**Abstract.** The rainfall-runoff transformation in catchments usually follows a variety of slower and faster flow paths to a mixture of “younger” and “older” water in streamflow. Previous studies have investigated the time-variable distribution of water ages in streamflow (Transit Time Distribution, TTD) by stable isotopes of water ( $\delta^{18}\text{O}$ ,  $\delta^2\text{H}$ ) together with transport models based on StorAge Selection (SAS) functions. This function traditionally formulated based on soil moisture to mimic preferential release of younger water as the system becomes wetter. However, besides soil moisture, it is plausible to assume that precipitation intensity may also play a critical role in how quickly water flows through a catchment. In this study, we tested whether fast flow and its transit times are controlled by soil moisture only or also by precipitation intensity in a heterogeneous catchments with a significant fast runoff response component. We analyse high-resolution  $\delta^{18}\text{O}$  data (weekly and event streamflow  $\delta^{18}\text{O}$  samples) in a 66 ha agricultural catchment. We estimate TTDs by a tracer transport model based on SAS functions. We test two scenarios of the SAS function parameter for the quick release of young water into streamflow, one as a function of soil moisture only, and one as a function of both soil moisture and precipitation intensity. The results that accounting for both soil moisture and precipitation intensity to define the shape of SAS functions for quick flow, improved the tracer simulation in streamflow (increase in Nash-Sutcliffe Efficiency from 0.31 to 0.51). Even though the estimation of the TTs younger than 90 days were similar for both SAS approaches, the shorter travel times (TTs younger than 7 days) were not represented well when only accounting for soil moisture in the SAS function parameterization, in particular, in the summer and autumn months. This is due to flow processes that promote the direct contribution of precipitation to the stream (e.g. tile drain) and infiltration excess overland flow processes. It appears that a significant portion of event water bypasses the soil matrix through fast flow paths (overland flow, tile drains, and/or preferential flow paths) also in dry soil condition for both low and high-intensity precipitation. Thus, in catchments where preferential flows and overland flow are important flow processes, soil-wetness-dependent and precipitation-intensity-conditional SAS functions may be required to better describe and identify the mechanisms behind the quick streamflow generation and their time scale.

## 1 Introduction

The focus of hydrological research has expanded from the quantitative estimation of water fluxes to better descriptions of underlying hydrological processes by estimating the water age of various storage and runoff components in catchments

(Beven, 2006; McDonnell & Beven, 2014; Sprenger et al., 2019). Water age can give crucial information about the pathways through which water moves in catchments and their dynamics. This information can help to identify the partitioning of precipitation into distinct fluxes, such as overland flow, lateral subsurface flow, and deep percolation. These are useful for understanding the fate of pollutants and sediments, which is essential in managing water resources sustainably.

The time it takes for precipitation to reach the stream is referred to as water transit time, while water age is the time that has elapsed since precipitation entered the catchment (Rinaldo et al., 2011; Botter et al., 2011; Benettin et al., 2022). The age distribution of water stored in the catchment is referred to as the residence time distribution (RTD). Depending on a catchment's physical characteristics and on hydrometeorological conditions, transit times may vary between seconds and decades. Therefore, the Transit Time Distribution (TTD) is essential for representing transport processes in catchments (McGuire & McDonnell, 2006; Botter et al., 2011; Klaus & McDonnell, 2013; Benettin et al., 2022).

Conservative environmental tracers, such as the stable isotopes of oxygen ( $\delta^{18}\text{O}$ ) and hydrogen ( $\delta^2\text{H}$ ) in water, have been widely used to investigate water ages as well as runoff generation processes (Kirchner et al., 2000; Fenicia et al., 2008; McGuire & McDonnell, 2006; Klaus & McDonnell, 2013; Wang et al., 2023) and their time variance (Fenicia et al., 2010; McDonnell & Beven, 2014; Benettin et al., 2022; Wang et al., 2023). These tracers play a critical role in estimating where, how, and how quickly water is mobilized from the landscape, especially for quantifying water age distributions along surface and subsurface flow paths (McDonnell & Beven, 2014; Sprenger et al., 2019).

Recent developments in sampling techniques have improved the spatiotemporal resolution of the measured stable isotope data, e.g., hourly  $\delta^{18}\text{O}$  of precipitation (von Freyberg et al., 2022; Welb et al., 2022), or sub-daily to daily  $\delta^{18}\text{O}$  of streamflow (von Freyberg et al., 2022; Dahlke et al., 2014). This has improved our ability to track the partitioning of precipitation into different hydrological fluxes such as root water uptake, plant transpiration, overland flow, lateral subsurface flow, groundwater recharge, and eventually streamflow (Hrachowitz et al., 2015; Abbott et al., 2016; Knighton et al., 2019; Knighton et al., 2020; Kübert et al., 2023). Tracer-aided hydrological models have been developed and made it possible to investigate the contributions of distinct runoff generation mechanisms, such as overland flow or groundwater flow by solving water, tracer and associated water age balances (Botter et al., 2011) to estimate water transit times (Hrachowitz et al., 2013; Benettin et al., 2015; Lutz et al., 2018; Kuppel et al., 2018; Remondi et al., 2019; Wang et al., 2023, 2024).

Recent advances in TTD estimation have improved our ability to describe the relationship between storage and discharge in hydrological systems using the StorAge selection (SAS) approach (Botter et al., 2011; Rinaldo et al., 2015). The SAS function describes the probability with which water parcels of different age in a catchment's storage are released, therefore representing the relative contribution of young and old water to streamflow (Botter et al., 2011; Rinaldo et al., 2015). However, SAS functions cannot be directly observed. Instead, they are typically inferred from calibration of a tracer-aided hydrological model that fits modelled tracer and streamflow signals to observed ones. They can be defined either as time-variable or invariable functions (Hrachowitz et al., 2013) with various functional shapes, such as beta (van der Velde et al., 2012), Dirac delta (Harman, 2015) or gamma (Harman, 2015) distributions.

Previous studies showed that soil moisture (soil storage) is a controlling factor for the time-variable shape of the SAS function, thus accounting for the higher probability of the release of young water as a catchment's soil wets up (Harman, 2015; Hrachowitz et al., 2016; Benettin et al., 2017; Kaandorp et al., 2018; Harman, 2019). This is sometimes also referred "inverse storage effect" (Harman, 2015). The wetness-dependent time-variability of SAS functions was implemented in

hydrological models to simulate ~~the~~ tracer fluctuations in streamflow in catchments, such as Claduègne (Hachgenei et al., 2024), Gårdsjön (van der Velde et al., 2015), Elsbeek and Springendalse Beek (Kaandorp et al., 2018), Plynlimon (Benettin, et al., 2015; Harman, 2015), and several Scottish catchments (Hrachowitz et al., 2013). ~~Time~~-variable ~~parameterization~~ of the SAS function depending on catchment wetness may be needed in catchments due to various factors. These factors include: (i) the dominance of a single process dependent on soil moisture conditions like Hafren catchment in Wales (Benettin, et al., 2015; Harman, 2015) or saturation-excess overland flow in the Bruntland Burn catchment in Scotland (Benettin et al., 2017a) (ii) other site-specific hydrological characteristics that may be primarily influenced by catchment wetness.

~~...basing the shape of the SAS function on soil moisture may not fully capture the complexity of hydrological responses in catchments. Danesh-Yazdi et al. (2018) and Rodriguez and Klaus (2019) suggest that such a parameterization of SAS functions based on storage, and thus representing (soil) wetness, may not capture all relevant transport processes due to nonlinear relationships between storage and streamflow as observed in catchments like the flashy Weierbach in Luxembourg (Rodriguez and Klaus, 2019) and the Hydrological Open Air Laboratory in Austria (Vreugdenhil et al., 2022). This may in particular be true for catchments with moderate to low infiltration capacity of soils, where the intensity and duration of precipitation can also play a critical role in how quickly water is mobilized from the landscape (Blöschl, G. 2022).~~

~~Headwater catchments are often characterized by quick flow processes, such as overland flow and preferential flow through macropores in the shallow subsurface (Weiler and McDonnell, 2007; Klaus et al., 2013; Angermann et al., 2017; Loritz et al., 2017; Maier et al., 2021). In transport models, this preferential flow process is implicitly encapsulated in the SAS functions (Hrachowitz et al., 2021). So far, the rapid response has therefore been mostly considered as preferential flow or as saturation excess overland flow as function of soil moisture. However, a rapid response can also occur when rainfall intensities exceed the infiltration capacity (i.e. Hortonian runoff generation).~~ Therefore, it remains to be tested whether accounting for precipitation intensity in addition to soil moisture to parameterize time-variable SAS functions may yield improved representations of stream tracer dynamics in specific environments.

