to the W of the FdP playa-lake sediments, (d) the geometry of an erosive pediment to the E of the FdP playa-lake sediments, (e) the sinistral-normal, La Nava Fault, which separates the FdP and La Nava (N) playa-lake and (F) picture of a left-lateral strike-slip fault associated with La Nava fault.

2.4 Hydrological features of the FdP playa-lake

135   The FdP playa-lake occupies a conspicuously eccentric location at the SW edge of a topographically closed watershed of about 150 km². The flat surface - flooded seasonally - has an NE-SW elongated ellipsoidal shape (6.8 km long and 2.5 km wide), which it is, in turn, aligned with the Ratosa playa-lake to the NE and the Campillos playa-lakes to the SW of the FdP watershed. (Fig. 2). The FdP playa-lake is defined as a hyper saline lake of the Cl-(SO$_4$)-Na-(Mg)-(Ca) type. Concentration of dissolved solids range from 18 to 200 g/l in the surface water (Rodríguez-Rodríguez, 2002). The FdP playa-lake has a lifespan of at least

140   26 kyrs and probably longer than 45 kyrs (Höbig et al., 2016). Under natural conditions, the FdP playa-lake receives surface and subsurface runoff from its watershed. The outputs correspond only to evapotranspiration (Rodriguez-Rodriguez et al., 2016). In summer, the FdP is completely dry, but minimum piezometric levels under the playa floor ranges from -20 to -30 cm (Kohfahl et al., 2008). This is consistent with a discharge-type playa-lake with a hydrogeological basin that is almost coincident with the surface watershed (Kohfahl et al., 2008). In the past, the playa-lake was the lowest part of the

145   hydrogeological basin, and received water inputs also from the N and NE sectors from a spring located in the foothills of the carbonate aquifer of Mollina mountain range (by means of the Santillán stream; Fig. 3) and, most probably, groundwater inputs also from the Sierra de Humilladero mountain range (Figs. 2 and 3), although no springs have been observed in this carbonate aquifer. Both aquifers are intensively exploited at present (e.g., Rodríguez-Rodríguez et al., 2015), but in natural regime there are estimations of the recharge in both aquifers being 25-30% of the average precipitation in the region (c. 440 mm/year)

150   (Martos-Rosillo et al., 2015). Below the playa-lake, a hypersaline stable groundwater brine has been developed via evapotranspiration and convection processes (Kohfahl et al., 2008; Benavente et al., 1993). The high salinity and density of the water in the playa-lake surface favour the slow percolation of this brine below the lake. This brine is detached from the fresh groundwater of the aquifer by a freshwater – saltwater interface, similar to that of coastal aquifers, being the playa-lake perimeter the equivalent to the coastal shore. A summary of relevant studies about the hydrogeology of the FdP playa-lake can

155   be found in Rodríguez-Rodríguez et al. (2016).

3 Methodology

3.1 Hydrological data compilation and water level calculation

   We use hydrological information of FdP playa-lake from several sources (e.g. scientific reports from the Geological Survey

160   of Spain and the Andalusian Autonomous Government) to elaborate the hydrograph of the daily evolution of the water level in the playa-lake. The water level above and below the lake floor was obtained from an automatic water level sensor installed in a piezometer placed inside the lake basin. Depth was expressed as altitude above the sea level (m a.s.l.).

We reconstructed the paleo-water level of the FdP playa-lake to compare with lake sediments. To do that, we conducted water
balances every 50 yrs over the last 35 kyrs (700 water balances). We applied a lake water balance equation developed in previous studies of southern Iberian playa-lakes (e.g. Rodríguez-Rodríguez et al., 2015). The lake water balance considers average climatic conditions and is expressed as:

$$\Delta V = P – E + Si − So + GD – GR, \tag{1}$$

where ΔV (mm) is the change in the lake water level, whose bathymetry is completely flat at 410 m a.s.l., P (mm) stands for precipitation onto the lake surface, and E (mm) is the direct evaporation from the flooded surface. Si stands for the surface runoff, which is calculated by means of a soil water balance. So is the surface outflow that, in the case of FdP playa-lake, is set to be 0. GD represents the groundwater discharge from the regional aquifer to the lake and GR is the groundwater recharge from the lake to the aquifer. We assume that $Si + GD - GR$ equals BD (Basin Discharge) i.e., the total volume of water runoff, surface and groundwater, flowing into the playa-lake from the watershed. In the case of FdP playa-lake, previous studies suggest that the limit of the surface watershed coincides with that of the groundwater watershed (e.g., Linares, 1990), so BD can be calculated easily. Consequently, eq. 1 is simplified to:

$$\Delta V = P – E + BD \tag{2}$$

Mean precipitation data (mm/year) were obtained from the sedimentary record of Padul peatland (See Fig. 1B for location), at about 80 km from FdP playa-lake to E, which is based on fossil pollen data (Camuera et al., 2022). There are no climatic differences between both locations. We filled data gaps by interpolation using linear regression between available data (Fig. 4). Atmospheric temperature data from 0 to 15 kyrs BP were obtained from Sea Surface Temperature (SST) reconstructions in the Alboran Sea by Català et al. (2019) and by Morcillo-Montalbá et al. (2021) from 15 to 35 kyrs BP. We made the correlation between the Cabo de Gata buoy (comparable to SST) and the weather station close to FdP playa-lake (Antequera weather station) and we obtained a meaningful correlation coefficient of 0.76. Consequently, we assume that the long-term air temperature in the surroundings of FdP playa-lake (~50 km from the seashore) varied in the same fashion and magnitude as SST. We used the paleo-temperature record to calculate potential evapotranspiration (PET) by the Thornthwaite method, using TRASERO software for the analysis and calculation of hydrological time series (Rodríguez-Hernández et al. 2007). We corrected these values by multiplying by 1.15 because this method usually underestimates real evapotranspiration (e.g. Rodríguez-Rodríguez et al., 2016). We obtained monthly potential E values that were later converted to annual potential E values. BD, obtained from the soil water balance, was calculated with the same software using monthly potential E and the water holding capacity (WHC) (Rodríguez-Hernandéz et al., 2007). The WHC is the amount of water a soil can hold without

generating runoff and it depends on the soil texture. We considered that water inputs only come from the watershed, which is assumed to have remained constant over the past 35 kyrs. We ran the calculations (Allen et al., 2011) using two values of WHC, 50 and 75 mm, to create two series of maximum lake level. We have applied low permeability values according to the rocks cropping out in the FdP watershed. We converted monthly water surplus to yearly surplus and then multiplied this value

