Abstract. This study presents a probabilistic model that partitions the precipitation phase based on hourly measurements from a network of radar-based disdrometers in eastern Canada. The network consists of 27 meteorological stations located in a boreal climate for the years 2020–2023. Precipitation phase observations showed a 2-m air temperature interval between 0–4°C where probabilities of occurrence of solid, liquid, or mixed precipitation significantly overlapped. Single-phase precipitation was found to occur more frequently than mixed-phase precipitation. Probabilistic phase-guided partitioning (PGP) models of increasing complexity using random forest algorithms were developed. The PGP models classified the precipitation phase and partitioned the precipitation accordingly into solid and liquid amounts. PGP_basic is based on 2-m air temperature and site elevation, while PGP_hydromet integrates relative humidity, surface pressure and precipitation rate. PGP_full includes all previous data, along with atmospheric reanalysis data, the 1000-850 hPa layer thickness, and temperature lapse rate. The PGP models were compared to benchmark precipitation phase partitioning methods. These included a single temperature threshold model set at 1.5°C, a linear transition model with dual temperature thresholds of –0.38 and 5°C, and a psychrometric balance model. Among the benchmark models, the single temperature threshold had the best classification performance (F1 score of 0.74) due to a low count of mixed-phase events. The other benchmark models tended to over-predict mixed-phase precipitation in order to decrease partitioning error. All PGP models showed significant phase classification improvement by reproducing the observed overlapping precipitation phases based on 2-m air temperature. PGP_hydromet and PGP_full displayed the best classification performance (F1 score of 0.84). In terms of partitioning error, PGP_full had the lowest RMSE (0.27 mm) and the least variability in performance. The RMSE of the single temperature threshold model was the highest (0.40 mm) and showed the greatest performance variability. An input variable importance analysis revealed that the additional data used in the more complex PGP models mainly improved mixed-phase precipitation prediction. The improvement of mixed-phase prediction remains a challenge. Relative humidity was deemed the

least important input variable used, due to consistent near water vapour saturation conditions. Additionally, the reanalysis atmospheric data proved to be an important factor to increase the robustness of the partitioning process. This study establishes a basis for integrating automated
40 phase observations into a hydrometeorological observation network and developing probabilistic precipitation phase models.

1 Introduction

Precipitation phase is a critical component in hydrological modelling. Simply put, the hydrological effect following either a snowfall or rainfall event is drastically different; snowfall
45 accumulates in winter and melts later in the spring or during winter melt events, while rain can either infiltrate or become runoff, potentially increasing streamflow in the short term. The precipitation phase also affects snowpack characteristics in different ways; a rain-on-snow event infiltrates the snowpack, increasing its liquid water content, and can create ice layers and change the snowpack internal characteristics (Singh et al., 1997; Wever et al., 2016), while snowfall
50 increases the depth of the snowpack. During individual precipitation events, errors in snowpack water equivalent (SWE) and depth are mainly caused by errors in precipitation partitioning (Leroux et al., 2023). On a seasonal basis, the precipitation phase significantly affects the ablation of the snowpack, particularly due to its impact on the snow albedo (Essery et al., 2013; Günther et al., 2019). As such, the cumulative effects of misclassified precipitation have a
55 significant impact on various seasonal values such as peak SWE, peak discharge date, and snow cover duration (Harder and Pomeroy, 2014).

As the climate warms, regions that typically experience winter snowfall are expected to face more rainfall in their winter precipitation, resulting in more rain-on-snow events (Jeong and Sushama, 2018; Ye et al., 2008; Musselman et al., 2018). Consequently, the proportion of runoff
60 caused by rain-on-snow events during the winter is projected to increase in these regions (Jeong and Sushama, 2018; Musselman et al., 2018). Effective precipitation partitioning methods are more important than ever to anticipate potentially damaging events and to monitor water resources at the catchment scale. This need is also felt for field monitoring of precipitation quantities. Indeed, solid precipitation is much more sensitive to undercatch (underestimation due
65 to the wind moving hydrometeors away from the gauge) than liquid precipitation (Rasmussen et al., 2012). Consequently, an inaccurate identification of the phase necessarily translates into an erroneous estimation of the precipitation quantity. Ehsani and Behrangi (2022) showed that undercatch for solid precipitation introduced a significant bias in gridded precipitation products at both the seasonal and annual scales at higher latitudes. This highlights the need to account for
70 the precipitation phase at the synoptic scale, especially when using precipitation products to bias-correct satellite precipitation estimates (Behrangi et al., 2019; Ehsani and Behrangi, 2022).

The modelling of the precipitation phase in operational hydrological models is often based on a single near-surface air temperature threshold (Harpold et al., 2017). While simple to implement, this method cannot predict mixed precipitation events, which tend to occur when falling hydrometeors of different sizes coexist and melt at different rates (Thériault and Stewart, 2010). As an alternative to the single-threshold approach, one can use a linear relationship to account for mixed-phase precipitation events that occur between those two thresholds. Furthermore, these types of methods can be refined into curvilinear functions, which would theoretically yield a more accurate phase identification (Feiccabrino et al., 2013). In both cases, the classification error is reduced when compared to the single threshold approach (Feiccabrino et al., 2013; Wen et al., 2013). The advantage of using temperature threshold-based models comes mainly from a data availability and computational requirement standpoint. Variables other than air temperature are known to influence the precipitation phase, such as relative humidity and atmospheric pressure (Behrangi et al., 2018; Dai, 2008; Jennings et al., 2018). Thus, precipitation partitioning models can be improved by using dew point temperature (e.g. Marks et al., 2013; Ye et al., 2013) or wet bulb temperature (e.g. Ding et al., 2014; Wang et al., 2019; Behrangi et al., 2018) instead of relying solely on air temperature, increasing the spatial robustness of such models.