The objective of this study is to test two alternative approaches to ~~determine~~ the shape of time-variable SAS functions for ~~fast runoff generation~~ in a flashy headwater catchment: (i) exclusively soil moisture ~~alone~~ controls the SAS function shape for ~~quick flows~~ release, and (ii) soil moisture and precipitation intensity jointly control the SAS function shape for ~~quick flows~~ releasesize.

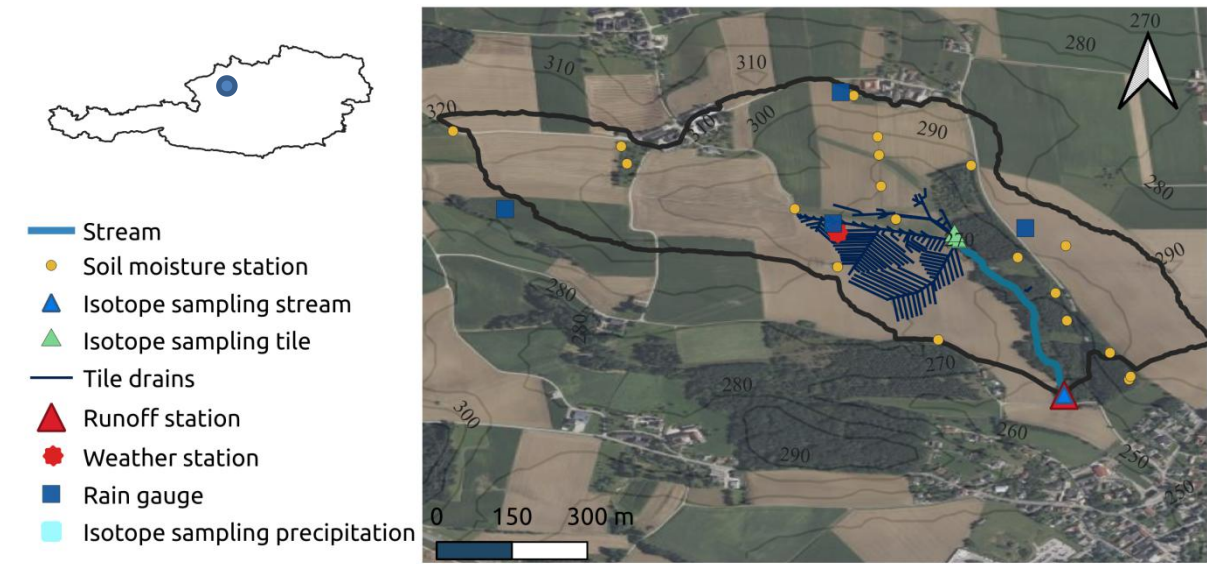

## 2 Methodology

### 2.1 Study Site

The Hydrological Open-Air Laboratory (HOAL) is a 66-hectare site located in Petzenkirchen, Austria (~~Blöschl et al., 2016~~) (Fig. 1). The catchment is ~~characterized~~ by a humid climate with an average annual air temperature of 9.5°C. The mean annual precipitation and runoff are 823 mm yr<sup>-1</sup> and 195 mm yr<sup>-1</sup>, respectively. The year 2015 was notably dry (P = 580 mm yr<sup>-1</sup>) while 2013, 2014, 2016, and 2017 had higher precipitation levels (> 700 mm yr<sup>-1</sup>) and were classified as relatively wet years. The elevation ~~is~~ between 268 and 323 m above sea level, with an average terrain slope of 8%. The predominant soil types are Cambisols (57%), Planosols (21%), ~~Kolluvisol~~ (16%), and Gleysols (6%). The soils are characterized by a high clay content of 20–30% (Blöschl et al., 2016; Eder et al., 2014). Land use primarily includes agriculture (87%) (crop cultivation of ~~maize~~, winter wheat, ~~rape~~ and barley), forest (6%), pasture (5%) and paved areas (2%) (Blöschl et al., 2016).

The concave part of the catchment (Fig. 1) was tile drained in the 1940s to reduce water logging because of the shallow, low-permeability soils and the catchment's use as agricultural land. The estimated drainage area from the tile drains is about 15% of the total catchment area (Fig. 1).

**Figure 1.** Map of the HOAL catchment (66 ha, Lower Austria) and location of devices for precipitation, weather station, soil moisture, isotope sampling from stream, and isotope sampling from precipitation (located approximately 300 m south of the catchment, light blue circle) (map image from © Microsoft, Bing Maps via Virtual Earth )

2.1.1 Hydrometeorological data

Hydro-meteorological data for the time period between October 2013 and 30-December 2018 were used for the analyses (Fig. 2a). precipitation was available from four weighing rain gauges (OTT Pluvio) (Fig. 1). The arithmetic mean of the four rain gauges was here in the following used as catchment average precipitation (Fig. 2a). Daily runoff at the catchment outlet was monitored using a calibrated H-flume with a pressure transducer (Fig. 2a). Daily soil moisture in the unsaturated zone was available through 19 permanent (Fig. 1). For this study, the catchment average soil water content was calculated across four different depths: 0.05 m, 0.10 m, 0.20 m, and 0.50 m and used for the analyses. Sensor specifications and additional details about the hydrometeorological data are provided in Blöschl et al. (2016).

2.1.2 Stable isotope data

$\delta^{18}\text{O}$  measurements for the time period between October 2013 and 30-December 2018 were used for the analyses (Fig. 2b-d). During this time period, precipitation isotope samples (Fig. 2b) were collected using an adapted Manning S-4040 automatic sampler, located approximately 300 meters south of the catchment (Fig. 1). This sampler, coupled with a rain gauge, collected water after every 5 mm. If the events intensities were less than 5mm, the mixing of precipitation at the end of with that of the following event can occur. For this events the average concentration of temporally separated events were used. In addition to weekly grab samples (Fig. 2d), discharge water at the catchment outlet was collected during precipitation events using an Isco 6712 automatic sampler for the period from 2013 onwards (Fig. 2c). Similar to discharge, water samples were collected at the outlet of tile drains at two location (Fig. 1) during precipitation events using an Isco 6712 automatic sampler.

Sample collection for stream and tile drain water was based on specific flow rate thresholds, varying the sampling frequency from 15 minutes to 2 hours depending on the anticipated length of the event. Analysis of these water samples for the stable 140 isotopes of oxygen ( $^{18}\text{O}/^{16}\text{O}$ ) and hydrogen ( $^2\text{H}/^1\text{H}$ ) was done using Picarro L2130-i and L2140-i laser spectrometers (cavity ring-down spectroscopy). The measurement uncertainties were  $\pm 0.1\text{‰}$  for  $\delta^{18}\text{O}$  and  $\pm 1.0\text{‰}$  for  $\delta^2\text{H}$ , respectively. All isotopic measurements are reported in per mil (‰) relative to Vienna Standard Mean Ocean Water (VSMOW). Both precipitation and streamflow event samples, as well as tile drainage samples, were aggregated to daily time intervals by calculating the volume-weighted average of the sampling fluxes based on their sampling frequency.

2.2 Hydrological model structure

The process-based model used in this study consists of five reservoirs based on the previously developed DYNAMITE modeling framework (Hrachowitz et al., 2014; Fovet et al., 2015). The reservoirs represent the storage components for snow ( $S_{snow}$ , Eq. 1), canopy interception ( $S_i$ , Eq. 2), unsaturated root zone ( $S_r$ , Eq. 3), fast response ( $S_f$ , Eq. 4) and groundwater with active and passive components ( $S_{s,a}$  and  $S_{s,p}$ , Eq. 5). Each of these had its own associated water fluxes (Fig. 3). The water balance and flux equations of the individual model components are given in Table 1 and a complete list of parameters and their upper and lower bounds can be found in Table 2. A detailed model description and rationale for the assumptions in the model architecture can be found in previous studies (Hrachowitz et al., 2014; Fovet et al., 2015).

