11 **Abstract**

12 The past few years have witnessed the rise of neural networks (NNs) applications for hydrological time
13 series modeling. By virtue of their capabilities, NN models can achieve unprecedented levels of
14 performance when learning how to solve increasingly complex rainfall-runoff processes via data, making
15 them pivotal for the development of computational hydrologic tasks such as flood predictions. The NN
16 models should, to be considered practical, provide a probabilistic understanding of the model mechanisms
17 and predictions and hints on what could perturb the model. In this paper, we developed two NN models,
18 i.e., Neural Hierarchical Interpolation for Time Series Forecasting (N-HiTS) and Network-Based
19 Expansion Analysis for Interpretable Time Series Forecasting (N-BEATS) with a probabilistic multi-
20 quantile objective and benchmarked them with long short-term memory (LSTM) for flood prediction across
21 two headwater streams in Georgia and North Carolina, USA. To generate a probabilistic prediction, a Multi-
22 Quantile Loss was used to assess the 95th percentile prediction uncertainty (95PPU) of multiple flooding
23 events. Extensive experiments demonstrated the advantages of hierarchical interpolation and interpretable
24 architecture, where both N-HiTS and N-BEATS provided an average accuracy improvement of ~5% over
25 the LSTM benchmarking model. On a variety of flooding events, both N-HiTS and N-BEATS demonstrated
26 significant performance improvements over the LSTM benchmark and showcased their probabilistic
27 predictions by specifying a likelihood objective.

28 **Keywords:** Probabilistic Flood Prediction; Neural Networks; N-HiTS; N-BEATS; LSTM; Headwater
29 Stream.

30 **Key Points**

31 • N-HiTS and N-BEATS predictions reflect interpretability and hierarchical representations of data
32 to reduce neural network complexities.
33 • Both N-HiTS and N-BEATS models outperformed the LSTM in mathematically defining
34 uncertainty bands.
35 • Predicting the magnitude of the recession curve of flood hydrographs was particularly challenging
36 for all models.

37 **Plain Language Summary**

38 Recent progress in NN accelerated improvements in the performance of catchment modeling. Yet flood
39 modeling remains a very difficult task. Focusing on two headwater streams, we developed N-HiTS and N-
40 BEATS models and benchmarked them with LSTM to predict flooding. N-HiTS and N-BEATS
41 outperformed LSTM for flood predictions. We demonstrated how the proposed models can be augmented
42 with an uncertainty approach to predict flooding that is interpretable without considerable loss in accuracy.

43 **1. Introduction**

44 The past few years have witnessed a rapid surge in the neural networks (NN) applications in hydrology. As
45 these opaque, data-driven models are increasingly employed for critical hydrological predictions, the
46 hydrology community has placed growing emphasis on developing trustworthy and interpretable NN
47 models. However, maintaining coherence while producing accurate predictions can be a challenging
48 problem (Olivares et al., 2024). There is a general agreement on the importance of providing probabilistic
49 NN prediction (Sadeghi Tabas and Samadi, 2022), especially in the case of flood prediction (Martinaitis et
50 al., 2023).

52 Flood occurrences have witnessed an alarming surge in frequency and severity globally. Jonkman (2005)
53 studied a natural disaster database (EM-DAT, 2023) and reported that over 27 years, more than 175000
54 people died, and close to 2.2 billion were affected directly by floods worldwide. These numbers are likely
55 an underestimation due to unreported events (Nevo et al., 2022). In addition, the United Nations Office for
56 Disaster Risk Reduction reported that flooding has been the most frequent, widespread weather-related
57 natural disaster since 1995, claiming over 600,000 lives, affecting around 4 billion people globally, and
58 causing annual economic damage of more than 100 billion USD (UNISDR, 2015). This escalating trend
59 has necessitated the need for better flood prediction and management strategies. Scholars have successfully
60 implemented different flood models such as deterministic (e.g., Roelvink et al., 2009, Thompson and
61 Frazier, 2014; Barnard et al., 2014; Erikson et al., 2018) and physically based flood models (e.g., Basso et
62 al., 2016; Chen et al., 2016; Pourreza-Bilondi et al., 2017; Saksena et al., 2019; Refsgaard et al., 2021) in
63 various environmental systems over the past several decades. These studies have heightened the need for

64 precise flood prediction (Samadi et al., 2025), they have also unveiled limitations inherent in existing
65 deterministic and physics-based models.

66 While evidence suggests that both deterministic and physics-based approaches are meaningful and useful
67 (Sukovich et al., 2014; Zafarmomen et al., 2024), their forecasts rest heavily on imprecise and subjective
68 expert opinion; there is a challenge for setting robust evidence-based thresholds to issue flood warnings and
69 alerts (Palmer, 2012). Moreover, many of these traditional flood models, particularly physically explicit
70 models, rely too strongly on a particular choice of numerical approximation and describe multiple process
71 parameterizations only within a fixed spatial architecture (e.g., Clark et al., 2015). Recent NN models have
72 shown promising results across a large variety of flood modeling applications (e.g., Nevo et al., 2022; Pally
73 and Samadi, 2022; Dasgupta et al., 2023; Zhang et al., 2023; Zafarmomen and Samadi, 2025; Saberian et
74 al., 2025) and encourage the use of such methodologies as core drivers for neural flood prediction
75 (Windheuser et al., 2023).

76 Earlier adaptations of these intelligent techniques showed promising for flood prediction (e.g., Hsu et al.,
77 1995; Tiwari and Chatterjee, 2010). However, recent efforts have taken NN application to the next level,
78 providing uncertainty assessment (Sadeghi Tabas and Samadi, 2022) and improvements over various
79 spatio-temporal scales, regions, and processes (e.g., Kratzert et al., 2018; Park and Lee, 2023; Zhang et al.,
80 2023). Nevo et al., (2022) were the first scholars who employed long short-term memory (LSTM) for flood
81 stage prediction and inundation mapping, achieving notable success during the 2021 monsoon season. Soon
82 after, Russo et al. (2023) evaluated various NN models for predicting depth flood in urban systems,
83 highlighting the potential of data-driven models for urban flood prediction. Similarly, Defontaine et al.
84 (2023) emphasized the role of NN algorithms in enhancing the reliability of flood predictions, particularly
85 in the context of limited data availability. Windheuser et al., (2023) studied flood gauge height forecasting
86 using images and time series data for two gauging stations in Georgia, USA. They used multiple NN models
87 such as Convolutional Neural Network (ConvNet/CNN) and LSTM to forecast floods in near real-time (up
88 to 72 hours).

89 In a sequence, Wee et al., (2023) used Impact-Based Forecasting (IBF) to propose a Flood Impact-Based
90 Forecasting system (FIBF) using flexible fuzzy inference techniques, aiding decision-makers in a timely
91 response. Zou et al. (2023) proposed a Residual LSTM (ResLSTM) model to enhance and address flood
92 prediction gradient issues. They integrated Deep Autoregressive Recurrent (DeepAR) with four recurrent
93 neural networks (RNNs), including ResLSTM, LSTM, Gated Recurrent Unit (GRU), and Time
94 Feedforward Connections Single Gate Recurrent Unit (TFC-SGRU). They showed that ResLSTM achieved
95 superior accuracy. While these studies reported the superiority of NN models for flood modeling, they
96 highlighted a number of challenges, notably (i) the limited capability of proposed NN models to capture

97 the spatial variability and magnitudes of extreme data over time, (ii) the lack of a sophisticated mechanism
98 to capture different flood magnitudes and synthesize the prediction, and (iii) inability of the NN models to
99 process data in parallel and capture the relationships between all elements in a sequential manner.

100 Recent advances in neural time series forecasting showed promising results that can be used to address the
101 above challenges for flood prediction. Recent techniques include the adoption of the attention mechanism
102 and Transformer-inspired approaches (Fan et al. 2019; Alaa and van der Schaar 2019; Lim et al. 2021)
103 along with attention-free architectures composed of deep stacks of fully connected layers (Oreshkin et al.
104 2020).

105 All these approaches are relatively easy to scale up in terms of flood magnitudes (small to major flood
106 predictions), compared to LSTM and have proven to be capable of capturing spatiotemporal dependencies
107 (Challu et al., 2022). In addition, these architectures can capture input-output relationships implicitly while
108 they tend to be more computationally efficient. Many state-of-the-art NN approaches for flood forecasting
109 have been established based on LSTM. There are cell states in the LSTM networks that can be interpreted
110 as storage capacity often used in flood generation schemes. In LSTM, the updating of internal cell states
111 (or storages) is regulated through several gates: the first gate regulates the storage depletion, the second one
112 regulates storage fluctuations, and the third gate regulates the storages outflow (Tabas and Samadi, 2022).
113 The elaborate gated design of the LSTM partly solves the long-term dependency problem in flood time
114 series prediction (Fang et al., 2020), although, the structure of LSTMs is designed in a sequential manner
115 that cannot directly connect two nonadjacent portions (positions) of a time series.

116 In this paper, we developed attention-free architecture, i.e. Neural Hierarchical Interpolation for Time
117 Series Forecasting (N-HiTS; Challu et al., 2022) and Network-Based Expansion Analysis for Interpretable
118 Time Series Forecasting (N-BEATS; Oreshkin et al., 2020) and benchmarked these models with LSTM for
119 flood prediction. We developed fully connected N-BEATS and N-HiTS architectures using multi-rate data
120 sampling, synthesizing the flood prediction outputs via multi-scale interpolation.

121 We implemented all algorithms for flood prediction on two headwater streams i.e., the Lower Dog River,
122 Georgia, and the Upper Dutchmans Creek, North Carolina, USA to ensure that the results are reliable and
123 comparable. The results of N-BEATS and N-HiTS techniques were compared with the benchmarking
124 LSTM to understand how these techniques can improve the representations of rainfall and runoff
125 dispensing over a recurrence process. Notably, this study represents a pioneering effort, as to the best of
126 our knowledge, this is the first instance in which the application of N-BEATS and N-HiTS algorithms in
127 the field of flood prediction has been explored. The scope of this research will focus on:

128 **(i) Flood prediction in a hierarchical fashion with interpretable outputs:** We built N-BEATS and
129 N-HiTS for flood prediction with a very deep stack of fully connected layers to implicitly capture input-
130 output relationships with hierarchical interpolation capabilities. The predictions also involve programming
131 the algorithms with decreasing complexity and aligning their time scale with the final output through multi-
132 scale hierarchical interpolation and interpretable architecture. Predictions were aggregated in a hierarchical
133 fashion that enabled the building of a very deep neural network with interpretable configurations.

134 **(ii) Uncertainty quantification of the models by employing probabilistic approaches:** a Multi-
135 Quantile Loss (MQL) was used to assess the 95th percentile prediction uncertainty (95PPU) of multiple
136 flooding events. MQL was integrated as the loss function to account for probabilistic prediction. MQL
137 trains the model to produce probabilistic forecasts by predicting multiple quantiles of the distribution of
138 future values.

139 **(iii) Exploring headwater stream response to flooding:** Understanding the dynamic response of
140 headwater streams to flooding is essential for managing downstream flood risks. Headwater streams
141 constitute the uppermost sections of stream networks, usually comprising 60% to 80% of a catchment area.
142 Given this substantial coverage and the tendency for precipitation to increase with elevation, headwater
143 streams are responsible for generating and controlling the majority of runoff in downstream portions
144 (MacDonald and Coe, 2007).

145 The remainder of this paper is structured as follows. Section 2 presents the case study and data, NN models,
146 performance metrics, and sensitivity and uncertainty approaches. Section 3 focuses on the results of flood
147 predictions including sensitivity and uncertainty assessment and computation efficiency. Finally, Section 4
148 concludes the paper.

149

150 **2. Methodology**

151 **2.1. Case Study and Data**

152 This research used two headwater gauging stations located at the Lower Dog River watershed, Georgia
153 (GA; USGS02337410, Dog River gauging station), and the Upper Dutchmans Creek watershed, North
154 Carolina (NC; USGS0214269560, Killian Creek gauging station). As depicted in Figures 1, the Lower Dog
155 River and the Upper Dutchmans Creek watersheds are in the west and north parts of two metropolitan cities,
156 Atlanta and Charlotte. The Lower Dog River stream gauge is established southeast of Villa Rica in Carroll
157 County, where the USGS has regularly monitored discharge data since 2007 in 15-minute increments. The
158 Lower Dog River is a stream with a length of 15.7 miles (25.3 km; obtained from the U.S. Geological
159 Survey [USGS] National Hydrography Dataset high-resolution flowline data), an average elevation of

160 851.94 meters, and the watershed area above this gauging station is 66.5 square miles (172 km²; obtained
161 from the Georgia Department of Natural Resources). This watershed is covered by 15.2% residential area,
162 14.6% agricultural land, and ~70% forest (Munn et al., 2020).