200   by the FdP watershed / average flooded area relationship (W/AFS) to obtain the amount of yearly basin discharge (*BD*) in mm. *BD* includes the groundwater coming from the karstic aquifers and the surface runoff coming from all the FdP playa-lake watershed. We assume that when the water level is between 0 and 2 m, the AFS remains constant, so that the W/AFS relationship does not change (Rodríguez-Rodríguez et al., 2016). Then, we obtained the increase on the lake level (Δ*V*) for every 50 yrs. Considering the FdP playa-lake behaviour from 1983 to 2012, we also assume that the FdP water level must start

205   at 0 mm every year in most cases, then ΔV equals to lake level. Importantly, to obtain the maximum water level we must sum the Δ*V* to the water level at the end of the previous hydrological year during wet years. We cannot make calculations for every year because the step of our paleoclimate series is 50 years (Fig. 4). Hence, we chose the most humid period (*P* = 700 mm, *ETo* = 850 mm and runoff = 75 mm; Fig. 4) and made iterative calculations per year during 50 yrs, holding climate conditions the same, but changing the W/AFS relationship. Thus, we recalculated the AFS for every year depending on the water level

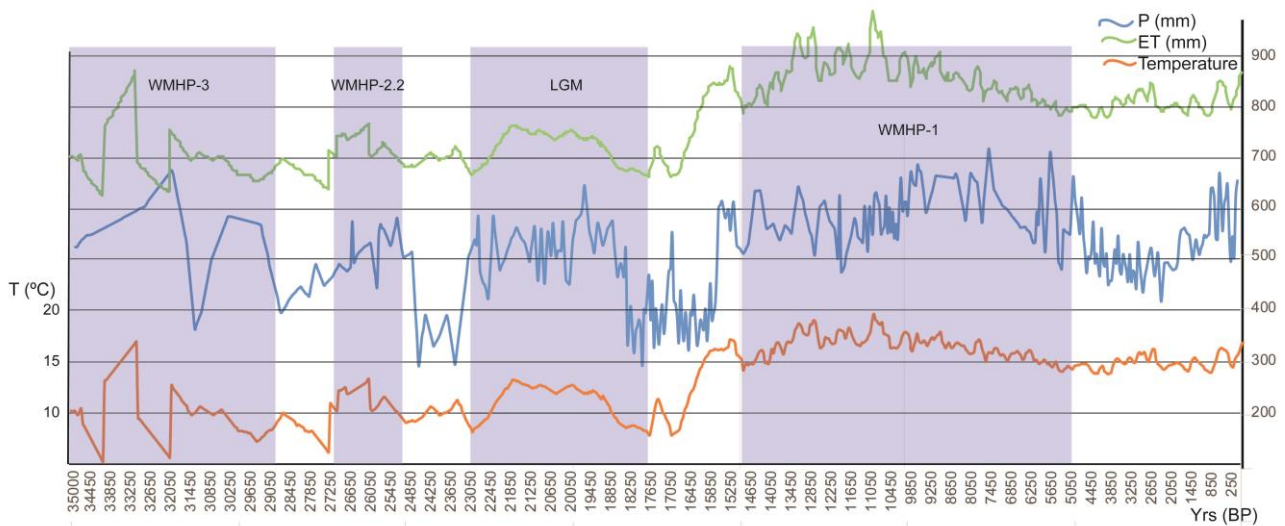
210   reached in the previous year.


Figure 4: Temperature, *ET* and precipitation reconstruction during the past 35,000 years in southern Iberia (Català et al., 2019; Morcillo-Montalbá et al., 2020; Camuera et al., 2022) and the FdP water level oscillation according to Höbig et al. (2016).

3.2 Geomorphological and structural data

We improved the previous cartography of the FdP playa-lake sediments by focusing on the recent erosive and depositional landforms. Using slope maps, ortho imagery and a 1:10,000 digital elevation model (Junta de Andalucía, 2002), we made an accurate cartography of playa-lake sediments associated with the FdP playa-lake. We also constrained the Pliocene to Pleistocene landforms (Fig. 3). We collected structural data from those structures that affect Pliocene to younger sediments, whose scale ranges from several 100 m to kilometric-scale (Fig. 3).

3.3 Compilation of geochronological and sedimentological data of the FdP sediments

We combined previously published geochronological data of FdP sediments to create a chronological framework for the lake evolution and discuss the reliability of the current age model. In this regard, Höbig et al. (2016) obtained seventeen AMS radiocarbon ages, conducted on bulk sediment, pollen, charcoal, remains of plants and seeds from the 14-m-long sediment core 2013-04, recovered from the southern margin of the lake (table 1, Fig. 5). In addition, we have used eight recent U-Th ages obtained from gypsum crystals of core 2012-PL1 (1.4 m long) collected from the central part of the basin (Obert et al., 2022). Radiocarbon dates were calibrated into calendar years using the IntCal 13 curve (Reimer et al., 2013). A Bayesian age-depth model was calculated using the "Rbacon" R-based package (version 2.5 - March 2023, Blaauw and Christen, 2011) (Fig. 5).

We investigate in detail the sedimentology of cores 2013-04 and 2012-PL1, which mostly comprises laminated clayey and carbonated sediments as well as different types of gypsum deposits ranging from gypsum sand to several cm-long prismatic selenite crystals. We primarily focus on the morphology of the gypsum crystals to evaluate either the primary or diagenetic origin of gypsum at various depths and use the criteria of Cody and Cody (1988) to identify different depositional environments between the FdP playa-lake sediments southern margin and its central part.

4 Results

4.1 Geology of the FdP watershed

In this section, we describe the morphology of sedimentary bodies originated during the FdP playa-lake development (Pleistocene to Holocene) and the recent structures that have been active at least during the last 2 Myrs and may influence the FdP watershed and its flooded area.

4.1.1 Geomorphology of Pleistocene to Holocene sedimentary bodies

We differentiate sediments from two young depositional environments: fine-grained partly evaporitic, lacustrine deposits related to the FdP playa-lake and colluvial Pleistocene and Holocene pediments.

Lacustrine sediments related to the current FdP playa-lake crop out quasi-horizontally at 410 m a.s.l. (lake base level, LBL) and extend to the NE, out of the playa-lake current area, where they reach altitudes of 425 m a.s.l. (Fig. 3). Here, they show a

smooth slope (from 1 to 1.5%) towards the SW (Fig. 3B). Towards the E, lacustrine deposits of the La Nava playa-lake are currently isolated from the FdP playa-lake sediments by a topographic high. Here, they are horizontal and are located 3 m above the FdP LBL (respective altitudes of 413 m *vs* 410 m; Figs. 3A and E).