**Figure 3.** The model structure used to represent the HOAL catchment. Light blue boxes indicate the hydrologically active, individual storage volumes that contribute to total discharge ( $Q_{tot}$ ): Snow storage ( $S_{snow}$ ), canopy interception ( $S_i$ ), fast-response bucket ( $S_f$ ), root zone ( $S_r$ ), and “active” groundwater ( $S_{s,a}$ ). The darker blue box  $S_{s,p}$  indicates a hydrologically “passive” mixing groundwater volume. Blue lines indicate snow and water fluxes while the orange lines indicate water vapor fluxes. Model parameters are shown in red adjacent to the model component they are associated with. All symbols are defined in Table 1 and Table 2.

180 Precipitation  $P$  (mm d<sup>-1</sup>) below the threshold temperature  $T_T$  (°C) enters the catchment as snow  $P_s$  (mm d<sup>-1</sup>, Eq. 6) and accumulates in the snow bucket  $S_{snow}$  (mm). Snowmelt  $P_m$  (mm d<sup>-1</sup>) was then computed with the degree-day method (Eq. 7), driven by the melt factor  $F_{melt}$  (mm d<sup>-1</sup> °C<sup>-1</sup>) as described by Gao et al. (2017) and Girons Lopez et al. (2020). Rainwater  $P_r$  (mm d<sup>-1</sup>), combined with snow melt  $P_m$  (mm d<sup>-1</sup>) passes through the canopy interception storage  $S_i$  (mm). Water that is not evaporated as interception evaporation  $E_i$  (mm d<sup>-1</sup>, Eq. 10) enters the unsaturated root zone  $S_r$  (mm) as throughfall  $P_e$  (mm d<sup>-1</sup>, Eq. 9) based on the water balance of the canopy interception storage (Nijzink et al., 2016) (Eq. 2). Water from the root zone  $S_r$  (mm) can either be released as (i) fast discharge  $R_f$  (mm d<sup>-1</sup>, Eq. 12), which is based on a critical storage capacity,  $Cap$ , calculated using  $S_{r,max}$  and the shape factor  $\gamma$  (-) (ii) slow recharge to the active groundwater storage  $S_{s,a}$  (mm) through a slower percolation flux  $R_s$  (mm d<sup>-1</sup>, Eq. 13) which is driven by the maximum percolation rate  $R_{s,max}$  (mm d<sup>-1</sup>) (iii) the combined flux of root-zone transpiration and soil evaporation  $E_a$  (mm d<sup>-1</sup>, Eq. 14) defined by the transpiration water stress factor  $L_p$  (-). The fast, preferential discharge  $R_f$  (mm d<sup>-1</sup>) is subsequently divided in several steps to account for fast flow paths. These are the preferential flow recharging groundwater  $R_{fs}$  (mm d<sup>-1</sup>, Eq. 15), the infiltration-excess overland flow reaching streamflow  $Q_o$  (mm d<sup>-1</sup>, Eq. 16) which is regularly observed in the HOAL catchment (Blöschl et al., 2016) and the lateral subsurface flux  $R_{fn}$  (mm d<sup>-1</sup>, Eq. 17). Firstly, the fast groundwater recharge  $R_{fs}$  (mm d<sup>-1</sup>, Eq. 15) is defined by the division parameter  $(1-C_p)$ . The remaining water  $R_{ff}$  (mm d<sup>-1</sup>, Eq. 15) is then further divided to account for infiltration-excess overland flow  $Q_o$  (mm d<sup>-1</sup>, Eq. 16) which is defined by the division parameter  $C_n$  (-) and the threshold parameter  $P_{tresh}$  (mm d<sup>-1</sup>) (Horton, 1933). We assumed a constant value for the division parameter  $C_n$  (-) to limit the number of calibration parameters in the spirit of model parsimony. After subtraction of fast groundwater recharge and overland flow, the remaining fast and lateral subsurface flux  $R_{fn}$  (mm d<sup>-1</sup>, Eq. 17) enters the fast storage component  $S_f$  (mm, Eq. 4). If the maximum capacity of  $S_f$  (mm, Eq. 4) is exceeded, water was released as saturation excess overland flow  $Q_{of}$  (mm d<sup>-1</sup>, Eq. 18). Otherwise, it was released to the stream as fast flow  $Q_f$  (mm d<sup>-1</sup>, Eq. 19).

Groundwater storage was separated into an “active” groundwater storage  $S_{s,a}$  and a hydrologically “passive” storage volume  $S_{s,p}$  (mm).  $S_{s,p}$  (mm) does not change over time if there are no deep infiltration losses, so that  $dS_{s,p}/dt=0$  (Zuber, 1986; Hrachowitz et al., 2016). This “passive” storage does not contribute to runoff but its role is to isotopically mix water of the “active” storage with water of the “passive” storage which is represented as  $S_{s,tot} = S_{s,a} + S_{s,p}$ . The use of the total groundwater storage  $S_{s,tot}$  facilitates contributions from both  $S_{s,a}$  and  $S_{s,p}$  to the age structure of the outflow  $Q_s$  (mm d<sup>-1</sup>, Eq. 24). Water enters the groundwater storage as a sum of slow percolation  $R_s$  (mm d<sup>-1</sup>) and fast recharge  $R_{fs}$  and is released as base flow  $Q_s$  (mm d<sup>-1</sup>, Eq. 24) and deep infiltration losses  $Q_l$  (mm d<sup>-1</sup>, Eq. 25).

### 2.3 Tracer transport model

Inserted[htuerk]: ; Wang et al., 2023

Inserted[htuerk]: <sp>

2.3.1 Rank StorAge Selection (rSAS) function

210 We combined the hydrological model as described in the previous chapter with a transport model that utilizes the age-rank StorAge Selection (rSAS) function which ranks stored water volumes by age (Harman, 2015; Benettin et al., 2017) to capture the variability of outflow age over time. The general theoretical framework of the transport model relies on the studies of Botter et al. (2009), van der Velde et al. (2012), Harman (2015) and Benettin et al. (2015). At any given time  $t$ , each storage  $S_{T,m,j}(t)$  defined within the hydrological model (Fig. 2) stores water of different ages. That is represented as  $T$  and traces back to past precipitation inputs at age  $T = 0$ . The age distribution of storage at time  $t$  is termed  $p_s(T, t)$ . The outfluxes (e.g., evapotranspiration and discharge) consist of specific age subsets from the storage, resulting in distinct age-ranked distributions for the water leaving the storage. These are termed  $p_{E,T}(T, t)$  for evapotranspiration and  $p_{Q,T}(T, t)$  for discharge. At each given time  $t$ , the total water volume in storage is also characterized by its tracer composition and distributions  $C_S(T, t)$  which traces back to past precipitation inputs. In the case of an ideal tracer, it is equal to the water stable isotope composition of past precipitation ( $P_{\delta^{18}O}$ ) upon entering the catchment at time  $t-T$ , i.e.,  $C_P(t-T)$ . As a result, output fluxes are characterized by water stable isotope compositions ( $Q_{\delta^{18}O}$ ,  $Q_{\delta^2H}$  which is  $C_Q(t-T)$  for streamflow and  $(ET_{\delta^{18}O}$ ,  $ET_{\delta^2H}$  which is  $C_{ET}(t-T)$  for evapotranspiration.