163 Killian Creek gauging station at the Upper Dutchmans Creek watershed is established in Montgomery
164 County, NC, where the USGS has regularly monitored discharge data since 1995 in 15-minute increments.
165 The Upper Dutchmans Creek is a stream with a length of 4.9 miles (7.9 km), an average elevation of 642.2
166 meters (see Table 1), and the watershed area above this gauging station is 4 square miles (10.3 km²) with
167 less than 3% residential area and about 93% forested land use (the United States Environmental Protection
168 Agency).

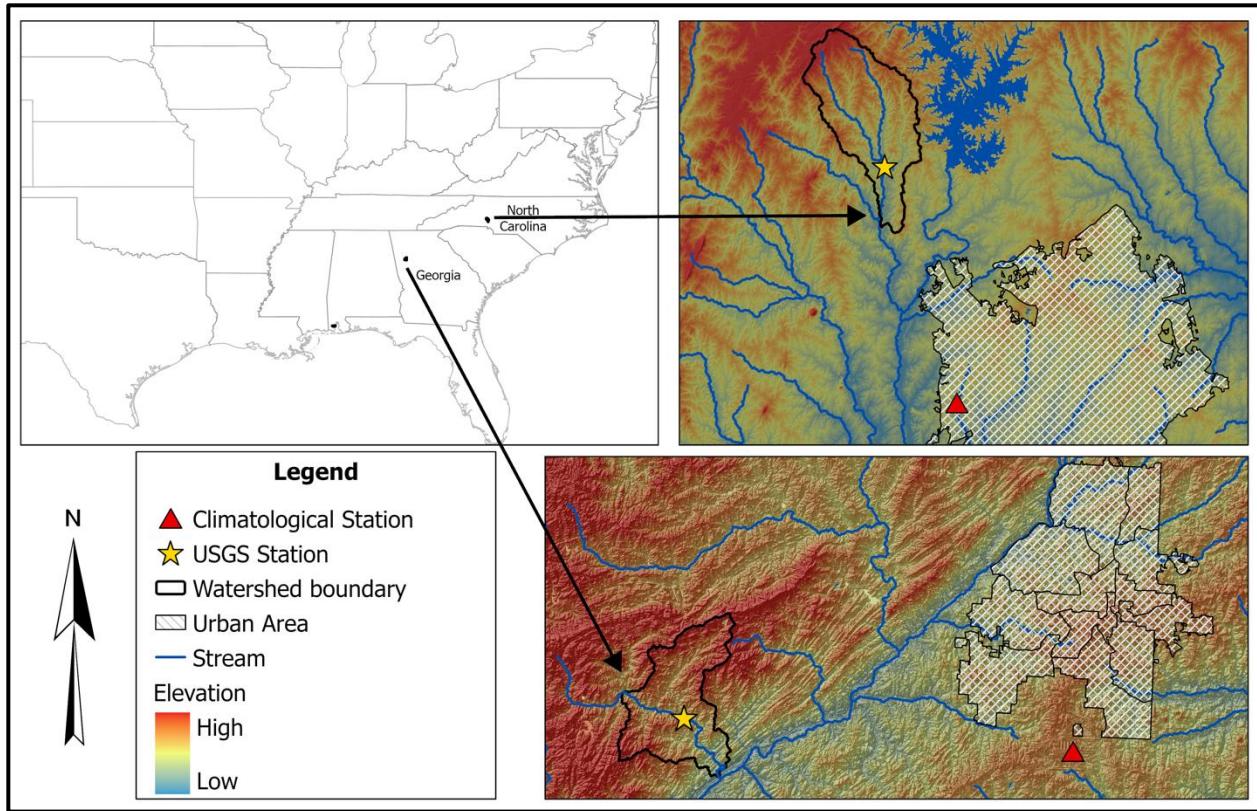

169 The Lower Dog River has experienced significant flooding in the last decades. For example, in September
170 2009, the creek, along with most of northern GA, experienced heavy rainfall (5 inches, equal to 94 mm).
171 The Lower Dog River, overwhelmed by large amounts of overland flow from saturated ground in the
172 watershed, experienced massive flooding in September 2009 (Gotvald, 2010). The river crested at 33.8 feet
173 (10.3 m) with a peak discharge of 59,900 cfs (1,700 m³/s), nearly six times the 100-year flood level
174 (McCallum and Gotvald, 2010). In addition, Dutchmans Creek experienced significant flooding in February
175 2020. According to local news (WCCB Charlotte, 2020), the flood in Gaston County caused significant
176 infrastructure damage and community disruption. Key impacts included the threatened collapse of the
177 Dutchman's Creek bridge in Mt. Holly and the closure of Highway 7 in McAdenville, GA.

178

179 Table 1. The Lower Dog River and Upper Dutchmans Creek's physical characteristics.

Watershed	USGS Station ID	Average Elevation	Stream Length	Watershed area
	Number	(m)	(km)	(km ²)
Lower Dog River watershed, GA	USGS02337410	851.9	25.3	172
Upper Dutchmans Creek watershed, NC	USGS0214269560	642.2	7.9	10.3

180

181

182 Figure 1. The Lower Dog River and The Upper Dutchmans Creek watersheds are in GA and NC. The
 183 proximity of the watersheds to Atlanta and Charlotte (urban area) are also displayed on the map.

184 To provide the meteorological forcing data, i.e., precipitation, temperature, and humidity, were extracted
 185 from the National Oceanic and Atmospheric Administration's (NOAA) Local Climatological Data
 186 (LCD). We used the NOAA precipitation, temperature, and humidity data of Atlanta Hartsfield Jackson
 187 International Airport and Charlotte Douglas Airport stations as an input for neural network algorithms. The
 188 data has been monitored since January 1, 1948, and July 22, 1941, with an hourly interval which was used
 189 as an input variable for constructing neural networks.

190 To fill in the missing values in the data, we used the spline interpolation method. We applied this method
 191 to fill the gaps in time series data, although the missing values were insignificant (less than 1%). In addition,
 192 we employed the Minimum Inter-Event Time (MIT) approach to precisely identify and separate individual
 193 storm events. The MIT-based event delineation is pivotal for accurately defining storm events. This method
 194 allowed us to isolate discrete rainfall episodes, aiding a comprehensive analysis of storm events. Moreover,
 195 it provided a basis for event-specific examination of flood responses, such as initial condition and cessation
 196 (loss), runoff generation, and runoff dynamics.

197 The hourly rainfall dataset consists of distinct rainfall occurrences, some consecutive and others clustered
198 with brief intervals of zero rainfall. As these zero intervals extend, we aim to categorize them into distinct
199 events. It's worth noting that even within a single storm event, we often encounter short periods of no
200 rainfall, known as intra-storm zero values. In the MIT method, we defined a storm event as a discrete rainfall
201 episode surrounded by dry periods both preceding and following it, determined by an MIT (Asquith et al.,
202 2005; Safaei-Moghadam et al., 2023).

203 There are many ways to determine MIT value. One practical approximation is using serial autocorrelation
204 between rainfall occurrences. MIT approach uses autocorrelation that measures the statistical dependency
205 of rainfall data at one point in time with data at earlier, or lagged times within the time series. The lag time
206 represents the gap between data points being correlated. When the lag time is zero, the autocorrelation
207 coefficient is unity, indicating a one-to-one correlation. As the lag time increases, the statistical correlation
208 diminishes, converging to a minimum value. This signifies the fact that rainfall events become
209 progressively less statistically dependent or, in other words, temporally unrelated. To pinpoint the optimal
210 MIT, we analyzed the autocorrelation coefficients for various lag times, observing the point at which the
211 coefficient approaches zero. This lag time signifies the minimum interval of no rainfall, effectively
212 delineating distinct rainfall events.

213

214 **2.2. NN Algorithms**

215 In this study, three distinct neural network (NN) architectures were developed to perform multi-horizon
216 flood forecasting. Each NN was coupled with a MQL objective to generate probabilistic predictions and
217 quantify predictive uncertainty. Throughout the manuscript, the term parameters are used exclusively to
218 refer to the network's weights and biases for clarity and consistency.

219

220 **2.2.1. LSTM**

221 LSTM is an RNN architecture widely used as a benchmark model for flood neural time series
222 modeling. LSTM networks are capable of selectively learning order dependence in sequence prediction
223 problems (Sadeghi Tabas and Samadi, 2022). These networks are powerful because they can capture the
224 temporal features, especially the long-term dependencies (Hochreiter et al., 2001) and are independent of
225 the length of the data sequences input, meaning that each sample is independent from another one.

226 The memory cell state within LSTM plays a crucial role in capturing extended patterns in data, making it
227 well-suited for dynamic time series modeling such as flood prediction. An LSTM cell uses the following
228 functions to compute flood prediction.

$$i_t = \sigma(A_i x_t + B_i h_{t-1} + c_i) \quad (\text{Equation 1})$$

$$f_t = \sigma(A_f x_t + B_f h_{t-1} + c_f) \quad (\text{Equation 2})$$

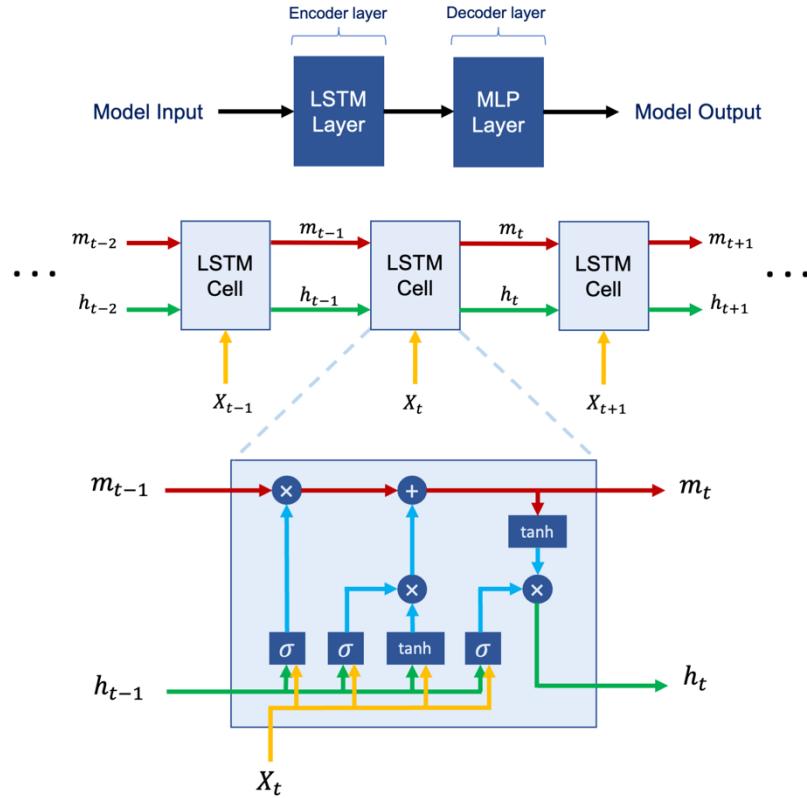

$$o_t = \sigma(A_o x_t + B_o h_{t-1} + c_o) \quad (\text{Equation 3})$$

$$m_t = f_t \odot m_{t-1} + i_t \odot \tanh(A_g x_t + B_g h_{t-1} + c_g) \quad (\text{Equation 4})$$

$$h_t = o_t \odot \tanh(m_t) \quad (\text{Equation 5})$$

229 Where x_t and h_t represent the input and the hidden state at time step t , respectively. \odot denotes element-
230 wise multiplication, \tanh stands for the hyperbolic tangent activation function, and σ represents the
231 sigmoid activation function. A , B , and c are trainable weights and biases that undergo optimization during
232 the training process. m_t and h_t are cell states at time step t that are employed in the input processing for
233 the next time step. m_t represents the memory state responsible for preserving long-term information, while
234 h_t represents the memory state preserving short-term information. The LSTM cell consists of a forget gate
235 f_t , an input gate i_t and an output gate o_t and has a cell state m_t . At every time step t , the cell gets the data
236 point x_t with the output of the previous cell h_{t-1} (Windheuser et al., 2023). The forget gate then defines if
237 the information is removed from the cell state, while the input gate evaluates if the information should be
238 added to the cell state and the output gate specifies which information from the cell state can be used for
239 the next cells.