The FdP watershed presents both depositional and erosive pediments. They are characterized by red soils, sometimes called "red rendzinas", "terra rossa" or chromic luvisols, developed over Miocene limestones, which are very abundant in the Mediterranean (Sandler et al., 2015). Occasionally, these soils also include carbonate crusts, so-called calcretes, which typically form in Mediterranean climate (Alonso-Zarza et al., 2010). The most intensive development of such red Mediterranean soils occurred from the Miocene to the Late Pleistocene, due to the numerous climate fluctuations in those periods (Atalai, 2002). Pleistocene ages seem to be consistent with our observations, as red soils overlie Pliocene to Pleistocene conglomerates and sandstones, and are covered by Holocene lacustrine deposits (Fig. 3A). Their thickness varies from 0 to 0.5 m in the case of erosive pediments whilst they reach more than 1 m in the case of colluvial pediments (glacis deposits). They all constitute flat surfaces that are situated about 10 to 70 m above the current FdP LBL (Figs. 3A, 3C and 3D). The best-preserved one is located to the W of the FdP playa-lake sediments, at about 470 m a.s.l. (Fig. 3C). It is related to an erosive pediment that truncates Tortonian to Messinian calcarenite beds (Fig.3C) and extends over 1,000 hm^2. Headwater erosion from both Atlantic rivers and FdP streams are eroding this thin red soil (Fig. 3A). The thickest depositional pediments are found in depressed areas (at ca. 420 m a.s.l.), close to the current FdP LBL (Fig. 3A). The red rendzinas soils in these deposits have a complete soil profile.

4.1.2 Tectonic structures and kinematics

The structures involving Tortonian to Holocene sediments are faults that can be grouped into three sets:

The NE-SW striking, La Nava fault zone, related to the western branch of the HTZ, affects Tortonian to Messinian sediments SE of the FdP playa-lake sediments (Figs. 3A and 3F). This fault is approx. 10 km long and extends to the S of the Campillos playa-lake system. Fault surfaces strike N20-45ºE and dip between 70-90º to the WNW. Slickenlines show pitches up to 15º to the SSW (Fig. 3F). This, combined with kinematic indicators such as S-C-like structures and calcite and gypsum slickenfibres, indicates a dominant left-lateral strike-slip movement and a subordinate normal movement throwing the western block down (Figs. 3A and 3F). Other highly dipping NE-SW faults affect Jurassic and Pliocene outcrops to the W of the FdP playa-lake sediments (Fig. 3A).

WNW-ESE to NW-SE trending right-lateral faults constitute the 10 km long, Las Latas fault zone, that coincides with the southern water divide of the FdP watershed. Fault surfaces strike N60-85ºE and dip 65-90º towards the NNE. Slickenlines show pitches up to 35º to the ESE. Kinematic indicators such as S-C-like structures, indicates a dominant right-lateral strike-slip movement with a subordinate normal component, which lowers the northern block where the FdP watershed is located (Fig. 3A). We interpret this fault zone as a synthetic Riedel fault of the ABSZ (Figs. 2 and 3A). Other WNW-ESE faults are found in the W margin of the FdP watershed (Fig. 3A).

The western water divide of the FdP watershed coincides with the hinge zone of a kilometre-scale antiform, deforming Tortonian to Messinian units. Its axis plunges. 25º towards the SW and its hinge zone is locally truncated by a Pleistocene erosive pediment (Figs. 3A and 3C).

4.2   Chronological framework and description of sedimentary facies

The radiocarbon dates of the sediments in core 2013-04, from the southern margin of the lake, range from 0.8 to 45 kyr BP (Table 1) (Höbig et al., 2016). They show large dispersion and age reversals, especially in the lower section, which may be due to reworking of older sediments in the basin, up to 45 kyrs old, as suggested by the oldest obtained ages (Fig. 5). Nevertheless, the relatively low Gelman and Rubin Reduction Factor (<1.05), the convergence test and the stable log-posterior time-series suggest a relatively reliable age model and good fitting (Fig. 5A). According to this model, the sedimentation rate in the core 2013-04 comprises the last 26.4 cal kyr BP. For core 2012-PL1, the available ages correspond only to the deeper and central section of the 1.4 m-long core (0.73 to 1.39 m, Table 1) and the analytical errors of the ages are up to 50% in some cases (LFP-6 and LFP-7, excluded in the model), so ages must be taken with caution. The age of gypsum crystals in the sediment provided by Obert et al. (2022) ranges from 34±1.5 to 47±2.7 cal kyrs BP, with no age reversals considering the large analytical errors of some ages. The chronological model for core 2012-PL1 suggests that the deepest cores section is at least 40-50 kyr old (Fig. 5B).

Table 1. Chronological data from FdP playa-lake cores 2013-04 and 2012-PL1 (Höbig et al., 2016 and Obert et al., 2022, respectively, see locations in Fig. 3). Conventional radiocarbon ages from Höbig et al. (2016) were re-calibrated using IntCal 20 curve (Reimer et al., 2020). In core 2012- PL1, "dc" refers to the activity ratios corrected with the conventional approach (see Obert et al., 2022).

Core	Location	Sample ID	Depth (m)	Material	Conv. age (a BP)	Cal. age (a BP)	2σ(cal a BP)

The previous and posterior model memory distributions are shown as green and grey lines, respectively, in the memory plot. (b) Sedimentary**
305 **sequence, lithology and age-depth model (95% confidence interval and red median line) of core 2012-PL1. For age model references, see Table1.**

The sediments in core 2013-04 (Fig. 6A) are essentially composed of fine-grained materials, primarily clays and carbonate (calcitic, aragonitic or dolomitic) muds, along with evaporites represented by gypsum and halite. Gypsum shows several crystal
310 morphologies, including single or twinned micro- and macrolenticular crystals (which often developed interstitially in the clay or mud), mm to cm-scale prismatic crystals and subangular to rounded gypsum sand grains, interpreted previously by Höbig et al. (2016) as "detrital" gypsum (Fig. 6). These authors also assessed different lithofacies in core 2013-04 based on macro- and microscopic observation and geochemical data (Fig. 6A). Lithofacies 2 contains layers of cm-thick massive clays with microcrystals of lenticular gypsum, while lithofacies 3a and 3b are mainly formed by beds of carbonate mud with

315 microlenticular gypsum crystals that sometimes are embedded into the mud. In turn, centimetre-thick layers of dolomitic mud and gypsum sand grains, both with interstitial mm-size lenticular gypsum crystals, are the principal components of lithofacies 4 and 5, only differentiated by the abundance of gypsum sand layers, more frequent in lithofacies 5. Less abundant are prismatic crystals and cm-size macrocrystals of lenticular gypsum.