2.3.2 Integration of rank StorAge Selection (rSAS) function concept and hydrological model

The water age balance (Equation 2727) is formulated individually for each of the  $j$  storage components of the model such as canopy interception or the root zone, based on their transport dynamics. The change in water storage is the difference between age-ranked input volumes  $I_{T,j}(T, t)$  ( $\text{mm d}^{-1}$ ) and age-ranked output volumes  $O_{T,j}(T, t)$  ( $\text{mm d}^{-1}$ ) (Botter et al., 2011; Harman, 2015; and van der Velde et al., 2012).

$$\frac{\delta S_{T,j}(T, t)}{\delta t} + \frac{\delta S_{T,j}(T, t)}{\delta T} = \sum_{n=1}^N I_{T,n,j}(T, t) - \sum_{m=1}^M O_{T,m,j}(T, t) \tag{27}$$

$\partial S_{T,j}(T, t) / \partial T$  is the aging process of water in storage,  $N$  and  $M$  are number of inflows and outflows from that storage component (e.g., for the root zone these would be  $E_a$ ,  $R_f$ , and  $R_s$  (Fig. 3). Each age-ranked outflow  $O_{T,m,j}(T, t)$  (Equation 28) from a specific storage component  $j$  (Fig. 3) depends on the outflow volume  $O_{m,j}(t)$  which is estimated by the hydrological balance component of the model (see chapter 2.2) and the cumulative age distribution  $P_{o,m,j}(T, t)$  of that outflow.

$$\tag{28}$$

The cumulative age distribution  $P_{o,m,j}(T, t)$  (Eq. 29), which is the backward transit time distribution TTD of that outflow in cumulative form, depends on the age-ranked distribution of water in the storage component  $j$ , represented by  $S_{T,j}(T, t)$  for time step  $t$  and the probability density function, which in this case is SAS function  $\omega_{o,m,j}$  (or  $\Omega_{o,m,j}$  in its cumulative form) of that flux.

$$P_{O,m,j}(T, t) = \Omega_{O,m,j}(S_{T,j}(T, t), t) \tag{29}$$

The SAS function  $\omega_{o,m,j}$  (or  $\Omega_{o,m,j}$  in its cumulative form) is a probability density function of normalized rank storage  $S_{T,norm,j}(T, t)$  (Equation 31) at time  $t$ , which can also be formulated as residence time distribution RTD of storage component  $j$  (e.g., root zone) at time  $t$  (Equation 30). Normalizing the age-ranked storage helps prevent rescaling  $\omega_{o,m,j}$  at each time step

to conserve mass balance. Therefore, we used normalized rank storage (Equation 5) to bind the age-ranked storage to the interval [0,1].

$$p_{O,m,j}(T,t) = \overline{\omega}_{O,m,j}(S_{T,j}(T,t),t) \frac{\delta S_{T,j}}{\delta T} \tag{30}$$

(31)

$\delta^{18}\text{O}$  signals from entering the catchment as precipitation to leaving it as streamflow can be tracked through each individual storage component based on the tracer balance (Equation 32 e.g., Harman, 2015; Benettin et al., 2017).

(32)

Where  $C_{o,m,j}$  is the  $\delta^{18}\text{O}$  composition in outflow  $m$  from storage component  $j$  at time  $t$ ,  $C_{s,j}$  is the  $\delta^{18}\text{O}$  composition of water in storage at time  $t$

2.3.3 Time-variable and conditional SAS functions

Previous studies found a difference in transport processes between wet and dry periods (Weiler and McDonnell, 2007; Beven, 2010; Beven and Germann, 2013; Klaus et al., 2013; Loritz et al., 2017; Hrachowitz et al., 2021). This suggests that SAS functions are also time-variable and can be formulated as varying between preferential release of younger water, preferential release of older water or no preference (uniformly selected) (van der Velde et al., 2012; van der Velde et al., 2015; Hrachowitz et al., 2016). In this study, we used a beta distributions with shape and scale parameters  $\alpha$  (–) and  $\beta$  (–) as SAS functions. When both parameters of beta distributions are equal to 1 ( $\alpha = \beta = 1$ ), this indicates no selection preference for specific ages (uniform selection). If  $\alpha < \beta$  (or  $\alpha > \beta$ ), it indicates a selection preference for younger (or older) water. To limit the number of parameters, we kept “ $\beta$ ” equal to 1. The time variability of the SAS function shape is then based on age-ranked storage and the shape parameter ( $\alpha$ ) which is bounded [0,1] for the preference of younger storage and bounded [ $\alpha > 1$ ] for the preference of older storage. In the following we use this approach for the root zone storage  $S_r$ .

In contrast, all other storage components (e.g., snow, groundwater) were based on uniform sampling ( $\alpha = 1, \beta = 1$ ). Despite the shape parameters being fixed to uniform sampling in each of these storage components, the resulting overall SAS function, aggregating the individual storage components, is nevertheless time-variable due to the different time scales of and the temporally varying contributions from the individual components (Equation 30).

Previous studies have shown that as soil moisture increases, preferential flow increasingly bypasses small pore volumes, leading to the release of younger water (Weiler and McDonnell, 2007; Beven, 2010; Loritz et al., 2017; Hrachowitz et al., 2021). To mimic this behaviour, SAS functions for the fast preferential flow  $R_f$  (mm d<sup>-1</sup>) were formulated with a time-variable shape factor  $\alpha(t)$  (Fig. 4), which varied between 0 to 1 for each time step  $t$ . The variation of  $\alpha(t)$  was done by following Hrachowitz et al. (2013) and van der Velde et al. (2015), by varying it as a function of the stored water volume  $S_r(t)$  and the maximum storage capacity ( $S_{r,max}$ ) as shown in Equation 33 and Figure 4 (Scenario 1):

Inserted[htuerk]:

$$\alpha(t) = 1 - \frac{S_r(t)}{S_{r,max}}(1 - \alpha_0) \tag{33}$$

where  $\alpha_0$  is a calibration parameter representing a lower bound between [0,1], so that  $\alpha(t)$  can vary between  $\alpha_0$  and 1;  $\alpha(t) = 1$  indicates a uniform sampling SAS function at low soil moisture (dry soil) (Fig. 4a, A). This formulation (Scenario 1, Figure 4a) leads to an increasing preferential release of younger water as the system becomes wetter.

**Figure 4.** The two tested scenarios for determining the shape of the time-variable SAS function for fast flux  $R_f$  (mm d<sup>-1</sup>) (Fig. 3).

The age-ranked storage probability function is shown as vertical bars in all panels (A,B,C), with the light blue color representing young water (at the top of the vertical bars), while the dark blue color represents old water (at the bottom of the vertical bars). (a) **Scenario 1** (S1), the time-variable SAS function depends on the ratio of current storage  $S_r$  to maximum storage capacity  $S_{r,max}$  with the preference for young water increasing as storage increases from A to B (33). (b) **Scenario 2** (S2), the condition (A to B) only applies **only** when precipitation intensity does not exceed the threshold intensity ( $P_{thresh}$ ). **If precipitation intensity exceeds the threshold intensity ( $P_{thresh}$ ),** young water is **preferred with higher probability** (C) regardless of the current wetness state. This **mimics the** rainfall bypassing the soil storage as fast overland or subsurface lateral flow.

Previous research highlighted the non-linearity of flow processes in the HOAL catchment, where precipitation can quickly generate fast runoff and bypass the soil storage as fast overland or subsurface lateral flow (Blöschl et al., 2016; Exner-Kittridge et al., 2016; Vreugdenhil et al., 2022; Hövel et al., 2023; Szeles et al., 2024). To mimic and test this in our study, SAS functions for the fast preferential flow  $R_f$  (mm d<sup>-1</sup>), were formulated with a time-variable shape factor  $\alpha(t)$  vary as a

function of soil moisture as it is in Equation 33 (Scenario 1, Figure 4a), but additionally became equal to  $\alpha_0$  (-) (lower bound) when precipitation intensity  $P_I$  (mm d<sup>-1</sup>) exceeded a certain threshold  $P_{thresh}$  (Scenario 2, Figure 4b, Equation 34).

(34)

This formulation (Scenario 2, Figure 4) leads to an increasing preferential release of younger water with increasing soil moisture. Additionally, higher probability of release of younger water bypass the soil-stored water when precipitation intensity  $P_I$  (mm d<sup>-1</sup>) exceed the threshold intensity ( $P_{thresh}$ ). This formulation mimic rainfall bypassing the soil storage as fast overland or subsurface lateral flow.