240 We used two LSTM layers with 128 cells in the first two hidden layers as encoder layers, which were then
241 connected to two multilayer perceptron (MLP) layers with 128 neurons as decoder layers. The LSTM
242 simulation was performed with these input layers along with the *Adam* optimizer (Kingma and Ba,
243 2014), \tanh activation function, and a single lagged dependent-variable value to train with a learning rate
244 of 0.001. The architecture of the proposed LSTM model is illustrated in Figure 2.

245

246 Figure 2. The structure of LSTM programmed in this research. We used *tanh* and *sigmoid* as activation
 247 functions along with 2 layers of LSTM, 2 layers of MLP, and 128 cells in each layer.

248

249 2.2.2. N-BEATS

250 N-BEATS is a deep learning architecture based on backward and forward residual links and the very deep
 251 stack of fully connected layers specifically designed for sequential data forecasting tasks (Oreshkin et al.,
 252 2020). This architecture has several desirable properties including interpretability. The N-BEATS
 253 architecture distinguishes itself from existing architecture in several ways. First, the algorithm approaches
 254 forecasting as a non-linear multivariate regression problem instead of a sequence-to-sequence
 255 challenge. Indeed, the core component of this architecture (as depicted in Figure 3) is a fully connected
 256 non-linear regressor, which takes the historical data from a time series as input and generates multiple data
 257 points for the forecasting horizon. Second, most existing time series architectures are quite limited in depth,
 258 typically consisting of one to five LSTM layers. N-BEATS employs the residual principle to stack a
 259 substantial number of layers together, as illustrated in Figure 3. In this configuration, the basic block not
 260 only predicts the next output but also assesses its contribution to decomposing the input, a concept that is
 261 referred to as "backcast" (see Oreshkin et al. 2020).

262 The basic building block in the architecture features a fork-like structure, as illustrated in Figure 3 (bottom).
 263 The l -th block (for the sake of brevity, the block index l is omitted from Figure 3) takes its respective input,
 264 x_l , and produces two output vectors: \hat{x}_l and \hat{y}_l . In the initial block of the model, x_l corresponds to the
 265 overall model input, which is a historical lookback window of a specific length, culminating with the most
 266 recent observed data point. For the subsequent blocks, x_l is derived from the residual outputs of the
 267 preceding blocks. Each block generates two distinct outputs: 1. \hat{y}_l : This represents the forward forecast of
 268 the block, spanning a duration of H time units. 2. \hat{x}_l : This signifies the block's optimal estimation of x_l ,
 269 which is referred to “backcast.” This estimation is made within the constraints of the functional space
 270 available to the block for approximating signals (Oreshkin et al., 2020).

271 Internally, the fundamental building block is composed of two elements. The initial element involves a
 272 fully connected network, which generates forward expansion coefficient predictors, θ_l^f , and a backward
 273 expansion coefficient predictor, θ_l^b . The second element encompasses both backward basis layers, g_l^b , and
 274 forward basis layers, g_l^f . These layers take the corresponding forward θ_l^f and backward θ_l^b expansion
 275 coefficients as input, conduct internal transformations using a set of basis functions, and ultimately yield
 276 the backcast, \hat{x}_l , and the forecast outputs, \hat{y}_l , as previously described by Oreshkin et al. (2020). The
 277 following equations describe the first element:

$$h_{l,1} = FC_{l,1}(x_l), \quad h_{l,2} = FC_{l,2}(h_{l,1}), \quad h_{l,3} = FC_{l,3}(h_{l,2}), \quad h_{l,4} = FC_{l,4}(h_{l,3}). \quad (\text{Equation 6})$$

$$\theta_l^b = \text{LINEAR}_l^b(h_{l,4}), \quad \theta_l^f = \text{LINEAR}_l^f(h_{l,4}) \quad (\text{Equation 7})$$

278 The LINEAR layer, in essence, functions as a straightforward linear projection, meaning $\theta_l^f = W_l^f h_{l,4}$. As
 279 for the fully connected (FC) layer, it takes on the role of a conventional FC layer, incorporating RELU non-
 280 linearity as an activation function.

281 The second element performs the mapping of expansion coefficients θ_l^f and θ_l^b to produce outputs using
 282 basis layers, resulting in $\hat{y}_l = g_l^f(\theta_l^f)$ and $\hat{x}_l = g_l^b(\theta_l^b)$. This process is defined by the following equation:

$$\hat{y}_l = \sum_{i=1}^{\dim(\theta_l^f)} \theta_{l,i}^f v_i^f, \quad \hat{x}_l = \sum_{i=1}^{\dim(\theta_l^b)} \theta_{l,i}^b v_i^b \quad (\text{Equation 8})$$

283 Within this context, v_i^f and v_i^b represent the basis vectors for forecasting and backcasting, respectively,
 284 while $\theta_{l,i}^f$ corresponds to the i -th element of θ_l^f .

285 The N-BEATS uses a novel hierarchical doubly residual architecture which is illustrated in Figure 3 (top
 286 and middle). This framework incorporates two residual branches, one traversing the backcast predictions

287 of each layer, while the other traverses the forecast branch of each layer. The following equation describes
 288 this process:

$$x_l = x_{l-1} - \hat{x}_{l-1} \quad , \quad \hat{y} = \sum_l \hat{y}_l \quad (\text{Equation 9})$$

289 As mentioned earlier, in the specific scenario of the initial block, its input corresponds to the model-level
 290 input x . In contrast, for all subsequent blocks, the backcast residual branch x_l can be conceptualized as
 291 conducting a sequential analysis of the input signal. The preceding block eliminates the portion of the signal
 292 \hat{x}_{l-1} that it can effectively approximate, thereby simplifying the prediction task for downstream blocks.
 293 Significantly, each block produces a partial forecast \hat{y}_l , which is initially aggregated at the stack level and
 294 subsequently at the overall network level, establishing a hierarchical decomposition. The ultimate forecast
 295 \hat{y} is the summation of all partial forecasts (Oreshkin et al., 2020).

296 The N-BEATS model has two primary configurations: generic and interpretable. These configurations
 297 determine how the model structures its blocks and how it processes time series data. In the generic
 298 configuration, the model uses a stack of generic blocks that are designed to be flexible and adaptable to
 299 various patterns in the time series data. Each generic block consists of fully connected layers with ReLU
 300 activation functions. The key characteristic of generic configuration is its flexibility. Since the blocks are
 301 not specialized for any specific pattern (like trend or seasonality), they can learn a wide range of patterns
 302 directly from the data (Oreshkin et al., 2020). In the interpretable configuration, the model architecture
 303 integrates distinct trend and seasonality components. This involves structuring the basis layers at the stack
 304 level specifically to model these elements, allowing the stack outputs to be more easily understood.

305 **Trend Model:** In this stack $g_{s,l}^b$ and $g_{s,l}^f$ are polynomials of a small degree p , functions that vary slowly
 306 across the forecast window, to replicate monotonic or slowly varying nature of trends:

$$\hat{y}_{s,l} = \sum_{i=0}^p \theta_{s,l,i}^f t^i \quad (\text{Equation 10})$$

307 The time vector $t = [0, 1, 2, \dots, H-2, H-1]^T/H$ is specified on a discrete grid ranging from 0 to
 308 $(H-1)/H$, projecting H steps into the future. Consequently, the trend forecast represented in matrix form is:

$$\hat{y}_{s,l}^{tr} = T \theta_{s,l}^f \quad (\text{Equation 11})$$

309 Where the polynomial coefficients, $\theta_{s,l}^f$, predicted by an FC network at layer l of stack s , are described by
 310 Equations (6) and (7). The matrix T , consisting of powers of t , is represented as $[1, t, \dots, t^p]$. When p is
 311 small, such as 2 or 3, it compels $\hat{y}_{s,l}^{tr}$ to emulate a trend (Oreshkin et al., 2020).

312 Seasonality model: In this stack $g_{s,l}^b$ and $g_{s,l}^f$ are periodic functions, to capture the cyclical and recurring
 313 characteristics of seasonality, such that $y_t = y_{t-\Delta}$, where Δ is the seasonality period. The Fourier series
 314 serves as a natural foundation for modeling periodic functions:

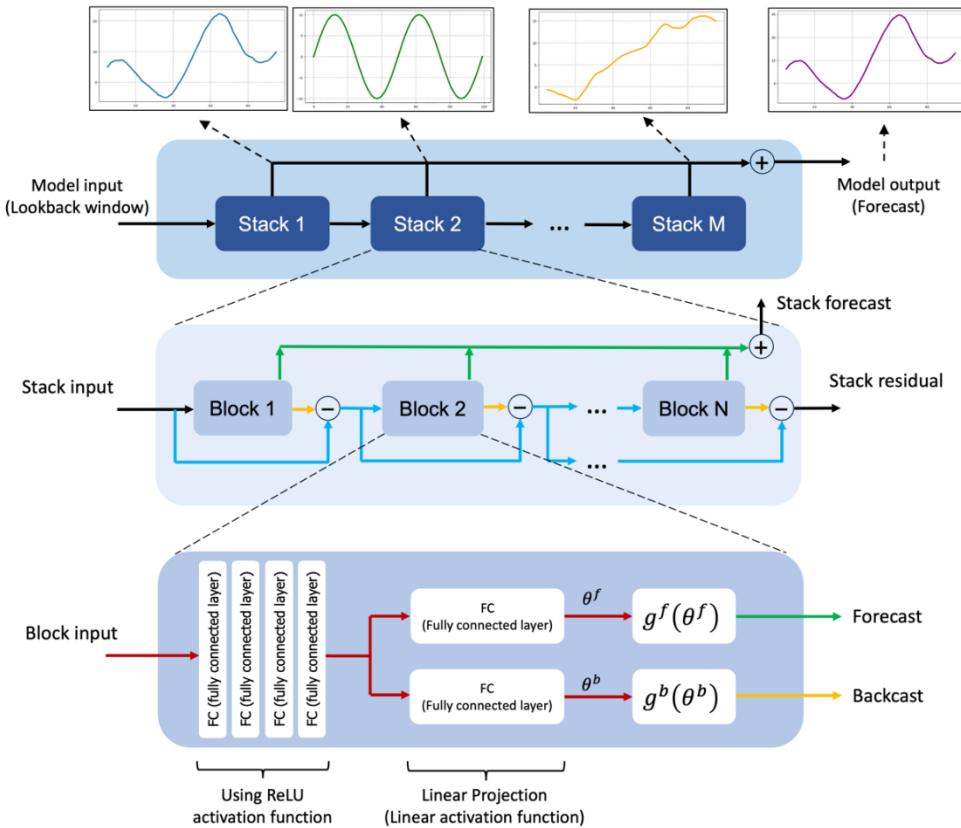

$$\hat{y}_{s,l} = \sum_{i=0}^{\frac{H}{2}-1} \theta_{s,l,i}^f \cos(2\pi i t) + \theta_{s,l,i+[\frac{H}{2}]}^f \sin(2\pi i t) \quad (\text{Equation 12})$$

315 Consequently, the seasonality forecast is represented in the following matrix form:

$$\hat{y}_{s,l}^{seas} = S \theta_{s,l}^f \quad (\text{Equation 13})$$

$$S = [1, \cos(2\pi t), \dots, \cos\left(2\pi \left[\frac{H}{2}-1\right] t\right), \sin(2\pi t), \dots, \sin\left(2\pi \left[\frac{H}{2}-1\right] t\right)] \quad (\text{Equation 14})$$

316 Where the Fourier coefficients $\theta_{s,l}^f$, that predicted by an FC network at layer 1 of stack s , are described by
 317 Equations (6) and (7). The matrix S represents sinusoidal waveforms. As a result, the forecast $\hat{y}_{s,l}^{seas}$
 318 becomes a periodic function that imitates typical seasonal patterns (Oreshkin et al., 2020).