In core 2012-PL1, the upper 20 cm are dominated by laminated grey clays intercalated with mm-thick layers of gypsum sand.

320 Between 20 and 120 cm depth, the core is composed of pale carbonate mud with embedded prismatic gypsum macrocrystals of centimetre-scale (Fig. 6). The deepest section shows a similar composition to the top, but the clays have a darker grey colour.

4.3 FdP hydrology

4.3.1 Pleistocene-Holocene water level evolution of the FdP playa-lake

The results of the hydrological modelling of the FdP playa-lake over the past 35 kyrs are shown in Fig. 7. This includes
330 modelling using WHC of 75 and 50 mm. For these calculations, first we considered that both the FdP watershed (W) and
average flooded surface (AFS) remained constant. When using WHC of 75 mm, the modelled runoff for the FdP watershed
during the entire period is relatively low (Fig. 7A). Consequently, the lake was probably dry during most of the time and
increases on the water level (ΔV) did not reach 0.5 m except for a humid period from 32 to 30 kyrs BP (Fig. 7A). We considered
that this model is not realistic because with similar precipitation and evapotranspiration values (350-700 mm for P and close
335 to 1000 mm for ETP) in the historic period from 1983 to 2022, much higher runoff values were observed (Rodríguez-Rodríguez
et al., 2016; Fig. 7). Consequently, WHC of 75 mm was discarded for additional analyses. When using a WHC of 50 mm,
runoff values in the FdP watershed during some periods are like present values (ca. 10-15% of precipitation). However, the
increase on the lake level (ΔV) is always below 2 m (Fig. 7B). Maximum values were obtained between 32 and 30 kyrs, when
the ΔV was up to 1.8 m, and from 10 to 4 kyrs, with values ranging from 0.5 to 1.8 m (Fig. 6B). ΔV during the last 1,000 yrs
340 ranged from 0.5 to 1 m, which is equal to the current ΔV FdP (Figs. 7 and 8).

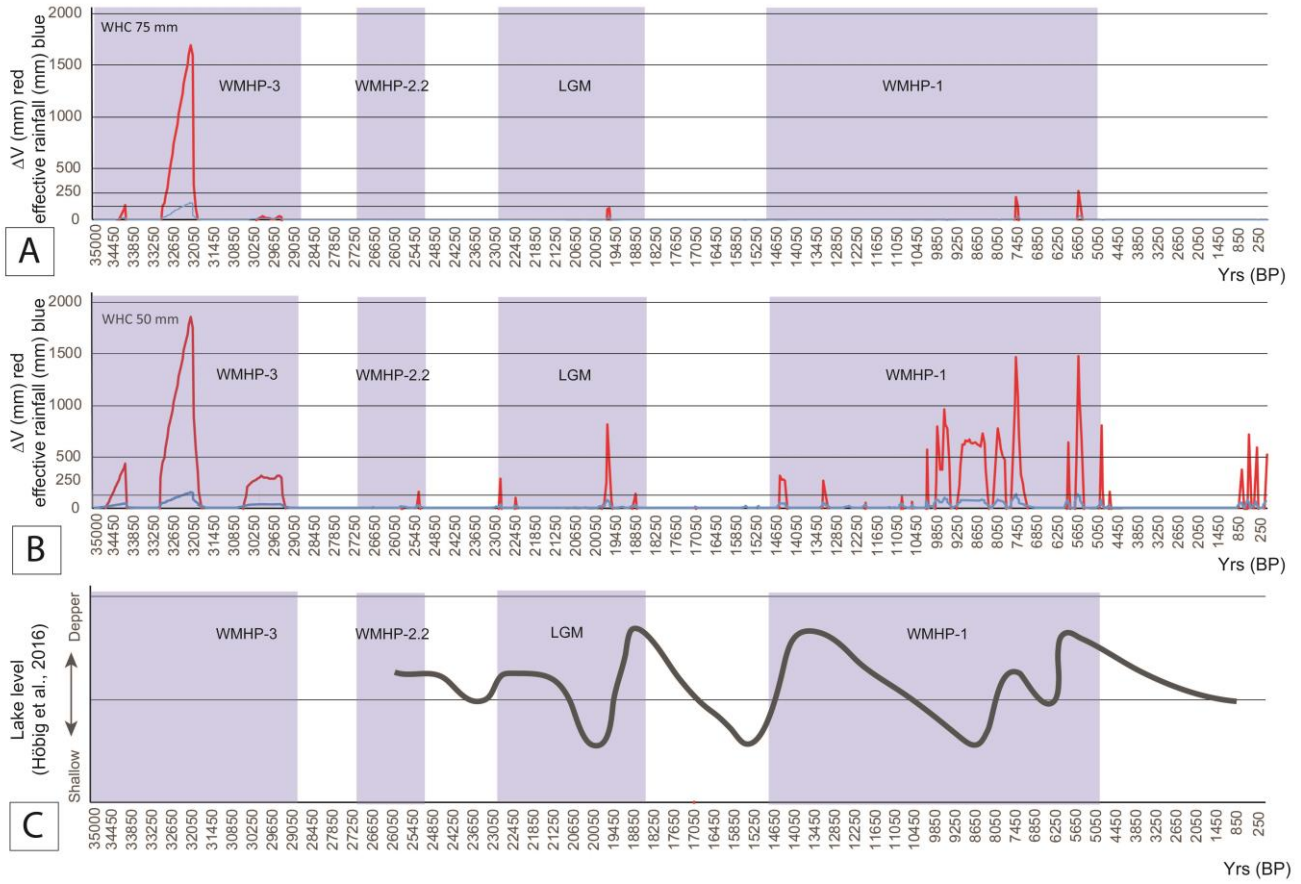
The FdP playa-lake probably behaved as a seasonal lake, then ΔV would be equal to the maximum water level. However,
during rainy periods, it probably behaved as a permanent lake. In this case, to obtain the maximum water lake level, we
recalculated the AFS for every year during extremely rainy periods of 50 yrs (P =700 mm, ETP = 850 mm and runoff = 75
mm; Fig. 7B), depending on the water level reached in the previous year (Fig. 9). We obtained that the FdP water level never
345 surpassed a height of 5 m over the lakebed. Because of the flat bathymetry of the FdP playa-lake, the W/AFS relationship used
to calculate the BD decreases from 11.1 to ca. 3 (i.e., W area tripled in size the AFS area) when the FdP water level increases
from 1 to 5 m (Fig. 10). Consequently, the water level stabilizes at ca. 5 m, when water inputs are equal to water outputs (Fig.
9). This lake level could be reached before 14 years in case of groundwater level increases. Given that there is not a clear
maximum water level, Figure 10 shows the FdP flooded area from 1 to 6 m above the lakebed. The contour of the lake deposit
350 outcrops is also indicated.