Phase partitioning models tend to rely on near-surface hydrometeorological variables because this information is easily accessible. However, the hydrometeor's initial phase as it leaves the cloud, the shape and size distribution of the precipitation particles, and the properties of the atmosphere from the cloud to the ground all determine the precipitation phase (Feiccabrino et al., 2015). As they fall, the hydrometeors exchange latent and sensible heat with their surroundings, linking their phase to the temperature and vapour deficit as they fall through the atmosphere. Additionally, both heat fluxes are also affected by the ventilation of the hydrometeor, which depends on its fall speed and the surrounding wind velocities (Stewart, 1992).

Atmospheric temperature gradients can vary with time, so the thickness of the melting atmospheric layer is also a key variable to consider, as it affects the time the hydrometeor spends in conditions favourable to melting. Empirical models approximate this layer thickness by computing the height difference between two selected pressure levels (Feiccabrino et al., 2015). Precipitation rates can also increase the energy required to melt hydrometeors. Indeed, at high precipitation rates, there is a larger volume to melt, thus increasing the likelihood of solid precipitation at warmer temperatures (Froidurot et al., 2014; Thériault and Stewart, 2010). Therefore, by accounting for the characteristics of the atmospheric layer, microphysical models can determine the precipitation phase of falling hydrometeors (Thériault and Stewart, 2010). Other models are instead based on the statistical relationship between the hydrometeorological variables and the precipitation phase. Such models compute the probability of a precipitation phase occurring considering a set of environmental conditions.

110 The methodology for calculating the probability of phase occurrence varies across studies and includes, for example, a curvilinear function (Dai, 2008), logistic regression (Behrangi et al., 2018; Froidurot et al., 2014; Jennings et al., 2018), and machine learning algorithms (Shin et al., 2022). These methods output a precipitation type rather than a fraction of solid and liquid precipitation, in the case of dual threshold models. However, the use of these methods is limited when dealing with mixed-phase precipitation, as they do not provide information on how the
115 precipitation is partitioned. Fortunately, mixed-phase events are less common than single-phase events (Dai, 2008) and are thus often omitted from studies using probabilistic methods.

In addition to selecting the appropriate variables to include in a phase partitioning model, the quality and availability of the validation dataset is a critical aspect to consider. Indeed, the scarcity of validation data was cited by Harpold et al. (2017) as a major factor hindering the
120 development of phase partitioning models. Direct manual phase observations collected from trained observers have been used to validate precipitation partitioning models (e.g. Behrangi et al., 2018; Dai, 2008; Froidurot et al., 2014; Jennings et al., 2018). Jennings et al. (2023) have also shown the possibility of using crowdsourced precipitation phase data. While such datasets are extensive in time and space, they do not provide quantitative information on the snow and
125 rain fractions in mixed-phase events, thus limiting the possible predicted precipitation phases to either solid or liquid.

High-frequency automatic measurements do not suffer from limitations caused by mixed-phase precipitation (Froidurot et al., 2014; Harpold et al., 2017), as the precipitation phase can be coupled with a concurrent precipitation amount. When both phase identification and
130 precipitation gauge measurements are made at a high frequency, phase-separated precipitation can be compiled for hourly or shorter time steps, thus allowing for mixed-phase partitioning. One possible validation approach based on automatic data is to use precipitation measurements collocated with snow cover height measurements (Harder and Pomeroy, 2013; Marks et al., 2013). A more direct automatic approach is to use a disdrometer, which identifies the phase of
135 the hydrometeor according to its size and falling speed. For instance, Wayand et al. (2016) utilized a disdrometer to associate precipitation phase with precipitation amounts, which helped evaluate multiple phase models. This combination of observations not only allows for the validation of a phase model, but also addresses a major limitation of previous studies, namely the partitioning of precipitation in the case of mixed-phase events. Another important factor to
140 consider is the time step of the validation data. While many conceptual hydrological models employ daily time steps to determine precipitation phase, sub-daily time steps greatly enhance the accuracy of modelled phase (Feiccabrino, 2020; Harder and Pomeroy, 2013). Therefore, it is necessary to use sub-daily time steps, such as 15 minutes or hourly, as a significant portion of the phase model's performance depends on the time step of interest.

145 There are many ways to improve the representation of the precipitation phase for hydrological
purposes. As pointed out in Harpold et al. (2017), the often too simple phase models need more
hydrometeorological observations for a successful partitioning of the precipitation phase. Such
observations include the relative humidity, as well as atmospheric information, like the
temperature and humidity lapse rate. Additionally, an important research limitation comes from
150 the lack of validation data. Direct observations, while commonly utilized, have limited
application for mixed phase precipitation due to their qualitative nature. A preferable solution
involves automated phase observations, as they enable the coupling with precipitation rate
measurements. However, direct phase observation datasets indicate the existence of a
temperature transition zone, where both snow and rain are possible. This highlights the
155 limitations of simplistic phase models that fail to capture the complex nature of phase
determination.

This study leverages a unique regional-scale radar disdrometer network coupled with
precipitation observations to develop a probabilistic phase partitioning model. The probabilistic
model follows a phase-guided partitioning (PGP) in the form of a chain of random forest models.
160 The precipitation phase is classified before partitioning to accurately replicate its intricate
behaviour and to take advantage of the significant amount of validation data available through
such a network. As such, the models classify the precipitation as either solid, liquid, or mixed
phase. The predicted phase then dictates the partitioning into solid and liquid fractions.
Additionally, multiple PGP models with lower data requirements are developed to evaluate the
165 possibility of utilizing such models in practical operations. This study begins with a description
of the precipitation dataset and hydrometeorological variables used, followed by the
methodology used to develop the PGP models. Finally, the results section presents an analysis
of the dataset and evaluates the model's phase classification and partitioning performance,
comparing it to benchmark models of differing levels of complexity.