319

320

Figure 3. The N-BEATS modeling structure, used in this research.

321 **2.2.3. N-HiTS**

322 N-HiTS builds upon the N-BEATS architecture but with improved accuracy and computational efficiency
 323 for long-horizon forecasting. N-HiTS utilizes multi-rate sampling and multi-scale synthesis of forecasts,
 324 leading to a hierarchical forecast structure that lowers computational demands and improves prediction
 325 accuracy (Challu et al., 2022).

326 Like N-BEATS, N-HiTS employs local nonlinear mappings onto foundational functions within numerous
 327 blocks. Each block includes an MLP that generates backcast and forecast output coefficients. The backcast
 328 output refines the input data for the following blocks, and the forecast outputs are combined to generate the
 329 final prediction. Blocks are organized into stacks, with each stack dedicated to grasping specific data
 330 attributes using its own distinct set of functions. The network's input is a sequence of L lags (look-back
 331 period), with S stacks, each containing B blocks (Challu et al., 2022).

332 In each block, a *MaxPool* layer with varying kernel sizes (k_l) is employed at the input, enabling the block
 333 to focus on specific input components of different scales. Larger kernel sizes emphasize the analysis of
 334 larger-scale, low-frequency data, aiding in improving long-term forecasting accuracy. This approach,
 335 known as multi-rate signal sampling, alters the effective input signal sampling rate for each block's MLP
 336 (Challu et al., 2022).

337 Additionally, multi-rate processing has several advantages. It reduces memory usage, computational
 338 demands, and the number of learnable parameters, and helps prevent overfitting, while preserving the
 339 original receptive field. The following operation is applicable to the input $y_{t-L:t,l}$ of each block, with the
 340 first block ($l = 1$) using the network-wide input, where $y_{t-L:t,1} \equiv y_{t-L:t}$.

$$y_{t-L:t,l} = \text{MaxPool} (y_{t-L:t,l}, k_l) \quad (\text{Equation 15})$$

341 In many multi-horizon forecasting models, the number of neural network predictions matches the horizon's
 342 dimensionality, denoted as H . For instance, in N-BEATS, the number of predictions $|\theta_l^f| = H$. This results
 343 in a significant increase in computational demands and an unnecessary surge in model complexity as the
 344 horizon H becomes larger (Challu et al., 2022).

345 To address these challenges, N-HiTS proposes the use of temporal interpolation. This model manages the
 346 parameter counts per unit of output time ($|\theta_l^f| = [r_l H]$) by defining the dimensionality of the interpolation
 347 coefficients with respect to the expressiveness ratio r_l . To revert to the original sampling rate and predict
 348 all horizon points, this model employs temporal interpolation through the function g :

$$\hat{y}_{\tau,l} = g(\tau, \theta_l^f), \quad \forall \tau \in \{t + 1, \dots, t + H\}, \quad (\text{Equation 16})$$

$$\tilde{y}_{\tau,l} = g(\tau, \theta_l^b), \quad \forall \tau \in \{t-L, \dots, t\}, \quad (\text{Equation 17})$$

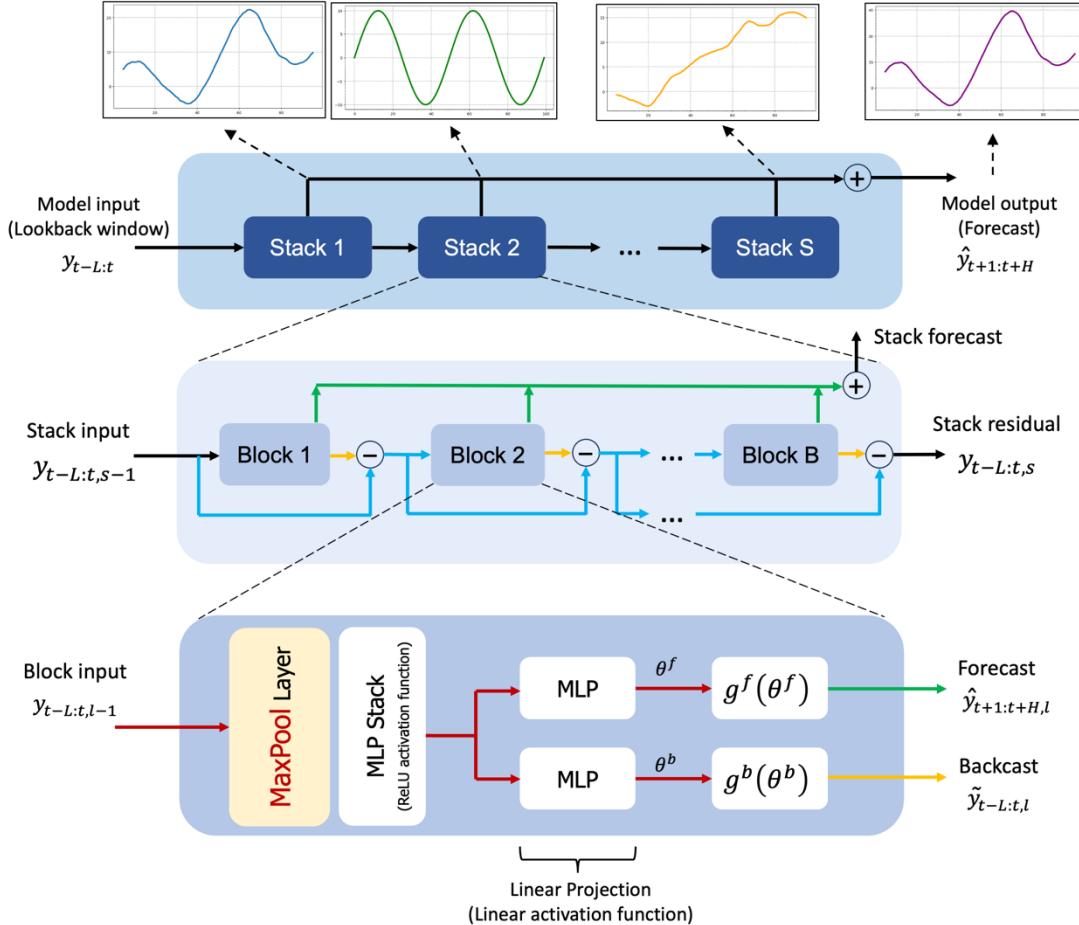

$$g(\tau, \theta) = \theta[t_1] + \left(\frac{\theta[t_2] - \theta[t_1]}{t_2 - t_1} \right) (\tau - t_1) \quad (\text{Equation 18})$$

$$t_1 = \arg \min_{t \in \tau: t \leq \tau} \tau - t, \quad t_2 = t_1 + 1/r_l \quad (\text{Equation 19})$$

349 The hierarchical interpolation approach involves distributing expressiveness ratios over blocks, integrated
 350 with multi-rate sampling. Blocks closer to the input employ more aggressive interpolation, generating lower
 351 granularity signals. These blocks specialize in analyzing more aggressively subsampled signals. The final
 352 hierarchical prediction, $\hat{y}_{t+1:t+H}$, is constructed by combining outputs from all blocks, creating
 353 interpolations at various time-scale hierarchy levels. This approach maintains a structured hierarchy of
 354 interpolation granularity, with each block focusing on its own input and output scales (Challu et al., 2022).
 355 To manage a diverse set of frequency bands while maintaining control over the number of parameters,
 356 exponentially increasing expressiveness ratios are recommended. As an alternative, each stack can be
 357 dedicated to modeling various recognizable cycles within the time series (e.g., weekly, or daily) employing
 358 matching r_l . Ultimately, the residual obtained from backcasting in the preceding hierarchy level is
 359 subtracted from the input of the subsequent level, intensifying the next-level block's attention on signals
 360 outside the previously addressed band (Challu et al., 2022).

$$\hat{y}_{t+1:t+H} = \sum_{l=1}^L \hat{y}_{t+1:t+H,l} \quad (\text{Equation 20})$$

$$y_{t-L:t,l+1} = y_{t-L:t,l} - \tilde{y}_{t-L:t,l} \quad (\text{Equation 21})$$

361

362 Figure 4. The structure of N-HiTS model programmed in this study. The architecture includes several
 363 Stacks, each Stack includes several Block, where each block consists of a MaxPool layer and a multi-
 364 layer which learns to produce coefficients for the backcast and forecast outputs of its basis.

365

366 2.3. Performance Metrics

367 To comprehensively evaluate the accuracy of flood predictions, we utilized a suite of metrics, including
 368 Nash-Sutcliffe Efficiency (NSE; Nash and Sutcliffe, 1970), persistent Nash-Sutcliffe Efficiency (persistent-
 369 NSE), Kling–Gupta efficiency (KGE; Gupta et al. 2009), Root Mean Square Error (RMSE), Mean
 370 Absolute Error (MAE), Peak Flow Error (PFE), and Time to Peak Error (TPE; Evin et al., 2023; Lobligeois
 371 et al., 2014). These metrics collectively facilitate a rigorous assessment of the model's performance in
 372 reproducing the magnitude of observed peak flows and the shape of the hydrograph.

373 NSE measures the model's ability to explain the variance in observed data and assesses the goodness-of-fit
 374 by comparing the observed and simulated hydrographs. In hydrological studies, the NSE index is a widely
 375 accepted measure for evaluating the fitting quality of models (McCuen et al., 2006). It is calculated as:

$$NSE = 1 - \frac{\sum_{i=1}^n (Q_{s_i} - Q_{o_i})^2}{\sum_{i=1}^n (Q_{o_i} - \bar{Q}_o)^2} \quad (\text{Equation 22})$$

376 Where Q_{o_i} represents observed value at time i , Q_{s_i} represents simulated value at time i , \bar{Q}_o is the mean
 377 observed values and n is the number of data points. An NSE value of 1 indicates a perfect match between
 378 the observed and modeled data, while lower values represent the degree of departure from a perfect fit.

379 As the models are designed to predict one hour ahead in one of the prediction horizons, the persistent-NSE
 380 is essential for evaluating their performance. The standard NSE measures the model's sum of squared errors
 381 relative to the sum of squared errors when the mean observation is used as the forecast value. In contrast,
 382 persistent-NSE uses the most recent observed data as the forecast value for comparison (Nevo et al., 2022).
 383 The persistent NSE is calculated as:

$$persistent - NSE = 1 - \frac{\sum_{i=1}^n (Q_{s_i} - Q_{o_i})^2}{\sum_{i=1}^n (Q_{o_i} - Q_{o_{i-1}})^2} \quad (\text{Equation 23})$$

384 Where Q_{o_i} represents the observed value at time i , Q_{s_i} represents the simulated value at time i , $Q_{o_{i-1}}$ is the
 385 observed value at the last time step ($i - 1$) and n is the number of data points.

386 The KGE is a widely used performance metric in hydrological modeling and combines multiple aspects of
 387 model performance, including correlation, variability bias, and mean bias. The KGE metric is calculated
 388 using the following equation:

$$KGE = 1 - \sqrt{(r - 1)^2 + (\alpha - 1)^2 + (\beta - 1)^2} \quad (\text{Equation 24})$$

389 Where r represents Pearson correlation coefficient between observed Q_o and simulated Q_s values.
 390 α represents bias ratio, calculated as $\alpha = \frac{\mu_s}{\mu_o}$ where μ_s and μ_o are the means of simulated and observed data,
 391 respectively. β represents variability ratio, calculated as $\beta = \frac{\sigma_s/\mu_s}{\sigma_o/\mu_o}$ where σ_s and σ_o are the standard
 392 deviations of simulated and observed data, respectively.

393 RMSE quantifies the average magnitude of errors between observed and modeled values, offering insights
 394 into the absolute goodness-of-fit, while MAE is a measure of the average absolute difference between the
 395 modeled values and the observed values and provides a measure of the average magnitude of errors. RMSE
 396 is calculated as:

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (Q_{o_i} - Q_{s_i})^2} \quad (\text{Equation 25})$$

397 and MAE is calculated as:

$$MAE = \frac{1}{n} \sum_{i=1}^n |Q_{o_i} - Q_{s_i}| \quad (\text{Equation 26})$$

398 Where Q_{o_i} represents observed value at time i , Q_{s_i} represents simulated value at time i , and n is the number
399 of data points. RMSE and MAE provide information about the magnitude of modeling errors, with smaller
400 values indicating a better model fit.