Figure 7: Model results showing ΔV in the FdP playa-lake (in red) and effective rainfall (in blue) using WHC of 75 mm (a) and 50 mm (b). (c) Variations on the FdP lake level according to Höbig et al., 2016.

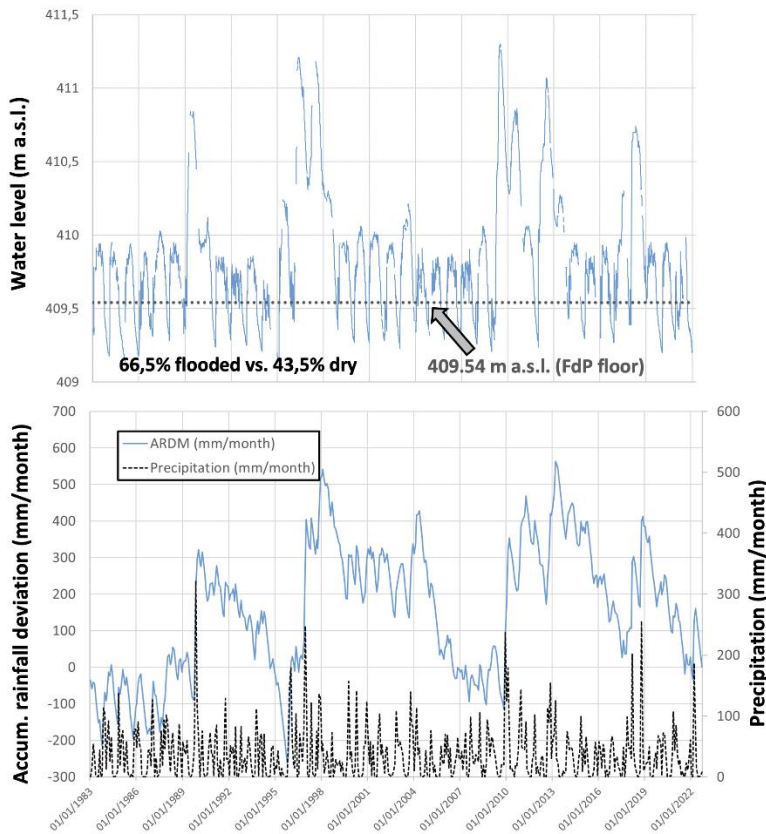
355


Figure 8: Variations on the FdP playa-lake water level from 1983 to 2022. These 4 decades include both dry and wet periods.
Figure 9: Results of the FdP water level assuming stable humid conditions during 17 years, when the water level stabilizes at ca. 5 m above the lakebed.

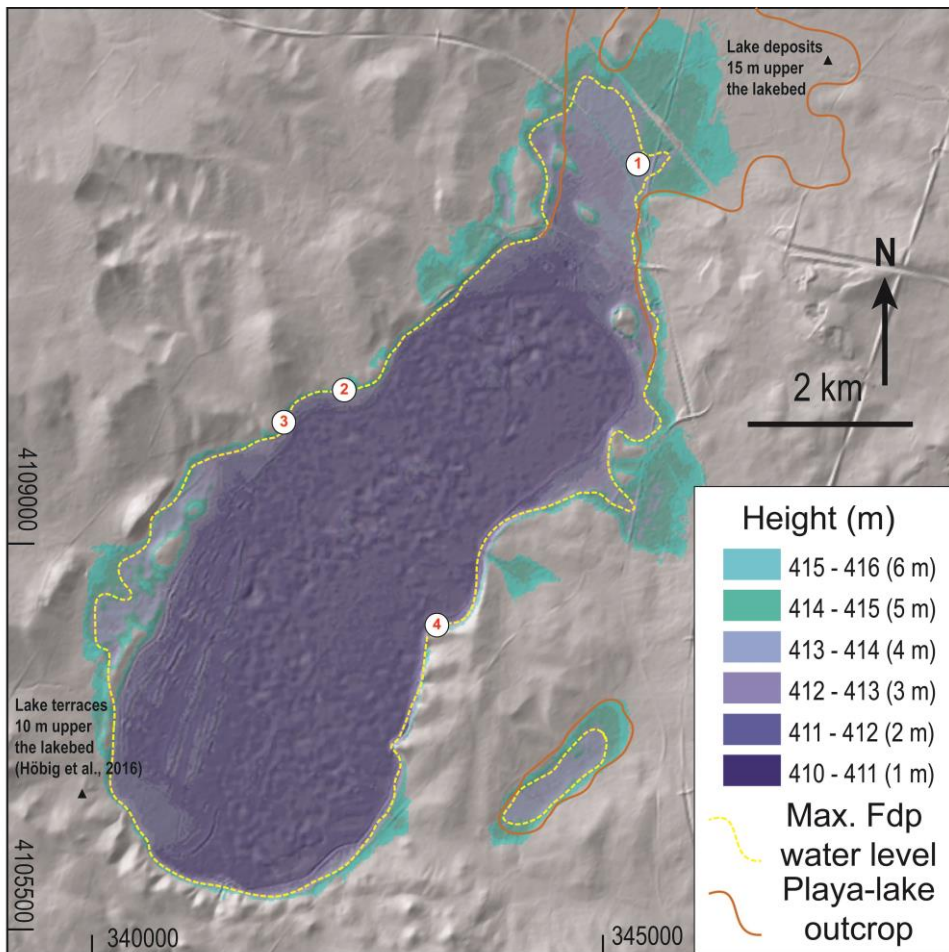
360


Figure 10: Simulation of the FdP playa-lake flooded area (AFS) if the water level reaches 1 m to 6 m using the current topography. The boundary of the Pleistocene to Holocene FdP playa-lake sediments is also displayed (See section 3.2. for methodology). The location of piezometers 1 to 4 is shown.