2.4 Model optimization

The model was run with a daily time step for the time period between October 2013 and 30 December 2018 to calibrate the 15 hydrological and 2 tracer transport parameters-model parameters (Table 2). We used the 1 year data from October 2013 to October 2014 as warm-up period. Using an objective criteria that combines 6 performance criteria- (Table 3) related to streamflow and tracer dynamics, we implemented the Differential Evolution algorithm (Storn and Price, 1997) to optimize model parameters. For model calibration and evaluation, we used six performance metrics (Table 3) that describe the model’s ability to simultaneously reproduce different signatures associated with streamflow  $Q$  (mm d<sup>-1</sup>) and  $\delta^{18}O$  dynamics of the streamflow (Eq. 35). These are the Nash-Sutcliffe Efficiencies (NSE) (Nash and Sutcliffe, 1970) of streamflow, of the logarithmic streamflow, of the flow duration curve and of the time series of seasonal runoff ratios (averaged over three months). For  $\delta^{18}O$  signals we used the Nash-Sutcliffe efficiency (NSE) of  $\delta^{18}O$  all measured samples (daily event and weekly grab samples) (Fig. 2c) and the mean square error of weekly grab samples (Fig. 2d). The individual performance metrics were aggregated into the Euclidean Distance,  $D_E$  to the perfect model, using equal weights for the 6 stream flow and 2 tracer signatures, respectively, according to:

$$DE = \sqrt{\frac{1}{2} \left( \sum_{i=m}^M \frac{(1 - E_{Q,m})^2}{M} + \sum_{i=n}^N \frac{(1 - E_{18O,n})^2}{N} \right)} \tag{35}$$

where  $M$  is the number of performance metrics with respect to streamflow,  $N$  is the number of performance metrics for tracers in each combination, and  $E$  is the evaluation matrix based on goodness-of-fit criteria.  $D_E$  is Euclidean distance to the ‘perfect model’, with zero indicating a perfect fit. We selected the 50 best parameter sets ranked by decreasing Euclidean distance  $D_E$  for model evaluation.

We used two scenarios for model calibration where the formulation for hydrological fluxes were identical but transport formulation were different for SAS function shape lower bound  $\alpha_0$  (-) as described in section 2.3.3: Scenario 1 (S1), with  $\alpha(t)$  as a linear function of wetness ( $S_r/S_{r,max}$ ) (Equation 33), and Scenario 2 (S2), with  $\alpha(t)$  being a linear function of wetness ( $S_r/S_{r,max}$ ) if precipitation intensity is less than threshold intensity ( $P_{thresh}$ ). However, if precipitation intensity exceed the threshold intensity ( $P_{thresh}$ )  $\alpha(t)$  was formulated as strong preference for young water with shape factor  $\alpha(t) = \alpha_0$  (-) (Equation 34).

We evaluated the performance of the model under two scenarios using six performance metrics, which are listed in Table 3 for the tracking period from October 2014 to December 2018. Next, we analyzed transit times in relation to hydrological and hydroclimatic drivers by categorizing water into different age thresholds. These thresholds included:  $T < 7$  days, representing "event" water;  $7 < T < 90$  days, representing young water with some delay; and  $90 < T < 365$  days, representing longer transit times. The streamflow age fraction  $F_Q$  ( $T < T_{age}$  days) is calculated based on the sum of TTD, where  $T < T_{age}$  days. For example, the age fraction of streamflow  $F_Q$  ( $T < 90$  days) is calculated based on the sum of TTDs, where  $T < 90$  days. We calculated the mean and maximum percentage of streamflow fractions for transit times  $T < 7$  days,  $7 < T < 90$  days,  $90 < T < 365$  days. We also compared the variation in mean and maximum percentage of streamflow water age fractions for different seasons, autumn (September, October, November), winter (December, January, February), spring (March, April, May), and summer (June, July, August) as well as for distinct wetness states (dry, drying, wet, wetting periods). Dry days were marked by flows less than the 25<sup>th</sup> quantile, while wet days were marked by flows higher than the 75<sup>th</sup> quantile. Drying days marked any decay between the 25<sup>th</sup> quantile and 75<sup>th</sup> quantile whereas wetting days are marked as any increase between the 25<sup>th</sup> quantile and 75<sup>th</sup> quantile.

Furthermore, we compared the relationship between transit times and hydrological and hydroclimatic drivers, specifically, streamflow  $Q$  (mm d<sup>-1</sup>), precipitation intensity (mm d<sup>-1</sup>), and volumetric soil water content  $SWC$  (%) for the tracking period as well as across different seasons and wetness states to understand variations in the control mechanisms. This analysis was conducted by comparing Spearman rank correlation coefficients of water age fractions with the hydroclimatic drivers.

3 Results

345 3.1 Model calibration results

The model parameters selected for the HOAL catchment for calibration period from October 2014 to December 2018 reproduced the general features of the hydrograph (Fig. 5). The best-performing model generally captured both the timing and magnitude of high and low flow events independent on the selected scenario (NSE<sub>Q</sub> = 0.61 for both scenarios, Figure 5a),

with the exception of ~~over-estimations~~ of low flows during ~~the~~ summer 2016 and underestimation of low flows during ~~the~~ winter 2017. The three-month averaged runoff ratio (RC) was reproduced, with NSE values of 0.89 for Scenario 1 and 0.83 for Scenario 2 (Fig. 5b, e). The flow duration curve (FDC) was reproduced, with Nash-Sutcliffe efficiency ( $NSE_{FDC}$ ) of 0.51 for Scenario 1 and 0.50 for Scenario 2 (Fig. 5d,e). ~~Low~~ flows were reproduced, with a median Nash-Sutcliffe efficiency of log-flows ( $NSE_{\log Q}$ ) ~~as~~ 0.65 (Fig. 5c,e). For several rain storms, the model reproduced the sharp  $\delta^{18}O$  fluctuations during events and a highly stable  $\delta^{18}O$  signal between consecutive events (Fig. 5c) for both scenarios. However, ~~S2~~ indeed showed considerable improvements for the very negative winter  $\delta^{18}O$  stream values in 2015 and 2018, ~~but also~~ for several events in summer 2016, 2017 and 2018. The performance metrics based on median  $\delta^{18}O$  signals were higher for Scenario 2 with e.g.  $NSE_{\delta^{18}O} = 0.51$  than for Scenario 1 with  $NSE_{\delta^{18}O} = 0.31$  (Fig. 5e). Overall, the Euclidian distance  $D_E$  for 50 best performing parameter sets decreased from 0.42 for Scenario 1 to 0.37 for Scenario 2, showing that Scenario 2 performed generally better than Scenario 1 (Fig. 5e).

### 3.2 Water transit times and residence times

By tracking the  $\delta^{18}\text{O}$  signals through the model, we estimated TTDs in streamflow and compare these distributions for different age thresholds,  $T < 7$  days,  $7 < T < 90$  days,  $T < 90$  days, and  $90 < T < 365$  days (see Section 2.4). It is important to acknowledge that the transit time results are inherently tied to the assumptions made and the uncertainties within the modeling process. Model calibration based on Scenario 2 resulted in more younger water bypassing storage as evidenced by the mean percentage of streamflow age fraction younger than 7 days  $F_Q(T < 7 \text{ days})$  being lower for Scenario 1 (2.87%) compared to Scenario 2 (4.03%) (see Table 4 and Figure 6a, Figure S2). This is also reflected in individual TTDs for fast preferential flow  $R_f$  (mm d<sup>-1</sup>) (Fig. 3), where on average 40% of fast preferential flow was from recent rainfall (age = 1 day) based on S2 and was 30% for S1 (Fig. 6e). However, the scenarios did not differ in the fraction of streamflow that is younger than 90 days  $F_Q(T < 90 \text{ days})$  where the mean percentage for Scenario 1 was 6.03% and for Scenario 6.53 % (see Table 4 and Figure 6b).