170 **2 Data**

2.1 Surface hydrometeorological measurements

The disdrometer network used for this study was deployed on the north shore of the St. Lawrence
River in the province of Quebec, Canada (Fig. 1). It is part of a larger hydrometeorological
observation network operated by Hydro-Quebec, a public utility responsible for the generation
and distribution of electricity in Quebec. The network lies between latitudes 47.23 and 52.13 °N,
175 and longitudes 63.17 to 75.29° W, spanning an area of roughly 532,594 km². The 27 stations
have been in operation for varying periods of time between the years 2019 and 2023, totalling
80 site-years. The site elevations range from 315 to 641 m above sea level (ASL), for an average

of 469 m ASL. The names, coordinates, and operational timeframes for each station are
180 presented in the Appendix A.

The sites have a mean annual 2-m air temperature of 0.2°C and a mean annual cumulative
precipitation of 902 mm, calculated from 160 site-years of daily observations. Figure 2 illustrates
the distribution of annual mean daily 2-m air temperature and precipitation, as well as the
elevation of the sites. The annual precipitation decreases with latitude, as the northern sites
185 (>51° N) experience an annual mean of 813 mm. The southernmost sites (<49° N) receive more
precipitation on average, with an annual mean of 1002 mm. However, the variability observed
at these sites is much greater than observed elsewhere. The sites' elevation follows mostly a
normal distribution within a 400 m range of the mean, with elevations generally increasing
northward. Following Köppen climate classification, the sites are nearly evenly split between
190 humid continental (Dfb) and humid subarctic (Dfc) climates. The study period spans from
October 1 to June 1 of the following year, as the chances of snowfall are practically non-existent
outside of these dates for the domain of interest.

Each site is equipped with a radar-based disdrometer (model WS100, Lufft), providing 15-min
phase identification. The WS100 is a K-band (24 GHz) Doppler radar that classifies droplets
195 into 11 size classes between 0.3 and 5.0 mm. The disdrometer assigns World Meteorological
Organization (WMO, table 4677) present weather codes for no precipitation (code 0), rain (code
60), freezing rain (code 67), mix of rain or drizzle and snow (code 69), and snowfall (code 70).
The precipitation phase is identified according to the hydrometeor diameter-fall velocity
relationships for water droplets outlined in Gunn and Kinzer (1949), as well as in Locatelli and
200 Hobbs (1974) for solid-phase precipitation particles. Rain and snow falling velocity as a function
of measured reflectivity from K-band Doppler radar was investigated in Atlas et al. (1973) and
remains an area of active research (e.g. Garcia-Benadi et al., 2020; Kneifel et al., 2011; Löffler-
Mang et al., 1999; Sarkar et al., 2015). For simplicity, the phase identification derived from the
diameter-fall velocity relationships are referred as observations in this study. In addition, each
205 site also provides measurements of SWE using a passive gamma ray monitoring system (model
CS725, Campbell Scientific) and snow depth using an ultrasonic sensor (SD, model SR50A,
Campbell Scientific).

The meteorological observations in this study come from weather stations operated by Hydro-
Quebec and SOPFEU, the province's wildfire prevention organization. The weather stations
210 provide 15-min accumulated precipitation (model Pluvio² by OTT, equipped with a single-Alt-
shield), allowing the coupling of precipitation with concurrent disdrometer phase identification.
The weather stations measure hourly air temperature (model CS109, Campbell Scientific) and
relative humidity (model HMP155a, Campbell Scientific) with sensors mounted at 2 m above

215 ground. Additionally, wind speed and direction are monitored at a 15-min interval with a ground
propeller anemometer (model 05103, Young) mounted 2 m and 10 m above ground.

Most of the study sites and weather stations are located in close proximity to each other.
Specifically, 67% of the study sites are within 3 km of or collocated with the nearest weather
station. The remaining stations are between a median distance of 7 km and a maximum distance
220 are separated by 28 km. To account for the elevation differences between the study sites and
weather stations, the air temperature measurements were adjusted using international standard
atmosphere methods. The discussion section will address the uncertainty related to the distance
between the study site and the weather station. The temporal resolution and detailed
specifications about the study sites' instruments are provided in Table 1.

225 2.2 Reanalysis products

Hourly atmospheric data from the ECMWF-ERA5 reanalysis (Hersbach et al., 2023) are added
to this study's dataset, to account for the energy transfer to falling hydrometeors in the
atmospheric levels closest to the surface. Furthermore, this will help assessing the potential
performance gain of incorporating gridded data, despite the spatial scale discrepancy with local
230 observational data. The added data include temperature profiles for pressure levels of 1000 and
850 hPa. The corresponding geopotential height of these levels is also added to the dataset. The
values from the nearest $0.25^\circ \times 0.25^\circ$ grid cell, roughly $28 \text{ km} \times 18 \text{ km}$ at the study sites' latitude,
are assigned to every study site. Additionally, the hourly surface atmospheric pressure from
ERA5-Land (Muñoz Sabater, 2019) is added to the dataset, as it was not measured at the weather
235 stations used in this study. The atmospheric pressure from the nearest $9 \text{ km} \times 9 \text{ km}$ grid space is
assigned to every study site. From this data, the thickness Δz between the 1000 and 850 hPa
layers (m) is calculated with:

$$\Delta z = \frac{z_{850} - z_{1000}}{g} \quad (1)$$

where z_{850} and z_{1000} correspond to the geopotential heights ($\text{m}^2 \text{ s}^{-2}$) at the top and bottom of the
240 layer, and g is the gravitational acceleration (9.81 m s^{-2}). The layer thickness between the two
pressure levels is correlated with the mean temperature of the layer and is also a commonly used
variable in operational meteorological models (Feiccabrino et al., 2015). The pressure levels
were selected based on their successful use in the classification of the precipitation phase at the
surface in prior studies (e.g. Bourguoin, 2000; Shin et al., 2022). The temperature lapse rate Γ
245 ($^\circ\text{C km}^{-1}$) is also calculated:

$$\Gamma = -\frac{\Delta T}{\Delta z} \times 1000 \quad (2)$$

where ΔT correspond to the temperature difference between the 850 and 100 hPa layers ($^{\circ}\text{C}$).

3 Methodology

3.1 Precipitation data processing

250 The observed 15-min precipitation amounts were compiled at the hourly time step. Each 15 min precipitation data segment was coupled with a disdrometer phase identification. Both valid, non-zero values were required for the data segment to be included in the analysis. A first filter was applied, where hourly precipitation rates $< 0.2 \text{ mm h}^{-1}$ were considered erroneous trace amounts, following standard WMO methodology (WMO, 2018). A second filter was also applied where
255 precipitation rates $> 110 \text{ mm h}^{-1}$ were considered erroneous (Smith et al., 2022). A neutral aggregating filter (Ross et al., 2020) was then applied to eliminate noise and diurnal oscillations in the precipitation data. Additionally, hourly precipitation exceeding 30 mm h^{-1} was visually inspected. Any data not consistent with nearby stations was considered invalid.

The disdrometers used in this study can identify freezing rain and a mix of rain and snow in
260 addition to snow and rain. However, as most hydrological models only interpret the effect of snow and rain, this study focuses on the prediction of solid and liquid precipitation. Therefore, the disdrometer identification of freezing rain and of mix of rain/drizzle and snow were aggregated, respectively with snow and rain events. For example, if an hourly precipitation has a fraction of rain and a mix of rain/drizzle and snow, it would be considered completely liquid
265 after the aggregation. The selected phase aggregation aims to group the phases that are most similar in terms of hydrological influence and average occurring temperature. These assumptions are supported by an analysis of the effect of each precipitation phase on the snowpack properties (height and snow water equivalent), as detailed in Appendix B.

When solid precipitation was identified, the universal transfer functions of Kochendorfer et al.
270 (2017) were applied to adjust for wind-induced gauge undercatch. To do so, local hourly wind speed and temperature measurements at gauge height were used, which were shown to provide appropriate corrections for sites in boreal climates (Pierre et al., 2019). The solid and liquid 15-min precipitation were then compiled at hourly time steps and partitioned into liquid and solid precipitation fractions, totalling 31,905 data points. The resulting phase partitioning was used to
275 classify the phase of each precipitation event as solid, liquid, or mixed, with respective dataset proportions of 71%, 22% and 7%.

Figure 3a shows the phase occurrence of the coupled 15-min precipitation data along an
interpolated 15-min 2-m air temperature. The phase occurrence in Fig. 3b shows that it is mostly
280 the mixed and liquid precipitation that are affected by the aggregation, and that very few freezing rain events aggregated with snow events result in the snow and solid phase distributions being

very similar. The aggregation of the mix of rain/drizzle and snow with rain results in an increase in liquid precipitation in the 0–5°C range. Mixed-phase precipitation occurs in the same air temperature range as that of the mix of rain/drizzle and snow, suggesting that this phase is often present in mixed-phase precipitation, thus validating the aggregation. A cursory analysis of the mixed-phase precipitation events revealed that events with a phase transition between snow and mix of rain/drizzle and snow account for roughly 75% of the mixed-phase events. Transitions from rain to snow are infrequent and represent roughly 15% of the mixed-phase precipitation events, while the remainder includes other phase combinations.

3.2 Model performance evaluation

The models presented in this study are evaluated for their ability to correctly predict the precipitation phase using a variety of performance metrics. First, the metrics used to quantify the predictive ability of the models are the precision (PRE) and the recall (REC), as well as the F1 score (Rokach et al., 2023). The combination of precision and recall is commonly used to evaluate model classification performance, as the metrics indicate different information. The precision indicates the proportion of correct predictions for a given phase, while the recall indicates the probability of detection for a given phase. By definition, model precision and recall are inversely proportional. The assessment of both metrics informs if a model over or underpredicts a given class. For instance, low precision and high recall indicate a class overprediction, while high precision and low recall indicate a class underprediction. Therefore, a model that achieves good performance in both metrics is desirable.

$$PRE = \frac{TP}{TP + FP} \quad (3)$$

$$REC = \frac{TP}{TP + FN} \quad (4)$$

where TP , FN , FP are the true positive, false negative and false positive counts respectively for a given phase. The F1 score, being the harmonic mean of the precision and recall, is a useful metric to quantify the general performance of the model.

$$F1 = 2 \left(\frac{PRE \times REC}{PRE + REC} \right) \quad (5)$$

These metrics are computed for each precipitation phase separately. A general score is also computed by weighing each phase's score according to its proportion in the dataset. As such, the weighted F1 score is used as a general classification performance metric, as it combines both

precision and recall, and harshly penalizes a poor score in either of them while also considering
315 the dataset imbalance.