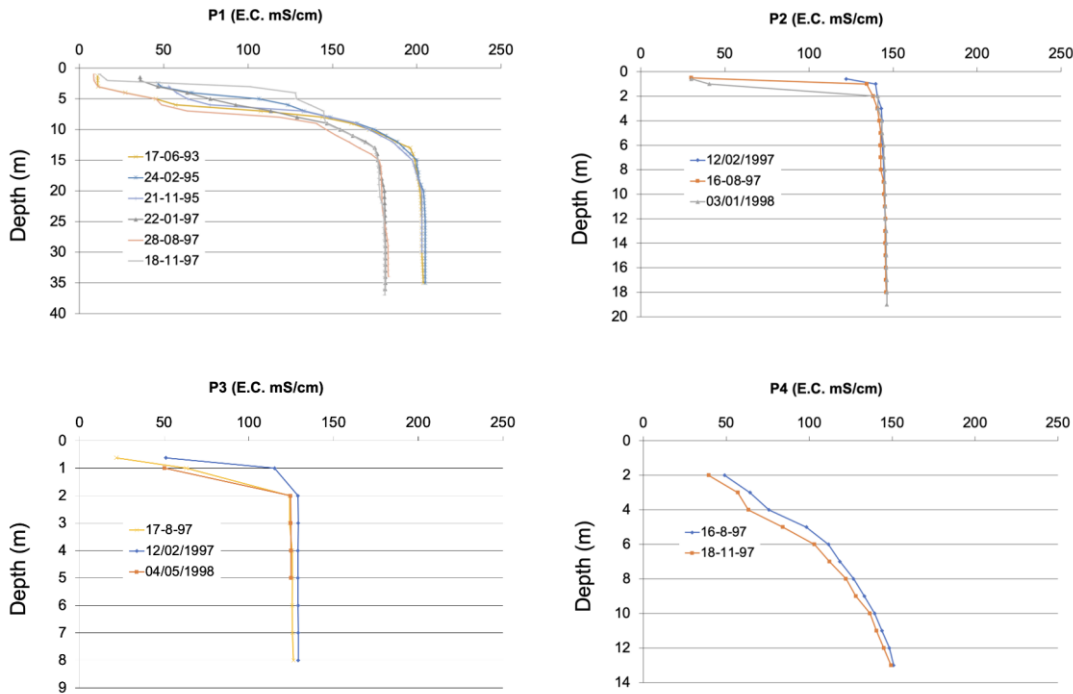
Several piezometers are installed at different depths to investigate the behaviour of the hypersaline groundwater brine below the playa-lake floor (Fig. 11). The distribution of electrical conductivity values of water in the studied profiles remained relatively constant during the study period (1993-1998) in the different piezometers. The measurements in P2 and P3 reveal a transition zone approximately 1 - 2 m thick between the water from local rainwater and runoff from the catchment, which remains in the upper level because of its lower density, and the brine beneath FdP playa-lake (Fig. 11). This transition zone is a result of mechanical dispersion and molecular diffusion processes. Within the transition zone, the theoretical Ghyben-Herzberg interface is located and it remains during hundred years once a playa-lake dries up. Meanwhile, in P4, the southernmost piezometer, the interface is not so clear (Fig. 11).


Figure 11: E.C. profiles of the groundwater in the piezometers shown in Fig. 10. Note that P1 is in an area nowadays outside the current playa-lake basin. Differences in E.C. between 1993/95 and 1997 profiles are attributed to differences in precipitation

380

5   Discussion

5.1   The FdP evolution through its sedimentary record

Previous works based on radiocarbon dates suggested that the FdP playa-lake is the oldest one investigated in the area. Earliest ages are ca. 26 kyrs in the southern sector (Höbig et al., 2016) and may be earlier than ca. 50 kyrs in the central basin, as

385   suggested by recent chronological analyses of gypsum (Obert et al., 2022). Moreover, drills did not reach the contact between the lacustrine sediments and the basement (Triassic rocks), so the FdP inception was probably even earlier.

In our work, the gypsum deposits observed in the core from the SW shore of the FdP playa-lake (2013-04; Figs. 3A, 4A and 12) differ largely from those observed in the core taken from its centre (2021-PL1, Figs. 3A, 4B and 12). The SW gypsum deposits exhibit a wide range of crystal variations and sizes, with majority of fine grains, while only selenite crystals larger

390   than 1 cm interbedded with mud are found in the lakebed in its central part (Fig. 5). The morphology of gypsum crystals in sediments of continental environments can offer hints to understand their depositional setting (Cody and Cody, 1988). According to these authors, larger prismatic crystals growth is chiefly independent of temperature, and they develop in

environments with relatively low concentrations of dissolved organic compounds. Also, larger gypsum crystals are expected to grow under relatively stable conditions. These stable conditions can be attributed to periods of water level high stands and

395 a more permanent playa-lake level (e.g. from 10 to 7.5 kyrs ago; Fig. 3). Despite the uncertainty in the ages obtained by Obert et al. (2022), and assuming that the results of their challenging U-Th measurements are correct, the age of the sediments in the central basin is older than 48 kyrs but may be as old as 98 kyrs, according to the age uncertainties. Importantly, sediments at about 0.7 m below the playa-lake floor in its central part are 34±1.5 kyrs (2012-PL1; Figs. 3A and 4B). This chronological model suggests that, either the sedimentation rate for the upper 0.7 m was considerably low (0.02 mm/yr) during the past 34

400 kyrs or, instead, part of the sediments that were deposited in the central area of the FdP playa-lake during the Holocene may have been eroded/dissolved more recently. The topographic and tectonic uplift of the northern part of the basin and subsidence of its southern part may have favoured exposure of the northern sediments to erosion because of slow tilting of the basin to the south, which is congruent with the kinematics of its faulted boundaries (Fig. 12). Remobilization of older lacustrine sediments because of waves produced by wind during highstand periods, and/or by aeolian erosion during lowstand periods would have

405 resulted in lakebed exposure and, consequently, migration of "reworked" gypsum grains to other parts of the basin. This agrees with the current slope showed by the lacustrine deposits at the NE corner of the FdP playa-lake sediments, which reaches 1.5% (Fig. 3B). Alternatively, it can not be ruled out that the FdP playa-lake splitted in some subbasins during its evolution. It could also explain the little resemblance between 2012PL1 and 2012-PL2 (Figs. 5 and 6).