3.3 Influence of hydrological and hydroclimatic variables on water age fractions

The influence of hydrological and hydroclimatic variables on water age fractions (0<T<7, T<90, 90<T<365 in days) were compared by Spearman rank correlation coefficients (r, p). Only precipitation intensity P<sub>i</sub> (mm d<sup>-1</sup>) was strongly correlated with the streamflow water age fraction younger than 7 days F<sub>O</sub> (T<7days) for both scenarios, with a slightly higher correlation coefficients for Scenario 1 (S1, r = 0.67, p < 0.05) compared to Scenario 2 (S2, r = 0.53, p < 0.05) (Fig. 7b). Similarly, water age fractions younger than 90 days F<sub>O</sub> (T< 90 days) were more correlated with precipitation intensity P<sub>i</sub> (mm d<sup>-1</sup>) than with volumetric soil water content SWC (%) or streamflow Q (mm d<sup>-1</sup>) (Fig. 7d, 7e, 7f). The correlation coefficients (r) with precipitation intensity P<sub>i</sub> (mm d<sup>-1</sup>) were r = 0.71, p < 0.05 for Scenario 1 and were r = 0.62, p < 0.05 for Scenario 2. For streamflow age fractions between 90 and 365 days F<sub>O</sub> (90<T<365 days) only Scenario1 resulted in strong correlation coefficients with precipitation intensity P<sub>i</sub> (mm d<sup>-1</sup>) (r = 0.58, p < 0.05) (Fig. 7h). No strong correlations were found for all other combinations of the water age fractions to streamflow Q (mm d<sup>-1</sup>) or volumetric soil water content SWC (%) (Fig. 7).

400

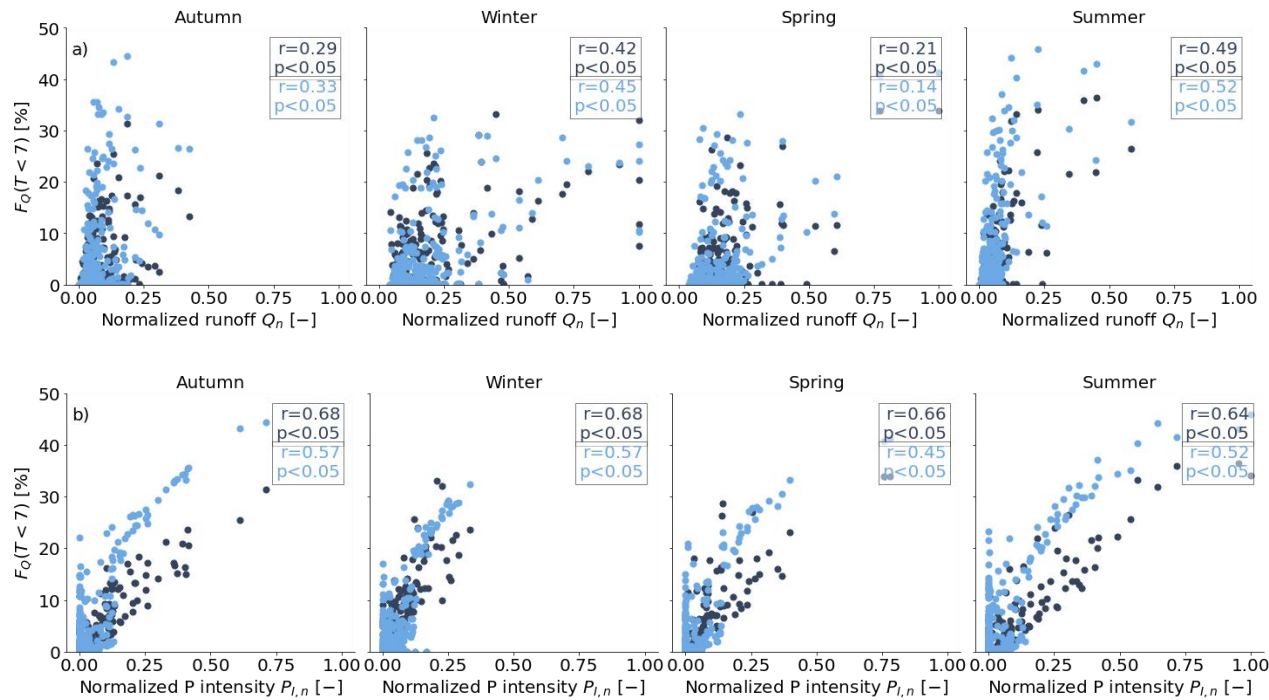

**Figure 7.** Spearman rank correlation of streamflow water age fractions with the hydrological and hydroclimatic variables, discharge  $Q$  [mm d<sup>-1</sup>], precipitation intensity  $P_i$  [mm d<sup>-1</sup>], and volumetric soil water content  $SWC$  [%]. Panel (a, b, c) show the correlations of streamflow age fractions younger than 7 days  $F_Q(T < 7 \text{ days})$ , (d, e, f) show the correlations of streamflow age fractions younger than 90 days  $F_Q(T < 90 \text{ days})$  and (g, h, i) correlations of streamflow age fractions older than 90 days but younger than 365 days  $F_Q(90 < T < 365 \text{ days})$  to discharge  $Q$  [mm d<sup>-1</sup>], precipitation intensity  $P_i$  [mm d<sup>-1</sup>], and volumetric water content  $SWC$  [%] respectively.

### 3.4 Linking water age fractions to hydrological and hydroclimatic drivers in different seasons

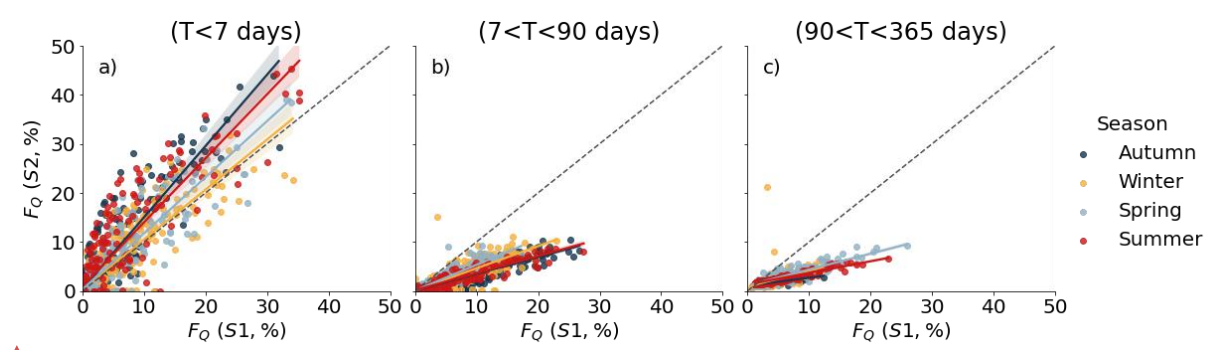

Scenario 2 resulted in a higher fraction of streamflow water younger than 7 days  $F_Q(T < 7 \text{ days})$ , especially during autumn and summer, compared to Scenario 1 (Fig. 8a, 9a). However, during spring and winter, both scenarios reproduced similar results for  $F_Q(T < 7 \text{ days})$ . On average, ~2% and ~4% of autumn recharge was younger than 7 days based on Scenario 1 and Scenario 2 respectively. For individual events, these values reached up to a maximum of 31% and 44 % based on Scenario 1 and Scenario 2 respectively (Table 5). Similarly, in the summer season, Scenario 2 resulted in a higher fraction of streamflow younger than 7 days with average of 4.48% compared to Scenario 1 (~3%). For water ages  $7 < T < 90$  days and  $90 < T < 365$  days, Scenario 1 resulted in higher fractions across all seasons compared to Scenario 2 (Fig. 9b, 10c; Table 5)

**Figure 8.**

4 Discussion

4.1 Soil moisture is not the only control of transit times

Previous studies have shown that soil moisture plays a significant role in catchment transit times in humid areas, such as Wüstebach and the Bruntland Burn catchment in Scotland (Benettin et al., 2017; Hrachowitz et al., 2021). However, in the HOAL catchment of this study, rainfall intensity, beyond soil moisture, was required to account for the complexity of the hydrological and transport response.

For both scenarios (S1: SAS function with soil moisture only, S2: SAS function with soil moisture and rainfall intensity), the mean fraction relatively short travel times in stream water ( $T \leq 7$ ,  $7 < T \leq 90$ , and  $T > 90$  days) positively correlated with modeled soil moisture (Table S1). This suggests that catchment soil moisture plays a role for young water release in the HOAL catchment, which is further supported by the reasonably good simulation results of stable isotopes of water when only using soil moisture in the SAS function (NSE = 0.31). Therefore, the results correspond well to earlier research, where increasing catchment wetness resulted in younger water reaching the stream (Weiler and Naef, 2003; Zehe et al., 2006; Hrachowitz et al., 2013; Remondi et al., 2018; Rodriguez et al., 2018; Sprenger et al., 2019).