Second, the model partitioning performance is evaluated based on the predicted solid and liquid
precipitation amounts. The metrics used are the coefficient of determination R^2 and the RMSE.
Due to the slightly asymmetric phase distribution and overlap between the phases shown in Fig.
3, different R^2 are calculated for the solid and liquid precipitation. Thereby, the metrics are
320 calculated on the phase-separated precipitation rather than on the precipitation fraction, as the
precipitation phase could be solid, liquid or mixed for a given temperature. Because of the
partitioning between solid or liquid precipitation, the RMSE is equal to the root mean squared
of the misclassified precipitation. Therefore, the RMSE is the same for both solid and liquid
precipitation, and a single score is presented. Finally, the partitioning performance metrics are
325 performed on different subsets of the dataset using a K-fold method. The K-fold validation
method is commonly used to assess the variability of model performance with machine learning
methods. By using different subsets of the dataset to train and validate the model K times, a more
general performance can be assessed. Because of the fewer liquid and mixed precipitation events
compared to solid precipitation events, the K-Fold is also stratified to maintain phase proportions
330 between training and validation sets from fold to fold. As such, in the case of the partitioning
validation, the variability of the precipitation amounts from fold to fold must be considered. The
performance metrics are repeated until the variance of the partitioning performance metrics
stabilizes. In this case, the validation was performed with 5-fold validation and was repeated six
times for a total of 30 validation folds.

335 **3.3 Phase-guided probabilistic precipitation phase model**

Machine learning algorithms are powerful tools for building classification and regression
models. Random forests (Breiman, 2001) are commonly utilized in the environmental sciences
due to their simple implementation and lower susceptibility to overfitting compared to other
models. The model is based on decision trees, where variables are randomly chosen at each node
340 to create a prediction. Therefore, the decision trees, each unique due to randomness, provide
predictions that are ultimately aggregated to generate a final well-informed prediction.

Given the overlapping phases of the data set, a Random Forest (RF) classifier is used to predict
the precipitation phase with a probabilistic approach. The procedure to develop the RF model is
illustrated in Fig. 4. To address the phase type imbalance, the data were adjusted by
345 undersampling the solid phase and increasing the weight of both liquid and mixed precipitation
phases in the dataset. To achieve this, only data points with air temperatures between -4 and 8°C
were kept in the analysis. The phase proportions resulting from the undersampling are 60% solid,
26% liquid and 14% mixed. The data were then split using an 80/20 ratio between the training
and validation sets respectively, resulting in 13,339 data points for training and 3,335 for

350 validation. To account for the prevalence of solid precipitation samples, the training and
validation sets were stratified to maintain the aforementioned phase proportions between the two
subsets (60% solid, 26% liquid, 14% mixed). Hyperparameters were optimized on the training
set to increase the model performance and reduce the chance of overfitting by using a stratified
5-fold cross validation and maximizing for a weighted F1 score. The RF classifier was then
355 retrained on the entire training data set and was ready for use on the validation set.

While the precipitation partitioning is straightforward when the predicted phase is either solid
or liquid, it is less so for predicted mixed phase, where a solid and liquid precipitation fraction
must be assigned. Thus, in the case of a predicted mixed phase, an RF regression model is
developed following the same steps described above. The loss function used to optimize the
360 regression model parameters is the mean-squared error (MSE), to increase the penalty on larger
errors. The Phase-Guided-Partitioning model predicts a precipitation phase, as well as a solid
and liquid precipitation partitioning according to the predicted phase, with the complete process
illustrated in Fig. 5.

Multiple PGP models using a combination of atmospheric variables were developed. The subsets
365 of input variables of the PGP models accommodate different levels of data availability, ranging
from the strictest minimum data requirements (e.g., in an operational context) to atmospheric
variables, with each subset fully incorporating the previous subsets (see Table 2). This approach
will help to quantify the impact of some atmospheric variables that are not measured at surface
weather stations. The simplest model, PGP_basic, includes only 2-m air temperature and site
370 elevation. Next, PGP_hydromet includes all related near-surface hydrometeorological data, such
as relative humidity, atmospheric pressure, and precipitation rate. Finally, the PGP_full model,
as discussed in the previous sections, incorporates atmospheric data from reanalysis, specifically
the thickness of the 1000-850 hPa layer and temperature lapse rate.

3.4 Benchmark phase partitioning models

375 The benchmark models used for this study are common methods of increasing complexity found
in hydrological models. First, a single 2-m air temperature threshold (ST) model is used as a
baseline comparison. This model separates precipitation into solid and liquid phases based on a
calibrated air-temperature threshold. While this type of model is widely used, it is generally
associated with larger partitioning errors on a seasonal basis (Harpold et al., 2017). Second, a
380 linear transition (LT) model is used. It allows for mixed-phase precipitation, while still being of
low complexity. LT partitions the solid and liquid precipitation according to a linear relationship
between a snow and rain temperature threshold. Finally, the psychrometric energy balance (PB)
model is used, which is a phase partitioning method based on the mass energy and energy
balance of a sublimating ice sphere that integrates the relative humidity to estimate the

385 hydrometeor temperature (Harder and Pomeroy, 2013). The estimated hydrometeor temperature
is then used as an input in a two-parameter curvilinear relationship. All three benchmark models
are calibrated individually with the least squares method, minimizing the error with the observed
solid-phase fractions. The models and their calibrated values are given in Appendix C. The
precipitation phase can then be inferred from the predicted fractions. In other words, mixed phase
390 will be predicted in the instance of non-zero solid and liquid fractions, otherwise the predicted
phase is either solid or liquid. Previous studies that employed probabilistic models based on
direct phase observations (e.g. Behrangi et al., 2018; Jennings et al., 2018) were not included as
benchmark models. Mixed-phase precipitation is typically excluded from such studies, as there
is no effective method to accurately partition the precipitation due to the categorical nature of
395 direct phase observations. The above considerations make such models difficult to compare with
the PGP models presented in this study.