401 PFE quantifies the magnitude disparity between observed and modeled peak flow values. The PFE metric
402 is defined as:

$$PFE = \frac{|Q_{o_{max}} - Q_{s_{max}}|}{Q_{o_{max}}} \quad (\text{Equation 27})$$

403 Where $Q_{o_{max}}$ represents the observed peak flow value, and $Q_{s_{max}}$ signifies the simulated peak flow value.
404 The PFE metric, expressed as a dimensionless value, provides a quantitative measure of the relative error
405 in predicting peak flow magnitudes concerning the observed values. A smaller PFE denotes more accurate
406 modeling of peak flow magnitudes, with a value of zero indicating a perfect match.

407 TPE assesses the temporal alignment of peak flows in the observed and modeled hydrographs. The TPE
408 metric is computed as:

$$TPE = |T_{o_{max}} - T_{s_{max}}| \quad (\text{Equation 28})$$

409 Where $T_{o_{max}}$ signifies the time at which the peak flow occurs in the observed hydrograph, and $T_{s_{max}}$
410 represents the time at which the peak flow occurs in the simulated hydrograph. TPE that is measured in
411 units of time (hours), provides insight into the precision of peak flow timing. Smaller TPE values indicate
412 a superior alignment between the observed and modeled peak flow timing, while larger TPE values indicate
413 discrepancies in the temporal occurrence of peak flows.

414 The utilization of these five metrics, PFE, persistent-NSE, TPE, NSE, and RMSE, collectively provides a
415 robust and multifaceted assessment of flood prediction performance. This approach ensures that both the
416 magnitude and timing of peak flows, as well as the overall hydrograph shape, are accurately calibrated and
417 validated.

418

419 **2.4. Sensitivity and Uncertainty Analysis**

420 When implementing NN models, it's crucial to understand how each input feature affects the model's
421 performance or outputs. To achieve this, we systematically excluded each input feature from the model one
422 by one (the Leave-One-Out method). For each exclusion, we retrained the model without that specific input
423 feature and then tested its performance against a test dataset. This method helps in understanding which
424 input features are most critical to the model's performance and which ones have a lesser impact. It also
425 allows us to identify any input features that may be redundant or have little effect on the overall outcome,
426 thus potentially simplifying the model without sacrificing accuracy.

427 In this study, we utilized probabilistic approaches to quantify the uncertainty in flood prediction. This
428 method is rooted in statistical techniques employed for the estimation of unknown probability distributions,
429 with a foundation in observed data. More specifically, we leveraged the Maximum Likelihood Estimation
430 (MLE) approach, which entails the determination of MQL objective values that optimize the likelihood
431 function. The likelihood function quantifies the probability of MQL objective taking values, given the
432 observed realizations.

433 We incorporated the MQL as a probabilistic error metric into algorithmic architecture. MQL performs an
434 evaluation by computing the average loss for a predefined set of quantiles. This computation is grounded
435 in the absolute disparities between predicted quantiles and their corresponding observed values. By
436 considering multiple quantile levels, MQL provides a comprehensive assessment of the model's ability to
437 capture the distribution of the target variable, rather than focusing solely on point estimates.

438 The MQL metric also aligns closely with the Continuous Ranked Probability Score (CRPS), a standard tool
439 for evaluating predictive distributions. CRPS measures the difference between the predicted cumulative
440 distribution function and the observed values by integrating over all possible quantiles. The computation of
441 CRPS involves a numerical integration technique that discretizes quantiles and applies a left Riemann
442 approximation for CRPS integral computation. This process culminates in the averaging of these
443 computations over uniformly spaced quantiles, providing a robust evaluation of the predictive distribution
444 \hat{F}_t .

$$\text{MQL} (Q_\tau, [\hat{Q}_\tau^{q_1}, \dots, \hat{Q}_\tau^{q_i}]) = \frac{1}{n} \sum_{q_i} \text{QL} (Q_\tau, \hat{Q}_\tau^{q_i}) \quad (\text{Equation 29})$$

$$\text{CRPS} (Q_\tau, \hat{F}_t) = \int_0^1 \text{QL} (Q_\tau, \hat{Q}_\tau^{q_i}) dq \quad (\text{Equation 30})$$

$$\text{QL}(Q_\tau, \hat{Q}_\tau^q) = \frac{1}{H} \sum_{\tau=t+1}^{t+H} ((1-q)(\hat{Q}_\tau^q - Q_\tau) + q(Q_\tau - \hat{Q}_\tau^q)) \quad (\text{Equation 31})$$

445 Where Q_τ represents observed value at time τ , \hat{Q}_τ^q represents simulated value at time τ , q is the slope of the
446 quantile loss, and H is the horizon of forecasting.

447 Implementation-wise, let $\mathcal{D} = \{(X_t, y_{t+h})\}_{t=1}^N$ denote training pairs, where X_t is the past 24-h discharge
448 context and y_{t+h} the discharge h hours ahead. For a fixed horizon h and quantile levels $\{\tau_k\}_{k=1}^K$, each
449 model f_θ outputs the vector of conditional quantiles:

$$\hat{\mathbf{Q}}_{t+h} = f_\theta(X_t) = (\hat{Q}_{t+h}^{\tau_1}, \dots, \hat{Q}_{t+h}^{\tau_K}) \in \mathbb{R}^K \quad (\text{Equation 32})$$

450 Parameters θ are learned by minimizing the multi-quantile (pinball) loss:

$$\mathcal{L}(\theta) = \frac{1}{NK} \sum_{t=1}^N \sum_{k=1}^K \rho_{\tau_k} (y_{t+h} - \hat{Q}_{t+h}^{\tau_k}), \quad (\text{Equation 33})$$

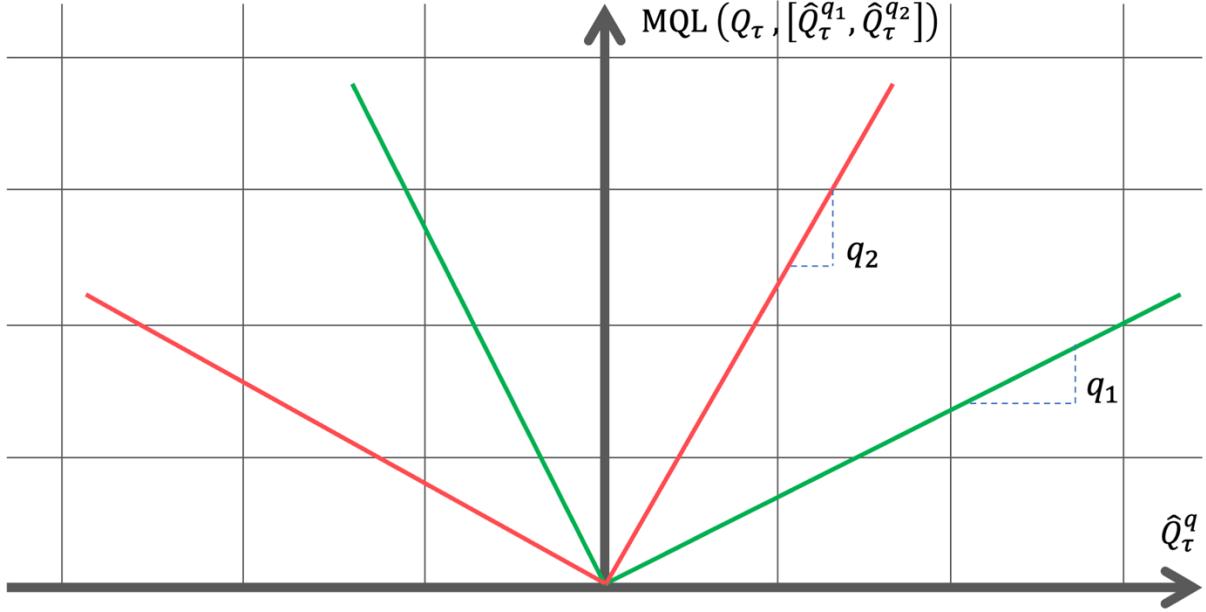

$$\rho_\tau(u) = \max(\tau u, (\tau - 1)u) = (\tau - \mathbb{1}_{\{u<0\}}) u$$

451 Because ρ_τ is convex and piecewise linear, its (sub)gradient with respect to $\hat{Q}_{t+h}^{\tau_k}$ is:

$$\frac{\partial \rho_\tau(y - \hat{Q}^\tau)}{\partial \hat{Q}^\tau} = \begin{cases} -(1-\tau), & y - \hat{Q}^\tau < 0, \\ -\tau, & y - \hat{Q}^\tau > 0, \end{cases} \quad (\text{Equation 34})$$

452 enabling backpropagation (Adam) without any sampling. Thus, each quantile $\hat{Q}_{t+h}^{\tau_k}$ is a direct network
453 output learned to satisfy the quantile condition under ρ_τ . Uncertainty intervals are formed from these
454 quantile predictions; for a 95% band we use $[\hat{Q}_{t+h}^{0.025}, \hat{Q}_{t+h}^{0.975}]$. The resulting bands quantify the uncertainty
455 conditional on X_t .

456 Incorporating MQL as a central metric in our study underscores its suitability for probabilistic forecasting,
457 particularly in the context of uncertainty quantification. Unlike traditional error metrics that focus on point
458 predictions, MQL captures both central tendencies and variability by penalizing errors symmetrically across
459 quantiles. This property ensures balanced and reliable assessments of the predictive distribution, ultimately
460 enhancing the robustness and interpretability of flood prediction models.

461

462 Figure 5. The MQL function which shows loss values for different values of q when the true value is Q_τ .

463 Furthermore, we employed two key indices, the R-Factor and the P-Factor, to rigorously assess the quality
 464 of uncertainty performance in our hydrological modeling. These metrics are instrumental in quantifying the
 465 extent to which the model's predictions encompass the observed data, thereby providing valuable insights
 466 into the model's predictive accuracy and reliability.

467 The P-Factor, or percentage of data within 95PPU, is the first index used in this assessment. The P-Factor
 468 quantifies the percentage of observed data that falls within the 95PPU, providing a measure of the model's
 469 predictive accuracy. The P-Factor can theoretically vary from 0% to a maximum of 100%. A P-Factor of
 470 100% signifies a perfect alignment between the model's predictions and the observed data within the
 471 uncertainty band. In contrast, a lower P-Factor indicates a reduced ability of the model to predict data within
 472 the specified uncertainty range.

$$P - Factor = \frac{Observations bracketed by 95PPU}{Number of observations} \times 100 \quad (\text{Equation 35})$$