Despite the selection of the SAS function based exclusively on catchment wetness being adequate for the HOAL catchment, the highly complex runoff generation mechanisms (Blöschl et al., 2016) with a quick runoff response particularly during autumn and summer months, highlighted the need for an additional control on the SAS function shape (Fig. 5c, 6a). Indeed, the model performance was better (Figure 5e) when including precipitation intensities in the SAS function (Figure 4b-). This indicates that the direct contribution of precipitation to streamflow during storm events with high precipitation intensities is important in the HOAL catchment. This behavior can be explained by several factors that promote fast runoff that bypass resident water.

The incorporation of both soil moisture and precipitation intensity in the SAS function accounts for non-linearity of flow processes, mimicking the behaviour of not only saturation-excess overland flow but also that of infiltration-excess flow and other subsurface fast runoff flow processes that bypass flow with minimal interaction with resident water (e.g. tile drain flow). Therefore, we included a non-linear threshold behavior in the SAS function with rainfall intensity, where changes in runoff processes or shifts in runoff regimes can occur. The non-linearity of flow processes in the HOAL catchment has been demonstrated through hydrometric analysis and visual observations, which have highlighted the potential controls of soil moisture and event precipitation (Blöschl et al., 2016; Exner-Kittridge et al., 2016; Vreugdenhil et al., 2022; Hovel et al., 2023; Szeles et al., 2024). Similarly, Vreugdenhil et al. (2022) showed that rainfall and soil moisture are significant and highly non-linear controls on overland flow and tile drainage flow in different parts of the HOAL used here. For instance, tile drainage in wetlands was more linearly related to soil moisture, whereas at the hillslope scale, it was more related to precipitation even at low-intensity rainfall. Therefore it is plausible to assume that in the HOAL catchment, overland flow exhibits a threshold behavior related to fast runoff generation occurring even at low-intensity rainfall.

Additionally, the HOAL catchment consists of a diverse range of soil types, with a high clay content between 20% and 30% (Blöschl et al., 2016). Different types of soils may introduce complexities due to surface and subsurface heterogeneity in soil hydraulic conductivity, which significantly influences the shapes of SAS functions (Danesh-Yazdi et al., 2018). As previously discussed by Danesh-Yazdi et al. (2018), subsurface heterogeneity in hydraulic conductivity imposes significant

variation in the shape of the SAS function. Therefore, assuming a smooth functional form for the SAS function in heterogeneous systems may ~~oversimplify~~ its intrinsic variability concerning age or age-ranked storage. This may also explain why incorporating soil moisture and precipitation intensity, as we did in Scenario 2, resulted in better model performance in the simulation of the  $\delta^{18}\text{O}$  signal in streamflow.

Besides, the tile drainage system, which covers only 15% of the catchment (Fig. 1), appeared to play an important role in fast flow generation. The close resemblance of the  $\delta^{18}\text{O}$  signal in the tile drainage system with the precipitation  $\delta^{18}\text{O}$  signal (Fig. 2e, 2f) provides evidence that some event precipitation contributes to the stream through the tile drain not only in winter but also in summer. A possible explanation for summer months is that larger cracks in the clayey soils, which are directly connected to the tile drainage system, allow for preferential flow that is more dependent on precipitation intensity than on soil moisture. This results corresponds with observations from Exner-Kittridge et al. (2016), who noted that in the HOAL catchment, macropore flow is observed in summer when the topsoil dries and forms cracks due to high clay content. This emphasizes the critical role of soil texture and structure in influencing water movement during rainfall events.

#### 4.2 Synthesis of streamflow generation processes in the HOAL catchment

The HOAL catchment exhibits a diverse and rapid hydrological response to precipitation events (Blöschl et al., 2016; Exner-Kittridge et al., 2016; Vreugdenhil et al., 2022). This is also evidenced by the on/off response of streamflow and the sharp transition between high-resolution event  $\delta^{18}\text{O}$  signals and highly stable weekly  $\delta^{18}\text{O}$  signals observed in the stream (Figure 2c, 2e, 2f). Tracer compositions measured at weekly intervals remained stable throughout the year (Fig. 2d). However, event-based samples and tile drainage samples showed similar  $\delta^{18}\text{O}$  patterns to precipitation (Fig. 2f), indicating a sharp transition between fast flow processes and more stable groundwater flow. For several rain storms, the model reproduced the sharp fluctuations during events and a stable  $\delta^{18}\text{O}$  signal between consecutive events (Fig. 5c) for both scenarios. Nevertheless, the model calibration based on Scenario 2 enhanced the model's sensitivity to the time scale of fast flow (Fig. 6a), further emphasizing the critical role of precipitation intensity in influencing hydrological responses in the catchment. In particular, infiltration-excess overland flow and precipitation-driven subsurface fast flow were identified as key flow processes, corroborating studies by Blöschl et al. (2016), Széles et al. (2020), and Silasari et al. (2017), who noted that both saturation-excess and infiltration-excess overland flow typically occur in valley bottoms during prolonged or intensive rainfall, with part of the event water entering the stream as overland flow. The hydrological behavior of the HOAL catchment supports earlier findings by Kirchner et al. (2023), who noted that a rapid hydrological response often indicates rainwater quickly moving to channels via overland flow or fast subsurface pathways.

#### 4.3 Catchment transit times

Transit time results indicated that event peaks were primarily a mixture of new precipitation water and the water less than 7 days old that had been stored in the catchment. During events, the percentage of streamflow water age fractions for  $T < 7$ ,  $7 < T < 90$ , and  $90 < T < 365$  days increased for both scenarios (Fig. 6a). However, on average, only ~4% of the water was younger than 7 days, and ~7% was younger than 90 days (Table 4). This aligns with the findings of previous studies that have identified the majority of water contributing to streamflow as being old, a phenomenon that has been termed the "old water paradox" (Kirchner, 2003; McDonnell et al., 2010).

Nevertheless, the fraction of stream water younger than 7 days increased from 1% to up to 45% on an event scale depending on storm size (Fig. 7b, 8e). This indicated that most precipitation did not mobilize old water in the first place; instead, it

Inserted[htuerk]: <sp>

drained directly into river networks and contributed to the stream via fast flow paths. This reflects results reported by Szeles et al. (2024), where their findings showed that the new water contribution averaged around 50% during peak flows in selected large events in the HOAL catchment. ~~Given that the slope of the catchment is relatively low at 8%, a possible explanation might be the presence of soil types with low to moderate permeability and the influence of agricultural land use (Szeles et al., 2024). Another reasons can be the high portion of agriculturally used land which tends to seal at the surface during heavy events, thus inhibiting infiltration.~~

#### 4.4 Catchment ~~Transit~~ times variability with hydrological and hydroclimatic conditions

~~Based on the assumptions in the model structure and parameters, the resulting fraction of water ages younger than 7 days and younger than 90 days was more strongly correlated with precipitation intensity than with streamflow or soil moisture for both scenarios. In contrast, older water ages (90 to 365 days) exhibited weak or negative correlations with these hydrological and hydroclimatic drivers (Fig. 7). The fraction of stream water younger than 7 days  $F_Q(T < 7 \text{ days})$ , positively correlated~~  
with precipitation intensities (Fig. 7b), implying that the volume of event water transmitted to streamflow increases ~~more proportionally~~ with storm size. Similar results were noted by Szeles et al. (2024), who used hydrograph separation methods and highlighted that new water fractions during events increased with precipitation intensity in the HOAL catchment.