3.5 Input variable importance analysis

A common way to interpret input variable importance for a machine learning model is to use
permutation importance, which helps decreasing the black-box aspect of machine learning
400 algorithms (McGovern et al., 2019). The performance of the model is computed according to a
chosen scoring scheme. Each variable of the model is then shuffled individually. The goal of this
step is to break the relationship between a variable and the desired prediction. After each shuffle,
a performance score is calculated to show the decrease in model performance. This process is
then repeated several times to account for data variability. Thus, the relative importance of each
405 input variable to the model can be quantified with the resulting performance decrease.
Permutation importance analysis provides only the importance of an input variable to the model,
not the inherent information provided by that variable. However, when shuffling a variable that
is highly correlated to another, the model can still find the shuffled variable's information when
performing permutation importance analysis. In practice, this is an important consideration as it
410 means the importance of either, or both, input variables can be lower. This analysis offers insight
into the crucial variables for the PGP models and how they can be further improved.

4 Results

4.1 Dataset analysis

The distribution of the hydrometeorological variables categorized by precipitation phase is
415 displayed in Fig. 6. The temperature distributions show a significant overlap between all three
phases from 1.5 to 3.6°C, similar to that reported in Jennings et al. (2023). Mixed precipitation
probability peaks at approximately 2.4°C. The distribution of relative humidity reveals that
precipitation is associated with near liquid water vapour saturation conditions, with a median

value of 97%, regardless of the precipitation phase. The mean precipitation rate is generally low, at 0.9 mm h⁻¹. The median precipitation rate for mixed-phase events is generally the highest at 0.8 mm h⁻¹, followed by liquid-phase events at 0.7 mm h⁻¹ and solid-phase events at 0.6 mm h⁻¹. Atmospheric pressure distributions are similar for both liquid and mixed-phase precipitation events. The mean air pressure during the solid precipitation events is comparable to that of the other phases, but there are more events between 90 and 92 kPa. The distribution for the thickness of the 1000-850 hPa layer closely mirrors that of air temperature, given their general correlation. The temperature lapse rate averages 4.9°C km⁻¹ and distributions, especially solid precipitation, show a bias toward the standard atmospheric lapse rate of 6.5°C km⁻¹.

The overlap of the phase distributions for each input variable, most notably the air temperature, indicates that a probabilistic approach is appropriate for predicting the precipitation phase. Indeed, between approximately 0 and 4°C, solid and liquid precipitation may occur separately or coexist. According to findings in previous studies, precipitation over land is more likely to occur in a single phase than in mixed phase precipitation (Dai, 2008; Froidurot et al., 2014), as is the case in this study, where only 13% of the precipitation data points are mixed phase. There is, however, a narrow 2-m air temperature range, between 2 and 2.5°C, where mixed-phase probability exceeds the probability of single-phase precipitation. An appropriate phase partitioning model must thus accurately predict the phase in the temperature interval where solid, liquid, and mixed precipitation occurrences overlap while also providing accurate partitioning when needed.

4.2 Phase classification

Figure 7 shows the phase density distribution of the benchmark models and the PGP models in comparison to the observations. The corresponding classification scores of the models, which were weighted to reflect the precipitation phase proportions in the dataset, are presented in Table 3. The phase density distributions show the limitations of benchmark phase partitioning models, namely that the mixed phase is absent or overrepresented compared to the observations. However, ST performs well in all three metrics due to the low likelihood of mixed phase occurrence. When evaluating the overall classification performance using the F1 score, LT follows ST because of a disparity between precision and recall that affects its F1 score. The lower recall score for LT can be attributed to its overprediction of the less frequent mixed phase, which, in turn, negatively affects the recall of other phases. This enhances the model's weighted precision by decreasing the number of false positives in non-mixed-phase prediction. The same reasoning can be more extensively applied to PB's weighted scores. The mixed phase's overlap with other phases significantly decreases the model's overall recall. Due to the relationships used to create the benchmark models, the overlap between all three phases is not accurately

455 represented. By including relative humidity, PB can model phase overlap, but this does not improve the modelled phase distribution density with respect to the observations.

The weighted F1 score for the PGP models shows that they have a more robust general performance, as they have high weighted precision and recall scores, while having a small disparity between both scores. The PGP models reproduce the observed phase overlap well, but slightly overpredict the mixed phase, affecting both the solid and liquid-phase predictions. 460 PGP_basic exhibits the greatest mixed phase overprediction, while the difference between PGP_hydromet and PGP_full is marginal. This result suggests possible improvements to PGP models, particularly for mixed-phase precipitation.

The phase-separated classification metrics provide further insight into the performance of the models, shown in Fig. 8. The F1 score provides an overall performance for each phase 465 prediction. PGP_full has the best F1 scores for both the solid and liquid phases, while PGP_hydromet has a higher F1 for the mixed phase. PGP_basic is generally the third best-performing model in terms of F1 score, except for the solid phase, where ST outperforms it. While it is not able to predict the mixed phase, ST has the highest scores for the liquid and solid precipitation phases out of the benchmark models. This is probably because mixed-phase 470 precipitation events are only roughly 13% of the samples, this low proportion does not significantly decrease the model's performance. LT performs slightly worse than ST for both solid and liquid phases F1 scores but has the highest mixed-phase F1 score out of the benchmark models.