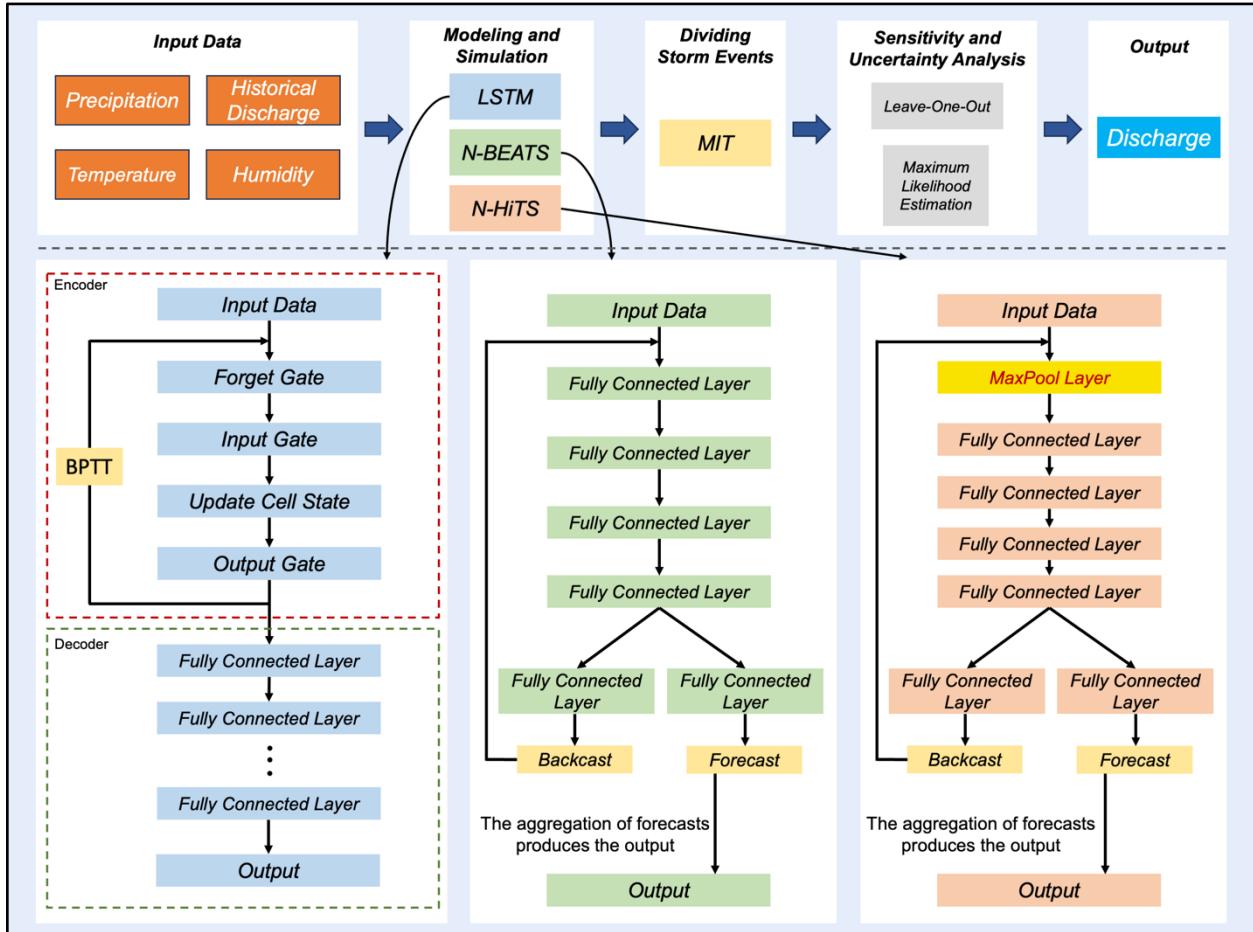

473 The R-Factor can be computed by dividing the average width of the uncertainty band by the standard
 474 deviation of the measured variable. The R-Factor, with a minimum possible value of zero, provides a
 475 measure of the spread of uncertainty relative to the variability of the observed data. Theoretically, the R-
 476 Factor spans from 0 to infinity, and a value of zero implies that the model's predictions precisely match the
 477 measured data, with the uncertainty band being very narrow in relation to the variability of the observed
 478 data.

$$R - Factor = \frac{Average\ width\ of\ 95PPU\ band}{Standard\ deviation\ of\ measured\ variables} \times 100 \quad (\text{Equation 36})$$

479 In practice, the quality of the model is assessed by considering the 95% prediction band with the highest P-
 480 Factor and the lowest R-Factor. This specific band encompasses most observed records, signifying the
 481 model's ability to provide accurate and reliable predictions while effectively quantifying uncertainty. A
 482 simulation with a P-Factor of 1 and an R-Factor of 0 signifies an ideal scenario where the model precisely
 483 matches the measured data within the uncertainty band (Abbaspour et al., 2007).

484 Figure 6 shows the workflow of programming N-BEATS, N-HiTS, and LSTM for flood prediction. As
 485 illustrated, the initial step involved cleaning and preparing the input data, which was then used to feed the
 486 models. The workflow for each model and their output generation processes are depicted in Figure 6. We
 487 segmented the storm events using the MIT approach, as previously described. Following this, we conducted
 488 a sensitivity analysis using the Leave-One-Out method and performed uncertainty analysis using the MLE
 489 approach to construct the 95PPU band. This rigorous methodology ensures a robust evaluation of model
 490 performance under varying conditions and highlights the models' predictive reliability and resilience. We
 491 employed the "NeuralForecast" Python package to develop the N-BEATS, N-HiTS, and LSTM models.
 492 This package provides a diverse array of NN models with an emphasis on usability and robustness.

493

496 Figure 6. The workflow of N-BEATS, N-HiTS, and LSTM implementation. The upper section of the
497 figure illustrates multiple steps from data preprocessing to model evaluation. The lower section provides a
498 detailed view of the workflow and implementation for each model, highlighting the specific processes and
499 methodologies employed in generating the outputs. Backpropagation Through Time (BPTT) trains LSTM
500 by unrolling the model through time, computing gradients for each time step, and updating weights based
501 on temporal dependencies.

503 3. Results and Discussion

504 3.1. Independent Storms Delineation

505 MIT's contextual delineation of storm events laid the groundwork for in-depth evaluation of rainfall events,
506 enabling isolation and separation of rainfall events that led to significant flooding events. The nuanced
507 outcomes of the MIT assessment contributed significantly to the understanding of rainfall variability and
508 distribution as the dominant contributor to flood generation.

509 During modeling implementation, the initial imperative was the precise distinction of storm events within
510 the precipitation time series data of each case study. Our findings demonstrate that on average a dry period
511 of 7 hours serves as the optimal MIT time for both of our case studies. This outcome signifies that when a
512 dry interval of more than 7 hours transpires between two successive rainfall events, these subsequent
513 rainfalls should be considered two distinct storm events. This determination underlines the temporal
514 threshold necessary for distinguishing between individual meteorological phenomena in two case studies.

515

516 **3.2. Hyperparameter Optimization**

517 In the context of hyperparameter optimization, we systematically considered and tuned various
518 hyperparameters for the N-HiTS, N-BEATS, and LSTM. We searched for learning rates on a log-uniform
519 grid between 1×10^{-4} and 1×10^{-3} , batch sizes {16, 32, 64}, input size {1, 6, 12, 24} hours. For the
520 LSTM, recurrent layers {1,2,3}, hidden units per layer {64,128,256}, activation {tanh, ReLU}, decoder
521 MLP depth {1,2,3}, and decoder MLP width {64,128,256} were varied during the simulation run. For N-
522 HiTS, stacks {2,3,4}, blocks per stack {2,3,4,5}, block MLP width {64,128,256}, and block MLP depth
523 {2,3,4} were explored. For N-BEATS, we searched stacks {2,3,4}, blocks per stack {2,3,4,5}, block MLP
524 width {64,128,256}, and block MLP depth {2,3,4}; the interpretable (trend/seasonality) basis was kept
525 fixed. Following extensive exploration and fine-tuning of these hyperparameters, the optimal
526 configurations were identified (see Table 2). For the N-HiTS model, the most favorable outcomes were
527 achieved with the following hyperparameter settings: 2000 epochs, "identity" for scaler type, a learning rate
528 of 0.001, a batch size of 32, input size of 24 hours, "identity" for stack type, 512 units for hidden layers of
529 each stack, step size of 1, MQLoss as loss function, and "ReLU" for the activation function. As shown in
530 Table 2, the N-HiTS model demonstrated superior performance with 4 stacks, containing 2 blocks each,
531 and corresponding coefficients of 48, 24, 12, and 1, showcasing the significance of these settings for flood
532 prediction.

533 This hyperparameter optimization was also conducted for the N-BEATS model. In this model, we
534 considered 2000 epochs, 3 stacks with 2 blocks, "identity" for scaler type, a learning rate of 0.001, a batch
535 size of 32, input size of 24 hours, "identity" for stack type, 512 units for hidden layers of each stack, step
536 size of 1, MQLoss as loss function, and "ReLU" for the activation function.

537 Moreover, the LSTM as a benchmark model yielded its best results with 5000 epochs, an input size of 24
538 hours, "identity" as the scaler type, a learning rate of 0.001, a batch size of 32, and "tanh" as the activation
539 function. Furthermore, LSTM's hidden state was most effective with two layers containing 128 units, and
540 the MLP decoder thrived with two layers encompassing 128 units. These meticulously optimized

541 hyperparameter settings represent the culmination of efforts to ensure that each model operates at its peak
542 potential, facilitating accurate flood prediction.

543 Table 2. Optimized values for the hyperparameters.

Hyperparameter	N-HiTS	N-BEATS	LSTM
Epoch	2000	2000	5000
Scaler type	identity	identity	standard
Learning rate	0.001	0.001	0.001
Batch size	32	32	32
Input size	24 hours	24 hours	24 hours
Stack type	Seasonality, trend, identity, identity	Seasonality, trend, identity	*
Number of units in each hidden layer	512	512	128
Loss function	MQLoss	MQLoss	MQLoss
Activation function	ReLU	ReLU	tanh
Number of stacks	4	3	*
Number of blocks in each stack	2	2	*
Stacks' coefficients	48,24,12,1	*	*

544 *Not applicable

545 In Table 2, "epoch" refers to the number of training steps, and "scaler type" indicates the type of scaler used
546 for normalizing temporal inputs. The "learning rate" specifies the step size at each iteration while optimizing
547 the model, and the "batch size" represents the number of samples processed in one forward and backward
548 pass. The "loss function" quantifies the difference between the predicted outputs and the actual target
549 values, while the "activation function" determines whether a neuron should be activated. The "stacks'
550 coefficients" in the N-HITS model control the frequency specialization for each stack, enabling effective
551 handling of different frequency components in the time series data.

552 Another hyperparameter for all three models is input size, which is a variable that determines the maximum
553 sequence length for truncated backpropagation during training and the number of autoregressive inputs
554 (lags) that the models considered for prediction. Essentially, input size represents the length of the historical
555 series data used as input to the model. This variable offers flexibility in the models, allowing them to learn
556 from a defined window of past observations, which can range from the entire historical dataset to a subset,

557 tailored to the specific requirements of the prediction task. In the context of flood prediction, determining
558 the appropriate input size is crucial to adequately capture the meteorological data preceding the flood event.
559 To address this, we calculated the time of concentration (*TC*) of the watershed system and set the input size
560 to exceed this duration. According to the Natural Resources Conservation Service (NRCS), for typical
561 natural watershed conditions, the *TC* can be calculated from lag time, the time between peak rainfall and
562 peak discharge, using the formula: $\text{Lag time} = \text{TC} \times 0.6$ (NRCS, 2009). Specifically, the average *TC* in
563 the Lower Dog River watershed and Upper Dutchmans Creek watershed was found to be 19 and 22 hours,
564 respectively. As these represent the average *TC* for our case studies, we selected the 24 hours for input data,
565 slightly longer than the average *TC*, ensuring sufficient coverage of relevant meteorological data preceding
566 all flood events.

567

568 **3.3. Flood Prediction and Performance Assessment**

569 In this study, we conducted a comprehensive performance evaluation of N-HiTS, N-BEATS, and
570 benchmarked these models with LSTM, utilizing two case studies: the Lower Dog River and the Upper
571 Dutchmans Creek watersheds. Within these case studies, we trained and validated the models separately
572 for each watershed across a diverse set of storm events from 01/10/2007 to 01/10/2022 (15 years) in the
573 Lower Dog River and from 21/12/1994 to 01/10/2022 (27 years) in the Upper Dutchmans Creek. The
574 decision to train separate models for each catchment was made to account for the unique hydrological
575 characteristics and local features specific to each watershed. By training models individually, we aimed to
576 optimize performance by tailoring each model to the distinct rainfall-runoff relationship inherent in each
577 catchment. All algorithms were tested using unseen flooding events that occurred between 14/12/2022 and
578 28/03/2023. Our targets were event-focused, where operational value focuses on performance during rising
579 limbs, peaks, and recessions. Evaluating over the entire continuous hydrograph (testing period) can dilute
580 or even mask differences. For this reason, we prioritized an event-centric assessment as the primary
581 evaluation approach rather than full-period metrics. In the Dog River gauging station, two winter storms,
582 i.e., January 3rd to January 5th, 2023 (Event 1) and February 17th to February 18th, 2023 (Event 2), as well
583 as a spring flood event that occurred during March 26th to March 28th, 2023 (Event 3) were selected for
584 testing. Additionally, three winter flooding events, i.e., December 14th to December 16th, 2022 (Event 4),
585 January 25th and January 26th, 2023 (Event 5), and February 11th to February 13th, 2023 (Event 6), were
586 chosen to test the algorithms across the Killian Creek gauging station in the Upper Dutchmans Creek. The
587 rainfall events corresponding to these flooding events were delineated using the MIT technique discussed
588 in Section 3.1.