Höbig et al. (2016) attributed the presence of rounded sand-size gypsum grains found throughout the entire length of core

410 2013-04 from the SW shore to periods when playa-lake water agitation caused sediment reworking and transportation from shallower to deeper areas. This is consistent with the hypothesis of lacustrine basin migration towards the SW as the elevation of the northern area could have produced a more energetic environment in the SW (Fig. 12). In this scenario, sediments from the NE may be continuously eroded, transported and deposited towards the SW, at different distances from the source area. Unfortunately, no scientific drilling reaching the contact between the lacustrine sediments and the underlying Triassic material

415 has been conducted in FdP playa-lake to date, either in the margins or in the central part of the basin. Further investigations on the FdP sedimentary sequence may shed light on the geometry of this contact. According to our hypothesis, this contact may be at a deeper position in the southern playa-lake sector than in its northern part, because of the southward tilting of the basin.

the evolution of the flooded area according to neotectonics and variations on climate. Black arrows show main sediment supply. MD:
Main depocenter. Core locations are represented by red dots.

5.2 Factors controlling the FdP flooded area geometry and evolution

Here we propose a hydrological model for the FdP playa-lake based on a water balance simplified to precipitation and surface
and subsurface runoff from the watershed as water inputs and evapotranspiration (ET) as water outputs (Rodríguez-Rodríguez
et al., 2016). According to this model, the watershed area is in equilibrium with the FdP average flooding surface (i.e.,
maintaining a constant W/AFS ratio) under almost unchanging climate conditions (precipitation and temperatures that control
the potential evapotranspiration). We considered that endorheic watershed size maintained along the FdP playa-lake lifespan,
along the last 35 kyrs. Although the watershed geometry could have changed, the FdP watershed area probably remained
constant. Some plausible increases/decrease on the FdP watershed (<10 km², 6% of the current watershed) would not imply
significant increases on the W/AFS relationship (Fig. 13).

Precipitation (*P*) and *ET* values have changed during the past 35 kyrs in southern Iberia: *P* ranged from 350 to 700 mm and
ET varied between 650 to 1000 mm (Fig. 4). With these climatic conditions, the FdP playa-lake probably behaved as a
discharge system since its inception. We chose the wettest period to calculate the highest expected water level (at approx. 6
kyrs before present: *P* = 700 mm and *ET* = 820 mm; Fig. 6) and we made iterative calculations by changing the W/AFS

435 relationship during 50 yrs (Fig. 9). Our calculations suggest that the maximum feasible lake water level under such climate conditions is 5 m. During some extremely wet periods described by Camuera et al. (2022) such as WMHP-3 (39–29 kyr BP), WMHP-2 (27–18.5 kyr BP; WMHP-2.2 at 27–25 kyr BP and WMHP-2.1 at 23–18.5 kyr) and WMHP-1 (15.5–5 kyr BP), the FdP playa-lake probably increased its hydroperiod to more than 80%. Indeed, it could have behaved as a permanent lake during short periods, as it currently occurs with other lakes in this area (e.g. Amarga Lake; Jiménez-Bonilla et al., 2023). During these

440 extremely wet periods, our model does not contemplate a possible water supply from the aquifer, which would reduce the time to reach the maximum water level (Fig. 9). However, the FdP water level probably never reached 5 m above the lakebed because of the variability of the Mediterranean climate conditions (dry periods alternate with wet periods). More than 10 humid years are needed to obtain this value (Fig. 9). Moreover, the lake level during the past 30 yrs never exceeded 2 m (Fig. 8). As can be deduced from Fig. 8, FdP playa-lake has been dry almost every summer, during the period with instrumental records

445 (1983 – 2022) except for two humid periods (1996-1997 and 2010-2011) in which the playa-lake remained flooded for two consecutive years. From the analyses of the data record obtained in the deepest part of the playa-lake's floor, during the daily record of the lake's hydroperiod, 9710 out of 14610 days, water level was higher than 409,54 m A.S.L. which is the altitude in which level drops to zero m (consequently, the playa-lake dry-out completely). So the average flooded period (hydroperiod) for this playa-lake, to date, is 66,5% (see Fig. 8 for details). Comparing our lake level reconstruction with that one of Höbig et

450 al. (2016), based on sediment sequence, we observe that the lake level is higher during the LGM and some periods of the Late glacial, but an opposite trend during the Holocene with relatively lower for the Höbig et al. (2016) reconstruction (Fig. 7). It could be due to a recharge to the karstic aquifers during the winter. Then, most playa-lake sediments should have been deposited in the lake shores between 0 and 5 m above the lakebed. Nevertheless, Pleistocene-Holocene FdP playa-lake sediments are distributed from 0 m to more than 15 m above lakebed, NE-ward of the playa-lake (Figs. 3A, 3B, 10 and 13). In

455 this regard, previous works have interpreted that some sandstone outcrops located to the S of the playa-lake, are lacustrine terraces, which are currently at 10 m above lakebed due to climate changes (Höbig et al., 2016). However, these outcrops show features pointing to a high energy environment between the continent and the ocean: angular clasts of a wide variety of sources and a calcareous cement (see Pliocene conglomerates and sandstones in Fig. 3). These rocks are similar to other continental-marine transitional Pliocene deposits found within the ADZ (Cruz-Sanjulián, 1991; see stars in Fig. 13). Moreover, these

460 conglomerates and sandstones are made up of clasts from the Alboran domain, which is currently out of the FdP endoreic watershed. Then, these sediments were deposited before the FdP watershed inception. We interpreted these sediments as the playa-lake basement instead of FdP playa-lake sediments. In contrast, to the NE of the current FdP playa-lake, these deposits are dark soils with a flat topography which correspond with old lake deposits, as we included in our results (Fig. 3).

The presence of playa-lake sediments at more than 10 m above lakebed to the NE suggests a displacement of the FdP playa-

465 lake towards the SW from the Late Pleistocene to the Holocene. Such behaviour is also consistent with the analyses of the EC profiles made in the piezometers (Fig. 11). The development and formation of a sharp transition zone between the underlying groundwater brine and the upper brackish-to-fresh discharge is detected in EC profile. As commented before, this chemocline is associated with fluctuations in the water level of the playa-lake due to both seasonal drying and climatic cycles, as well as

variations in the piezometric level of the aquifer. The observations indicate the existence of a brine reflux from the playa-lake

470 floor beneath the transition zone, like what has been studied in well-documented analogous playa-lakes elsewhere (i.e., the Tyrrell Basin; Macumber. 1992) and also in this same system (Kohfahl et al., 2008).