PB's poor F1 scores are explained by the overlaps between the phases shown in Fig. 7. The 475 model allows the predicted mixed phase to overlap with the predicted solid and liquid phases, which is the opposite behaviour of the observed phase density, where mixed-phase precipitation mostly exist in the solid and liquid phase overlap. Given the modelled phase density and the resulting classification scores, the phase prediction ability of both LT and PB suffers from overprediction of the mixed phase. This is evidenced by the significant disparity between the 480 precision and recall scores of LT and PB for the mixed phase. A high recall score signifies that the model minimizes the number of false negatives, which negatively affects the model's precision. Thus, overpredicting the mixed phase greatly reduces the models' precision for the mixed phase, while greatly increasing their recall for the mixed phase. Conversely, the conservative prediction of the liquid and solid phases increases the precision of the model but 485 decreases the recall for both phases.

Although they are not always the best models in terms of either precision or recall, the PGP models have the best general performance, making them more reliable for phase prediction. Thus, PGP models significantly reduces phase identification error by showing high precision and recall, with small disparities for solid and liquid phase prediction. However, PGP's main

490 distinguishing feature is its general ability to predict mixed-phase precipitation. Furthermore, the disparity between the precision and recall scores for the mixed phase is much smaller than for the other models studied, indicating that the overprediction of the mixed phase is much less severe for PGP.

4.3 Precipitation partitioning

495 Figure 9 displays how the regression metrics vary across validation folds. The precipitation rate variability has a significant impact on ST's performance, making its ability to partition precipitation highly variable from winter to winter. In contrast, LT and PB exhibit better performance than ST due to their ability to partition the solid and liquid phases, with much less variability in performance. The variability of R^2 for liquid precipitation is lower for LT and PB
500 than for solid precipitation, because fewer of these events occur. For all regression metrics, LT and PB have similar performance. This is most likely due to the very humid environment, which decreases the difference between the 2-m air temperature and the hydrometeor temperature computed for PB.

The average regression metrics in Table 4 shows the partitioning performance of the various
505 models. All models have a high R^2 for solid precipitation, likely due to the abundance of solid precipitation. However, model performance decreases for liquid precipitation R^2 , with ST being significantly lower than other models. This trend is also observed for the RMSE. While ST is the worst performing model, LT, PB and PGP_basic perform similarly in all regression metrics. The inclusion of hydrometeorological data in PGP_hydromet leads to a slight increase in
510 performance. Lastly, the inclusion of atmospheric data in PGP_full improves performance compared to the other models.

Generally, the performance of PGP_basic is similar to that of LT and PB, with slight differences. PGP_basic is more variable in its performance for solid precipitation R^2 and RMSE. This
515 variability can be attributed to the misclassification of precipitation events due to its limited input variables. The R^2 scores for PGP_hydromet are less variable than for PGP_basic, while its RMSE is the most variable out of the PGP models. PGP_full exhibits the lowest variability for both R^2 and is the only PGP model with RMSE variability similar to benchmark models LT and PB.

The broader RMSE score range of the PGP models highlights the impact of misidentified phases.
520 Misidentification can be more costly than for a benchmark model that systematically separates precipitation into solid and liquid phases for temperatures where mixed-phase events are possible. Furthermore, models such as LT and PB achieve partial accuracy in phase partitioning by forcing mixed-phase precipitation, but if a PGP model misclassifies the phase, the entire precipitation event may be incorrectly partitioned. However, PGP models do show that phase

525 identification prior to phase partitioning can reduce the overall error of a model for both solid and liquid precipitation. This suggests that improved phase identification, specifically with mixed-phase prediction, could greatly enhance the accuracy of precipitation partitioning from PGP models.

4.4 Input variable importance

530 Figure 10 shows the correlation matrix of PGP_full input variables. While the correlation of most input variable combinations is low, the 2-m air temperature and 1000-850 hPa layer thickness are highly correlated. The layer thickness is affected by environmental temperatures, as the air density is inversely proportional to its temperature. Therefore, as temperatures increase, the distance between two pressure levels also increase. There is a moderate negative
535 correlation between elevation and air pressure, probably because of the small range of study site elevations. The temperature lapse rate has a small correlation with almost all features.

The scoring scheme for permutation importance must be carefully selected according to the model and use case. In this instance, the PGP models tend to overpredict the mixed phase, which also negatively impact their ability to predict the other phases. In turn, this also affects the
540 models' partitioning error, which indicates that their overall performance is reliant on accurate phase classification. For these reasons, the chosen scoring scheme for the permutation importance is the weighted F1 score, to consider the classification of the imbalanced phase dataset.

Figure 11 shows the permutation importance of PGP_full input variables and the resulting
545 decrease in the weighted F1 score on the validation set. The 2-m air temperature is the most important variable, with its permutation decreasing the score by more than 0.2. The second most important variable is the 1000-850 hPa layer thickness, a result shared by Shin et al. (2022). Because of its high correlation with the 2-m air temperature, it is difficult to interpret the real importance of this variable. In terms of classification performance, the addition of this variable
550 seems to provide small improvements, as shown by the differences in classification metrics between PGP_hydromet and PGP_full.

For the remaining variables, the importance decreases sharply. However, while the individual importance of the variables is low, they improve the phase classification when combined. This suggests that the additional variables used in PGP_full likely improve mostly mixed-phase
555 prediction, which is supported by the model's performance in section 4.2. The elevation is used to approximate the atmospheric pressure of a site and can improve phase partitioning (e.g. Ding et al., 2014; Behrangi et al., 2018). Furthermore, atmospheric pressure is often cited as an important variable for phase partitioning (e.g. Behrangi et al., 2018; Dai, 2008; Jennings et al., 2018). The thinner air in low-pressure environments allows snow to reach the ground faster. The

560 temperature lapse rate provides key information regarding the amount of energy the hydrometeors absorb before reaching the ground.