589 Our results for the Lower Dog River case study explicitly demonstrated the accuracy of both N-HiTS and
590 N-BEATS in generating the winter and spring flood hydrographs compared to the LSTM model across all
591 selected storm events. Although, N-HiTS prediction slightly outperformed N-BEATS during winter
592 prediction (January 3rd to January 5th, 2023). In this event, N-HiTS outperformed N-BEATS with a
593 difference of 11.6% in MAE and 20% in RMSE. The N-HiTS slight outperformance (see Tables 3 and 4)
594 is attributed to its unique structure that allows the model to discern and capture intricate patterns within the
595 data. Specifically, N-HiTS predicted flooding events hierarchically using blocks specialized in different
596 rainfall frequencies based on controlled signal projections, through expressiveness ratios, and interpolation
597 of each block. The coefficients are then used to synthesize backcast through
598 $\tilde{y}_t - L: t, l$ and forecast $(\tilde{y}_{t+1}: t + H, l)$ outputs of the block as a flood value. The coefficients were locally
599 determined along the horizon, allowing N-HiTS to reconstruct nonstationary signals over time.

600 While the N-HiTS emerged as the most accurate in predicting flood hydrograph among the three models,
601 its performance was somehow comparable with N-BEATS. The N-BEATS model exhibited good
602 performance in two case studies. It consistently provided competitive results, demonstrating its capacity to
603 effectively handle diverse storm events and deliver reliable predictions. N-BEATS has a generic and
604 interpretable architecture depending on the blocks it uses. Interpretable configuration sequentially projects
605 the signal into polynomials and harmonic basis to learn trend and seasonality components while generic
606 configuration substitutes the polynomial and harmonic basis for identity basis and larger network's depth.
607 In this study, we used interpretable architecture, as it regularizes its predictions through projections into
608 harmonic and trend basis that is well-suited for flood prediction tasks. Using interpretable architecture,
609 flood prediction was aggregated in a hierarchical fashion. This enabled the building of a very deep neural
610 network with interpretable flood prediction outputs.

611 It is essential to underscore that, despite its strong performance, the N-BEATS model did not surpass the
612 N-HiTS model in terms of NSE, Persistent-NSE, MAE, and RMSE for the Lower Dog River case study.
613 Although both models showed almost the same KGE values. Notably, the N-BEATS model showcased
614 superior results based on the PFE metric, signifying its exceptional capability in accurately predicting flood
615 peaks. However, both N-HiTS and N-BEATS models overestimated the flood peak rate of Event 2 for the
616 Lower Dog River watershed. This event, which occurred from February 17th to February 18th, 2023, was
617 flashy, short, and intense proceeded by a prior small rainfall event (from February 12th until February 13th)
618 that minimized the rate of infiltration. This flash flood event caused by excessive rainfall in a short period
619 of time (<8 hours) was challenging to predict for N-BEATS and N-HiTS models. In addition, predicting
620 the magnitude of changes in the recession curve of the third event seems to be a challenge for both models.
621 The specific part of the flood hydrograph after the precipitation event, where flood diminishes during a

rainless is dominated by the release of runoff from shallow aquifer systems or natural storages. It seems both models showed a slight deficiency in capturing this portion of the hydrograph when the rainfall amount decreases over time in the Dog River gauging station.

Conversely, in the Killian Creek gauging station, the N-BEATS model almost emerged as the top performer in predicting the flood hydrograph based on NSE, Persistent-NSE, RMSE, and PFE performance metrics (see Tables 3 and 4). KGE values remained almost the same for both models. In addition, both N-BEATS and N-HiTS slightly overpredicted time to peak values for Event 5. This reflects the fact that when rainfall varies randomly around zero, it provides less to no information for the algorithms to learn the fluctuations and patterns in time series data. Both N-HiTS and N-BEATS provided comparable results for all events predicted in this study. N-HiTS builds upon N-BEATS by adding a MaxPool layer at each block. Each block consists of an MLP layer that learns how to produce coefficients for the backcast and forecast outputs. This subsamples the time series and allows each stack to focus on either short-term or long-term effects, depending on the pooling kernel size. Then, the partial predictions of each stack are combined using hierarchical interpolation. This ability enhances N-HiTS capabilities to produce drastically improved, interpretable, and computationally efficient long-horizon flood predictions.

In contrast, the performance of LSTM as a benchmark model lagged behind both N-HiTS and N-BEATS models for all events across two case studies. Despite its extensive applications in various hydrology domains, the LSTM model exhibited comparatively lower accuracy when tasked with predicting flood responses during different storm events. Focusing on NSE, Persistent-NSE, KGE, MAE, RMSE, and PFE metrics, it is noteworthy that all three models, across both case studies, consistently succeeded in capturing peak flow rates at the appropriate timing. All models demonstrated commendable results with respect to the TPE metric. In most scenarios, TPE revealed a value of 0, signifying that the models accurately pinpointed the peak flow rate precisely at the expected time. In some instances, TPE reached a value of 1, showing a deviation of one hour in predicting the peak flow time. This deviation is deemed acceptable, particularly considering the utilization of short, intense rainfall for our analysis.

Our investigation into the performance of the three distinct forecasting models yielded compelling results pertaining to their ability to generate 95PPU, as quantified by the P-Factor and R-Factor. These factors serve as critical indicators for assessing the reliability and precision of the uncertainty bands produced by the MLE. Our findings demonstrated that the N-HiTS and N-BEATS models outperformed the LSTM model in mathematically defining uncertainty bands, in terms of R-Factor metric. The R-Factor, a crucial metric for evaluating the average width of the uncertainty band, consistently favored the N-HiTS and N-BEATS models over their counterparts. This finding was consistent across a diverse range of storm events. In addition, coupling MLE with the N-HiTS and N-BEATS models demonstrated superior performance in

655 generating 95PPU when assessed through the P-Factor metric. The P-Factor represents another vital aspect
656 of uncertainty quantification, focusing on the precision of the uncertainty bands.

657 Figures 7 and 8 present graphical depictions of the predicted flood with 1-hour prediction horizon and
658 uncertainty assessment for each model as well as Flow Duration Curve (FDC) across two gauging
659 stations. As illustrated, the uncertainty bands skillfully bracketed most of the observational data, reflecting
660 the fact that MLE was successful in reducing errors in flood prediction. FDC analysis also revealed that N-
661 HiTS and N-BEATS models skillfully predicted the flood hydrograph, however, both models were
662 particularly successful in predicting moderate to high flood events (1800-6000 and >6000 cfs). In the FDC
663 plots, the x-axis denotes the exceedance probability, expressed as a percentage, while the y-axis signifies
664 flood in cubic feet per second. Notably, these plots reveal distinctive patterns in the performance of the N-
665 HiTS, N-BEATS, and LSTM models.

666 Within the lower exceedance probability range, particularly around the peak flow, the N-HiTS and N-
667 BEATS models demonstrated a clear superiority over the LSTM model, closely aligning with the observed
668 data. This observed trend is consistent when examining the corresponding hydrographs. Across all events,
669 the flood hydrographs generated by N-HiTS and N-BEATS exhibited a closer resemblance to the observed
670 data, particularly in the vicinity of the peak timing and rate, compared to the hydrographs produced by the
671 LSTM model. These findings underscore the enhanced predictive accuracy and reliability of the N-HiTS
672 and N-BEATS models, particularly in predicting moderate to high flood events as well as critical
673 hydrograph features such as peak flow rate and timing. The alignment of model-generated FDCs and
674 hydrographs with observed data in the proximity of peak flow further establishes the efficiency of N-HiTS
675 and N-BEATS in accurately reproducing the dynamics of flood generation mechanisms across two
676 headwater streams.

Event 4

686 Figure 8. 95 PPU band and FDC plots of N-HiTS, N-BEATS, and LSTM models with 1-hour prediction
687 horizon for the three selected flooding events in the Killian Creek gauging station.

688 To evaluate robustness across lead times, we extended the analysis to 3- and 6-hour prediction horizons.
689 The results are presented in Figures 9-12, and Tables 5 and 6. As expected, NSE and KGE decreased while
690 the absolute errors increased with horizon for all models; however, N-HiTS and N-BEATS continued to
691 outperform LSTM across both stations and events. At Killian Creek station, both N-HiTS and N-BEATS
692 preserved their lead, yielding higher NSE and lower MAE/RMSE than LSTM, while at the Lower Dog
693 River, N-BEATS remained slightly superior on the same metrics. KGE values stayed comparable between

694 the two feed-forward models, and peak-focused metrics (PFE and TPE) indicated that both still captured
 695 peak magnitude and timing reliably, compared to LSTM. Uncertainty bands widened with horizon as
 696 expected, but the likelihood-based 95PPU for N-HiTS and N-BEATS maintained tighter R-Factors and
 697 competitive P-Factors relative to LSTM, especially around moderate-to-high flows. Flow-duration
 698 diagnostics at multi-hour leads reinforced these findings, showing closer alignment of N-HiTS and N-
 699 BEATS to observations in the upper tail. Overall, the multi-horizon results corroborate the 1-hour horizon
 700 results: N-HiTS and N-BEATS deliver more accurate and reliable flood forecasts than LSTM, and their
 701 relative strengths persist at 3 and 6 hours ahead. For completeness, we also evaluated 12- and 24-hour lead
 702 times. During these horizons, all models' performances declined sharply (NSE < 0.4 across sites and
 703 events), so we restrict detailed reporting to 1–6 hours where performance remains operationally meaningful.

720 Figure 12. 95 PPU band and FDC plots of N-HiTS, N-BEATS, and LSTM models with 6-hour prediction
 721 horizon for the three selected flooding events in the Killian Creek gauging station.

722 To probe cross-catchment generalizability, we trained a single “regional” model by pooling Lower Dog
 723 River and Killian Creek, preserving per-site temporal splits and fitting a global scaler only on the pooled
 724 training portion to avoid leakage; evaluation remained strictly per site. Relative to per-site training, pooled
 725 fitting produced a small accuracy drop for N-HiTS and N-BEATS (~ 2 to 3 %). LSTM showed mixed
 726 performance to pooling, it improved in some storm events but degraded in others, so that, when averaged
 727 across both stations and storm events, LSTM’s regional performance was effectively unchanged relative to

728 the per-site training. Despite that, the regional N-HiTS/N-BEATS matched the accuracy of the best per-site
729 models within the variability observed across storm events and, importantly, consistently surpassed LSTM
730 at both basins. Mechanistically, N-HiTS's multi-rate pooling and hierarchical interpolation, and N-
731 BEATS's trend/seasonality basis projection, act as catchment-invariant feature extractors that support
732 parameter sharing across stations.

733 In our investigation, we conducted an analysis to assess the impact of varying input sizes on the performance
734 of the N-HiTS, as the best model. We implemented four different durations as input sizes to observe the
735 corresponding differences in modeling performance. Notably, one of the key metrics affected by changes
736 in input size was 95PPU, which exhibited a general decrease with increasing input size. As detailed in Table
737 7, we observed a discernible trend in the R-Factor of the N-HiTS model as the input size was increased.
738 Specifically, there was a decline in the R-Factor as the input size expanded. This trend underscores the
739 influence of input size on model performance, particularly in terms of 95PPU band and accuracy.

740 Overall, uncertainty analysis revealed that coupling MLE with N-HiTS and N-BEATS models
741 demonstrated superior performance in generating 95PPU, effectively reducing errors in flood prediction.
742 The MLE approach was more successful in reducing 95PPU bands of N-HiTS and N-BEATS models
743 compared to the LSTM, as indicated by the R-Factor and P-Factor. The N-BEATS model demonstrated a
744 narrower uncertainty band (lower R-Factor value), while the N-HiTS model provided higher precision.
745 Furthermore, incorporating data with various sizes into the N-HiTS model led to a narrower 95PPU and an
746 improvement in the R-Factor, highlighting the significance of input size in enhancing model accuracy and
747 reducing uncertainty.

Table 7. N-HiTS's R-Factor results for three storm events in each case study, using 1
hour, 6 hours, 12 hours, and 24 hours input size in training.