The presence of a well-defined interface 1 to 5 m wide towards the north of the playa-lake (P1; see Fig. 11), in an area where the FdP current playa-lake floor is absent, could indicate a potential migration of the lacustrine basin from the N-NE to the S-SW. This hypothesis is supported by two observations:

475 1. The interface is highly stable over time; therefore, once formed, it would take a considerable amount of time for it to be washed away.

  2. In piezometer 4, located further south, the interface is considerably weaker, suggesting that the playa-lake floor has not existed in this position for that long.

This finding supports the hypothesis of a lacustrine basin migration over time, potentially caused by tectonic factors. Indeed,

480 both Las Latas and La Nava faults affect Pliocene sediments. The location of earthquakes and focal mechanisms are compatible with their kinematics (Jiménez-Bonilla et al., 2024). Consequently, both faults were probably active during the Quaternary. Moreover, the SW-ward movement of the FdP playa-lake is consistent with the kinematics of recent faults which determine its boundaries. (Fig. 13; Jiménez-Bonilla et al., 2023). Thus, the left-lateral component of the La Nava fault would have induced the SW-ward displacement of the main FdP depocenter. Additionally, the relative uplift of the NE edge of the FdP playa-lake

485 is compatible with its SW tilting, associated with the downthrowning of the Las Latas fault hanging wall. According to this, the normal dip-slip component of both La Nava and the Las Latas faults would have produced the FdP relative sinking of the FdP playa-lake, preventing its siltation and its capture from Mediterranean streams (e.g., Tinajas stream; Fig. 13). Therefore, the long lifespan of the FdP playa-lake (>30 kyrs), which is unusual for playa-lakes in S Spain (compare with, for example, the 11 kyrs-old Ballestera playa-lake; García-Alix et al., 2022), would have been favoured by the tectonic activity in this area.

490 It is likely that the relict La Nava playa-lake (Figs 3A, 3E and 13) was formerly part of the FdP playa-lake and was subsequently separated by uplift of the La Nava fault footwall. Consequently, La Nava playa-lake is currently a recharge system linked to the FdP playa-lake. In summary, the FdP playa-lake geometry and evolution seem to be influenced, since the beginning, by the recent to active tectonic activity in the area, governed by the transpressive kinematics of the TSZ and the ABSZ. This tectonic scenery would be responsible for the NW-SE relief segmentation that has generated the ADA, favouring the inception

495 of several endorheic basins there. Focusing on the FdP playa-lake, and according to our results (Fig. 5), its inception occurred at least 50 kyrs ago, being its further evolution controlled by faults linked to the transpressive kinematics. In this regard, focal mechanisms of earthquakes and geomorphological studies support the current activity of both shear zones (Jiménez-Bonilla et al., 2015; 2023). Consequently, active tectonics seems to be a key factor in the shaping of these wetlands within this Betics fold-and-thrust belt segment.

5.2

6   Conclusions

510   Previous studies attributed the presence of lacustrine deposits surrounding the Fuente de Piedra playa-lake to climate fluctuation (Höbig et al., 2016). In this work, we applied a hydrological modelling for the Fuente de Piedra (FdP) playa-lake during its lifespan (> 35 kyrs). To this end, we reconstructed direct evaporation, ET and runoff from P and temperature previously published and we calculated the increase on the water level from the playa-lake bottom every 50 years. The increase on the water level never reached 2 m and iterative calculations show that the maximum water level is lower than 5 m. However,

515   we detected lacustrine deposits more than 10 m above the lakebed, then additional forces apart from climate changes, are evaluated here. According to geological results, we propose the SW-ward displacement of the FdP playa-lake during the Pleistocene-Holocene because of recent tectonic activity. This displacement is favoured by the activity of a left-lateral dominated La Nava fault and the dip-slip dominated Las Latas fault, that contribute to the downthrown and tilting of the block where the FdP playa-lake is located. Other lines of evidence support this hypothesis:

520   1.   There are lacustrine sediments related to the current FdP playa-lake more than 15 m above the lakebed at the NE corner of the playa-lake. In the E of the FdP playa-lake an isolated lacustrine deposit is located 3 m above the present FdP lakebed. The uplift and isolation of the patch is compatible with the La Nava fault kinematics.

2.   The presence of a well-defined water interface towards the north of the FdP watershed, above the maximum FdP water level, also indicates a SW migration of the FdP depocenter.

525   3.   The morphologies of gypsum found in the sediments indicate the existence of primary gypsum formed in-situ during certain periods. Significant amounts of reworked gypsum, probably transported from northern parts of the basin, were also deposited throughout most of the time covered by this sedimentary sequence, especially to the S. The SW-ward tilting of the playa-lake may have facilitated this process.

Our study confirms the importance of multidisciplinary investigations to understand the inception and development of wetlands
530   and saline playa-lakes in subtropical arid conditions.

Acknowledgements

We thank A. Lupión (Director of the Patronage of the Natural Reserve of Fuente de Piedra playa-lake) for support during field surveys and for providing historical monitoring data of the lake.

Funding

This study was supported by the (1) Tectonic conditioning and climate change effects on the hydrogeological evolution of wetlands and playa-lakes in the southern Spain research project (University of Pablo de Olavide), (2) GYPCLIMATE research project (PID2021-123980OA-I00) Spanish Ministry of Economy and Competitiveness - Regional Development European Fund (FEDER), (3) the project PGC2018-100914-B-I00, funded by the Ministerio de Ciencia e Innovacíon (Spanish Government)/AEI/10.13039/501100011033/ERDF, (4) the project UPO-1259543, funded by the Consejería de Economía, Conocimiento, Compañías y Universidad (Andalusian Government)/ERDF and (5) "Monitorizacion hidrológica y modelización de la relación laguna-acuífero en los mantos eólicos de Doñana. Seguimiento y ampliación del inventario" (Agreement between the Guadalquivir River Basin Authority and the University Pablo de Olavide). Dr. F.G acknowledges the Ramón y Cajal fellowship, RYC2020-029811-I and the grant PPIT-UAL, Junta de Andalucía-FEDER 2022-2026 (RyC-PPI2021-01). L.M. was funded by the FPU21/06924 grant of the Ministerio de Educación y Formación Profesional of Spain.