In contrast, the measured volumetric soil water content ~~SWC (%)~~ did not strongly correlate ~~for both scenarios~~ with shorter transit times  $F_Q(T < 7 \text{ days})$  and  $F_Q(T < 90 \text{ days})$  (Fig. 7c, 7f). This may seem contradictory, but it is plausible to assume that the effect of frequent fast flow in the HOAL catchment dominates and masks the underlying relationship between catchment wetness and transit times. ~~Similar results were found by Hövel et al. (2023) in an analyses of similar event runoff separation. More specifically, they showed that similar runoff responses had stronger correlations with precipitation than measured volumetric soil water content.~~

Stream water fractions with transit times less than 90 days,  $F_Q(T < 90 \text{ days})$  were weakly correlated with discharge  $Q$  (~~mm d<sup>-1</sup>~~) ( $r = 0.40$  for S1 and  $0.34$  for S2) but were strongly positively correlated with precipitation intensity,  $P_1$  (~~mm d<sup>-1</sup>~~) ( $r = 0.71$  for S1 and  $0.62$  for S2) (Fig. 8d and 8e). ~~The formulation in the model, results in the dominance of fast runoff flow paths and their persistence during both small and large precipitation events in the HOAL catchment. This~~ findings support the earlier study by Freyberg et al. (2018), who noted that low discharge sensitivity to high fractions of young water can indicate the dominance of fast runoff flow paths in the hydrological response. This ~~behavior~~ persists regardless of the magnitude of precipitation events, particularly under conditions where the landscape promotes rapid water movement, such as in catchments with certain soil types or topographic features (like in the HOAL catchment). Such ~~behavior~~ points also well-developed subsurface flow paths (such as tile drains at the hillslope scale) that ~~efficiently~~ transport water and solutes to the stream, highlighting the catchment's sensitivity to precipitation input.

#### 4.5 Implications and limitations

~~The findings of this paper have important implications for representing transport processes in small, flashy catchments, and for hydrological modelling at large. The application of the model in two different scenarios provided evidence of the critical role of precipitation intensity as an additional dominant control on transit times in the HOAL catchment. Scenario 1 resulted in a higher fraction of water ages  $F_Q(7 < T < 90 \text{ days})$  compared to Scenario 2 (Fig. 6b, Table 5) and did not simulate peaks in  $\delta^{18}\text{O}$  signals as strongly as Scenario 2. It is unsurprising that parameterizing the SAS function shape based exclusively on soil moisture results in the shape parameter  $\alpha(t)$  being closer to uniform sampling when soil is dry. This formulation,~~

therefore, lead to a higher probability of mobilizing older water ( $7 < T < 90$  days), rather than the faster transmission of new ( $T < 7$  days) water to the streamflow in dry soil condition (Fig. 6b, Table 5). Being conditional on the assumptions made throughout the modeling process, and notwithstanding potential uncertainties, high-frequency water-stable isotope data and

545 model calibrations provide relatively strong evidence to support the key findings of this study: both soil moisture and precipitation intensity significantly influence hydrological responses and transit times in the HOAL catchment. This led to non-linear flow behavior and a shift toward younger water ages in the stream, particularly during autumn and summer. Soil-wetness-dependent and precipitation-intensity-conditional SAS functions may, therefore, be necessary to better capture and identify the mechanisms driving rapid streamflow generation and their associated time scales, notably in catchments where

550 preferential flows and overland flow are dominant flow processes.

There are some limitations in this study that need to be addressed and tested in future research. The model calibration based on both scenarios overestimated low flows during the summer of 2016, despite relatively higher precipitation during that year. This overestimation is likely linked to groundwater recharge processes being more complex than represented in the model structure. The underestimation of low flows began after an occurrence of intense rainfall event ( $P > 50 \text{ mm d}^{-1}$ , Figure

555 2) followed by several moderate-intensity events. A potential explanation is the activation of flow paths down to the depth of the tile drainage system or dominant subsurface lateral flow, which may have diverted water directly to the stream, bypassing groundwater infiltration and promoting interflow. Another possibility is the potential presence of a low-permeability unsaturated transition zone between the root zone and the groundwater table which may have delayed groundwater recharge. This could also explain why low flows in the winter and spring of 2017 were conversely

560 underestimated. To fully evaluate these hypotheses and better estimate the recharge processes, additional field observations and more detailed studies focusing on subsurface dynamics and groundwater interactions are necessary.

Furthermore, the model calibration based on both scenarios showed limitations in simulating very low  $\delta^{18}\text{O}$  signals during the summer months, potentially due to the constant value assigned to the division parameter  $C_n (-)$  for infiltration-excess overland flows. This parameter was kept constant in this study to maintain model simplicity, as the primary focus was on

565 testing the role of precipitation intensity in water partitioning. However, correlation results with hydrological and hydroclimatic drivers (Fig. 7) suggest that  $C_n (-)$  might also be a function of rainfall intensity and could increase with higher precipitation intensities. This indicates the need for a more dynamic representation of  $C_n$  to better capture its response to changing rainfall conditions.

Lastly, model calibration resulted in an infiltration-excess overland flow threshold precipitation intensity parameter

570  $P_{\text{thresh}} (\text{mm d}^{-1})$  range between 10–15 ( $\text{mm d}^{-1}$ ) and 5–10 ( $\text{mm d}^{-1}$ ) for Scenario 1 and Scenario 2, respectively (Fig. S1). While this may seem surprising at first, it can be reasonably explained by surface sealing during rainfall, which inhibits infiltration, particularly in areas affected by agricultural land use in HOAL catchment. Additionally, macropore flow observed in the summer, when the topsoil dries and cracks due to its high clay content, may also contribute to this effect. This parameter was also identified as a threshold for partitioning rainfall into preferential flow pathways and overland flow, promoting fast

575 runoff with minimal interaction with resident water to simulate  $\delta^{18}\text{O}$  signals. Therefore, this threshold should not be considered a definitive marker for infiltration-excess overland flow. Instead, it can be a marker for any processes where the landscape promotes rapid water movement in HOAL catchment.

In this study, we ~~tested whether fast flow transit times are controlled by soil moisture alone or also by precipitation intensity in an agricultural headwater catchment. The results suggest~~ that both soil moisture and precipitation intensity exert a significant influence on transit times. The ~~data~~ also ~~support~~ the hypothesis that preferential ~~flow age fractions are linearly related to~~ soil moisture when precipitation intensity ~~is~~ below a threshold. However, when precipitation intensity ~~exceeds~~ a threshold, there ~~is~~ a higher probability of new water contributing to fast runoff with little exchange with stored water. The SAS functions based on both soil moisture and precipitation intensity resulted in an increased probability of rapid mobilization of young water  $F_Q$  ( $T \leq 7$  days), influenced by precipitation intensity particularly during autumn and summer months. Thus, in catchments where subsurface preferential flow and overland flow dominate, soil moisture-dependent and precipitation intensity-conditional SAS functions may be required to better ~~the age distribution of quick streamflow. Models that do not account for precipitation may underestimate the impact of intense precipitation events on quick runoff generation in flashy headwater catchments, particularly where infiltration excess overland flow or rapid tile drain flow are important runoff mechanisms when the soil is dry.~~

The findings also underscore the importance of the activation of fast flow paths in water quality variations within the catchment. Estimating young water contributions is essential not only for predicting how contaminants and nutrients are mobilized and transported during hydrological events but also for characterizing the underlying processes that govern the movement and mixing of water through the catchment. The results presented here ~~focus~~ on a small agricultural headwater catchment with substantial contributions from surface flow and shallow subsurface flow to streamflow. In other catchments with quick subsurface runoff and overland flow, accounting for precipitation ~~in transit times may also better reflect the hydrological dynamics and transport processes, and assist in developing effective water management strategies.~~

*Code and data availability.* An Python script that performs the calculations described in this paper will be deposited in an open-access Github archive repository and the link will be supplied with the final published paper.

*Data availability.* The data used in this study can be obtained from the Austrian Federal Agency for Water Management and upon request.

*Author contributions.* HT and MH jointly developed the model architecture for the catchment. HT performed the analysis presented here and drafted the paper. All authors discussed the design, contributed to the overall concept, and participated in the discussion and writing of the manuscript.

*Competing interests.* Some authors are members of the editorial board of the HESS journal.

*Acknowledgments.* We thank the Austrian Federal Agency for Water Management for providing the data Petzenkirchen catchment that we used in our analysis. This research is funded by the Austrian Science Fund (FWF–Österreichischer Wissenschaftsfonds) [grant number 10.55776/P34666]. The work of Hatice Turk was supported by the Doctoral School "Human River Systems in the 21st Century (HR21)" of the University of Natural Resources and Life Sciences, Vienna.