Input Size	1 hour	6 hours	12 hours	24 hours
Dog River, GA - Event 1	0.314	0.337	0.29	0.272

Killian Creek, NC - Event 5	0.584	0.503	0.557	0.483
Killian Creek, NC - Event 6	0.482	0.42	0.446	0.454

748

749 **3.4. Sensitivity Analysis**

750 In this study, we conducted a comprehensive sensitivity analysis of the N-HiTS, N-BEATS, and LSTM
751 models to evaluate their responsiveness to meteorological variables, specifically precipitation, humidity,
752 and temperature. The goal was to assess how the omission of input features impacts the overall modeling
753 performance compared to their full-variable counterparts.

754 To execute this analysis, we systematically trained each model by excluding meteorological variables one
755 or more at a time, subsequently evaluating their predictive performance using the entire testing dataset.
756 The results of our analysis indicated that N-HiTS and N-BEATS models exhibited minimal sensitivity to
757 meteorological variables, as evidenced by the negligible impact on their performance metric (i.e., NSE,
758 Persistent-NSE, KGE, RMSE, and MAE) upon input feature exclusion.

759 Notably, as shown in Table 8, the performance of the N-HiTS model displayed a marginal deviation
760 under variable omission, while the N-BEATS model exhibited consistent performance irrespective of the
761 inclusion or exclusion of meteorological variables. The structure of this algorithm is based on backward
762 and forward residual links for univariate time series point forecasting which does not take into account
763 other input features in the prediction task. These findings suggest that the predictive capabilities of N-
764 HiTS and N-BEATS models predominantly rely on historical flood data. Both models demonstrated
765 strong performance even without incorporating precipitation, temperature, or humidity data, underscoring
766 their ability in flood prediction in the absence of specific meteorological inputs. This capability
767 underscores the robustness of the N-HiTS and N-BEATS models, positioning them as viable tools and
768 perhaps appropriate for real-time flood forecasting tasks where direct meteorological data may be limited
769 or unavailable.

770 Table 8. Performance metrics' values for N-HiTS, N-BEATS, and LSTM models by excluding
771 meteorological variables one or more at a time.

Model	Excluded Variables	Persistent- NSE		KGE	RMSE	MAE
		NSE	NSE			
N-HiTS	Using all variables	0.996	0.92	0.988	22.66	4.19
	Without Precipitation	0.993	0.91	0.97	23.28	4.31
	Without Humidity	0.995	0.914	0.976	22.87	4.22
	Without Temperature	0.995	0.921	0.985	22.43	4.14

	Discharge only prediction	0.993	0.911	0.972	23.21	4.29
	Using all variables	0.994	0.978	0.992	11.80	2.13
	Without Precipitation	0.994	0.978	0.991	11.86	2.17
N-BEATS	Without Humidity	0.994	0.978	0.991	11.81	2.16
	Without Temperature	0.994	0.978	0.991	11.82	2.16
	Discharge only prediction	0.994	0.978	0.991	11.96	2.17
	Using all variables	0.992	0.865	0.926	29.52	8.15
	Without Precipitation	0.979	0.665	0.892	39.46	19.83
LSTM	Without Humidity	0.991	0.843	0.925	31.73	9.15
	Without Temperature	0.983	0.628	0.872	48.95	11.49
	Discharge only prediction	0.976	0.576	0.692	52.28	33.5

772

773 **3.5 Computational Efficiency**

774 The computational efficiency of the N-HiTS, N-BEATS, and LSTM models, as well as a comparative
 775 analysis, is presented in Table 9. The study encompassed the entire process of training and predicting over
 776 the testing period, employing the optimized hyperparameters as previously described. Regarding the
 777 training time, it is noteworthy that the LSTM model exhibited the quickest performance. Specifically,
 778 LSTM demonstrated a training time that was 71% faster than N-HiTS and 93% faster than N-BEATS in
 779 the Lower Dog River watershed, while it was respectively, 126% and 118% faster than N-HiTS and N-
 780 BEATS in the Upper Dutchmans Creek, over training dataset. This is because LSTM has simple
 781 architecture compared to the N-BEATS and N-HiTS and does not require multivariate features, hierarchical
 782 interpolation, and multi-rate data sampling. Perhaps, this outcome underscores the computational advantage
 783 of LSTM over other algorithms.

784 Conversely, during the testing period, the N-HiTS model emerged as the fastest and delivered the most
 785 efficient results in comparison to the other models. Notably, N-HiTS displayed a predicted time that was

786 33% faster than LSTM and 32% faster than N-BEATS. This finding highlights the computational efficiency
787 of the N-HiTS model in the context of predicting processes. Our experiments unveiled an interesting
788 contrast in the computational performance of these models. While LSTM excelled in terms of training time,
789 it lagged behind when it came to the testing period.

790 In the grand scheme of computational efficiency, model accuracy, and uncertainty analysis results, it
791 becomes evident that the superiority of the N-HiTS and N-BEATS models in terms of accuracy and
792 uncertainty analysis holds paramount importance. This significance is accentuated by the critical nature of
793 flood prediction, where precision and certainty are pivotal. Therefore, computational efficiency must be
794 viewed in the context of the broader objectives, with the accuracy and reliability of flood predictions taking
795 precedence in ensuring the safety and preparedness of the affected regions.

796 Table 9. Computational costs of N-HiTS, N-BEATS, and LSTM models in the Dog River and Killian
797 Creek gauging stations.

Model	Training Time over Train Datasets (seconds)		Predicting Time over Test Datasets (seconds)	
	Lower Dog River	Upper Dutchmans Creek	Lower Dog River	Upper Dutchmans Creek
N-HiTS	256.032	374.569	1533.029	1205.526
N-BEATS	288.511	361.599	2028.068	1482.305
LSTM	149.173	165.827	2046.140	1792.444

798

799 4. Conclusion

800 This study examined multiple NN algorithms for flood prediction. We selected two headwater streams with
801 minimal human impacts to understand how NN approaches can capture flood magnitude and timing for
802 these natural systems. In conclusion, our study represents a pioneering effort in exploring and advancing
803 the application of NN algorithms, specifically the N-HiTS and N-BEATS models, in the field of flood
804 prediction. In our case studies, both N-HiTS and N-BEATS models achieved state-of-the-art results,
805 outperforming LSTM as a benchmark model, particularly in one-hour prediction. While a one-hour lead
806 time may seem brief, it is highly significant for accurate flash flood prediction particularly in an area with
807 a proximity to metropolitan cities, where rapid response is critical. These benchmarking results are arguably
808 a pivotal part of this research. However, the N-BEATS model slightly emerged as a powerful and
809 interpretable tool for flood prediction in most selected events.

810 This study focused on short-lead, operational forecasting at gauged sites, using historical discharge to
811 deliver robust, low-latency updates. While the evaluation is limited to two Southeastern U.S. basins, the

812 architecture (e.g., N-HiTS) is flexible and can incorporate additional covariates and catchment attributes.
813 Extending the approach to ungauged or other basins is feasible through multi-basin training and transfer
814 learning or few-shot adaptation when even brief warm-up records are available. These extensions represent
815 promising directions for future work to assess geographic transferability under the same operational
816 assumptions.

817 In addition, the results of the experiments described above demonstrated that N-HiTS multi-rate input
818 sampling and hierarchical interpolation along with N-BEATS interpretable configuration are effective in
819 learning location-specific runoff generation behaviors. Both algorithms with an MLP-based deep neural
820 architecture with backward and forward residual links can sequentially project the data signal into
821 polynomials and harmonic basis needed to predict intense storm behaviors with varied magnitudes. The
822 innovation in this study, besides benchmarking the LSTM model for headwater streams, was to tackle
823 volatility and memory complexity challenges, by locally specializing flood sequential predictions into the
824 data signal's frequencies with interpretability, and hierarchical interpolation and pooling. Both N-HiTS and
825 N-BEATS models offered similar performance as compared with the LSTM but also offered a level of
826 interpretability about how the model learns to differentiate aspects of complex watershed-specific behaviors
827 via data. The interpretability of N-HiTS and N-BEATS arises directly from their model architecture.

828 In the interpretable N-BEATS framework, forecasts are decomposed into trend and seasonality stacks, each
829 represented by explicit basis coefficients that reveal how different temporal patterns contribute to the
830 prediction. Similarly, N-HiTS achieves interpretability by aggregating contributions across multiple distinct
831 time scales, allowing insight into the temporal dynamics driving each forecast. N-HiTS aims to enhance
832 the accuracy of long-term time-series forecasts through hierarchical interpolation and multi-scale data
833 sampling, allowing it to focus on different data patterns, which prioritizes features essential to understand
834 flood magnitudes. N-BEATS leverages interpretable configurations with trend and seasonality projections,
835 enabling it to decompose time series data into intuitive components. N-BEATS interpretable architecture
836 is recommended for scarce data settings (such as flooding event), as it regularizes its predictions through
837 projections onto harmonic and trend basis.

838 These approaches improve model transparency by allowing understanding of how each part of the model
839 contributes to the final prediction, particularly when applied to complex flood patterns. Both models also
840 support multivariate series (and covariates) by flattening the model inputs to a 1-D series and reshaping the
841 outputs to a tensor of appropriate dimensions. This approach provides flexibility to handle arbitrary
842 numbers of features. Like LSTM, both N-HiTS and N-BEATS models support producing probabilistic
843 predictions by specifying a likelihood objective. In terms of sensitivity analysis, both N-HiTS and N-
844 BEATS maintain consistent performance even when trained without specific meteorological input.

845 Although, during some flashy floods, the models encountered challenges in capturing the peak flows and
846 the dynamics of the recession curve, which is directly related to groundwater contribution to flood
847 hydrograph, both models were technically insensitive to rainfall data as an input variable. This suggests the
848 fact that both algorithms can learn patterns in discharge data without requiring meteorological input. This
849 ability underscores these models' robustness in generating accurate predictions using historical flood data
850 alone, making them valuable tools for flood prediction, especially in data-poor watersheds or even for real-
851 time flood prediction when near real-time meteorological inputs are limited or unavailable. In terms of
852 computational efficiency, both N-HiTS and N-BEATS are trained almost at the same pace; however, N-
853 HiTS predicted the test data much quicker than N-BEATS. Unlike N-HiTS and N-BEATS, LSTM excelled
854 in reducing training time due to its simplicity and limited number of parameters.

855 Moving forward, it is worth mentioning that predicting the magnitude of the recession curve of flood
856 hydrographs was particularly challenging for all models. We argue that this is because the relation between
857 base flow and time is particularly hard to calibrate due to ground-water effluent that is controlled by
858 geological and physical conditions (vegetation, wetlands, and wet meadows) in headwater streams. In
859 addition, the situations of runoff occurrence are diverse and have a high measurement variance with high
860 frequency that can make it difficult for the algorithms to fully capture discrete representation learning on
861 time series.

862 In future studies, it will be important to develop strategies to derive analogs to the interpretable
863 configuration as well as multi-rate input sampling, hierarchical interpolation, and backcast residual
864 connections that allow for the dynamic representation of flood times series data with different frequencies
865 and nonlinearity. A dynamic representation of flood time series is, at least in principle, possible by
866 generating additive predictions in different bands of the time-series signals, reducing memory footprint and
867 compute time, and improving architecture parsimony and accuracy. This would allow the model to "learn"
868 interpretability and hierarchical representations from raw data to reduce complexity as the information
869 flows through the network.

870 While a single station provides valuable localized information, particularly for small, headwater streams
871 where runoff closely follows immediate meteorological conditions, it may not capture the spatial
872 heterogeneity of larger watersheds. In our study, the applied methods successfully captured runoff
873 magnitude and dynamics in small basins for an operational setting. However, broader spatial coverage and
874 distributed data would likely enhance model accuracy for larger regions. Consequently, our conclusions are
875 specifically scoped to the selected basins and forecast horizons, and broader generalizations would require
876 multi-region investigations in future work.

877 Finally, the performance of N-HiTS, N-BEATS, or other neural network architectures could be further
878 enhanced with robust uncertainty quantification. Approaches such as Bayesian Model Averaging (BMA)
879 with fixed or flexible priors (Samadi et al., 2020) or Markov Chain Monte Carlo (MCMC) optimization
880 methods (Duane et al., 1987) could capture both aleatoric and epistemic uncertainties. We leave these
881 strategies for future exploration in the context of neural flood time-series prediction.