The precipitation rate has a minor impact on the performance of the model. Nevertheless, it may hold significance for the prediction of the mixed phase. The precipitation rate is linked to the precipitation phase as it increases the energy required to completely melt falling precipitation
565 (Froidurot et al., 2014; Thériault et al., 2010). However, its effect is minimal, most likely due to the small proportion of mixed-phase events. Finally, the model ranks relative humidity as the least important feature. This outcome is unexpected because relative humidity was shown to have a significant effect on phase partitioning (e.g. Behrangi et al., 2018; Jennings et al., 2018). One explanation could be the high percentage of data points near water vapour saturation,
570 resulting in the variable being less regionally significant than more heterogeneous regions such as mountain ranges. Besides, this could account for the PB model's underwhelming classification accuracy since it utilizes relative humidity to determine the precipitation phase and the fact that it was developed for the drier climate near the Canadian Rockies.

5 Discussion

575 5.1 Model performance and input variable importance

The classification and regression metrics of the PGP models show that phase classification prior to phase partitioning reduces the partitioning error of solid and liquid precipitation, while also providing a more reliable phase prediction than benchmark models. The use of radar-based disdrometer measurements enabled the partitioning step of the model by providing precipitation
580 fractions for mixed-phase events, a flaw mentioned in other studies (Froidurot et al., 2014; Jennings et al., 2018). Out of the benchmark models, ST displayed the best classification performance, despite not allowing for mixed-phase precipitation. The tendency of overpredicting mixed-phase precipitation of both LT and PB reduced their overall classification performance. This general behaviour was also observed in Leroux et al. (2023), where simpler
585 methods outperformed methods based on a precipitation phase fraction. However, ST showed significantly worse partitioning performance compared to LT and PB. The limitations of precipitation fraction-based models are highlighted by the fact that LT and PB were the worst performing phase classification benchmark models, despite being the best partitioning benchmark models. These models were calibrated to minimize partitioning error, but in doing
590 so, they are biased toward predicting mixed-phase precipitation. The mixed-phase prediction of the benchmark models could be artificially constrained to reduce overprediction and improve classification performance. Such constraints would, however, increase the benchmark models' partitioning error, given that they were calibrated according to solid precipitation fractions.

Therefore, there is a trade-off between classification and partitioning error for precipitation
595 fraction-based models such as LT and PB.

PGP_basic, while showing an improvement in phase classification, did not significantly
outperform the partitioning of benchmark models LT and PB. PGP_hydromet showed improved
phase classification, notably for mixed phase, and partitioning. PGP_full showed further
increase in overall performance, while also reducing the partitioning error variability. However,
600 all PGP models tended to over predict the mixed phase as shown in Fig. 7. Reducing the
overprediction of mixed phase is a persistent challenge in improving precipitation phase
modelling, as noted in previous studies (Casellas et al., 2021; Leroux et al., 2023).

The permutation importance analysis showed that most input variables used, apart from the 2-m
air temperature, are of low importance. However, the classification performance improvement
605 of PGP_hydromet and PGP_full show the cumulative importance of the additional variables
used, most notably for mixed-phase prediction. Despite many studies demonstrating its impact
on precipitation phase, relative humidity was found to be the least important factor. This is likely
due to the regional homogeneity, with most observations occurring near liquid water vapour
saturation. The site elevation was considered important for phase classification, even though it
610 is a constant variable. This suggests that an atmospheric pressure estimated by the elevation
could provide enough information relevant to improve phase classification. Still, out of the
hydrometeorological variables, the atmospheric pressure had the most impact on phase
classification performance. This is in line with other studies that found it has a significant impact
on the precipitation phase (e.g. Behrangi et al., 2018; Dai, 2008; Jennings et al., 2018), although
615 generally to a lesser extent than relative humidity, when considering the regional variability.

The precipitation rate's low importance is most likely because it affects mixed-phase prediction,
thus has low impact for overall performance. According to Thériault et al. (2010), higher
precipitation rates raise the likelihood of larger hydrometeors, which require more energy to
melt. Consequently, there is an increased likelihood of mixed-phase precipitation occurring in
620 the form of partially melted hydrometeors. As noted by Feiccabrino et al. (2015), higher
precipitation rates can lead to snowfall happening at warmer temperatures due to the presence
of unstable air below the isothermal layer.

The permutation importance of 1000-850 hPa layer thickness is second to the 2-m air
temperature. However, because of the high correlation of the pair of variables combined with
625 the moderate classification improvement of PGP_full, the real importance of the 1000-850 hPa
layer is most likely low. While the importance of the temperature lapse rate is low, the
partitioning results demonstrated that incorporating gridded atmospheric variables alongside
local observations led to a reduction in the variance of the regression performance. This finding
is noteworthy because few studies, as pointed out by Harpold et al. (2017), have explored the

630 impact of incorporating atmospheric reanalysis data into phase modelling. Froidurot et al. (2014)
indicated that models using atmospheric data did not greatly improve the phase prediction, as is
the case in this study's classification performance. Furthermore, Dai (2008) emphasizes the
terrain-dependent nature of lapse rates. Thus, even though the study sites in the region are
relatively similar in terms of terrain, the importance of lapse rates in the modelling process was
635 still significant, contrary to the fairly homogenous relative humidity measurements.

5.2 Coupled precipitation data uncertainty

There are uncertainties regarding the results due to the dataset and assumptions employed.
Hydrological models commonly limit the precipitation phases to solid or liquid. Nonetheless,
this dataset includes a considerable quantity of mixed snow and rain/drizzle events, and it is
640 uncertain how hydrological models should handle this precipitation phase. The phase
aggregation step considered the behaviour of the snowpack following the different phases
detected by the disdrometers. Following a mix of rain/drizzle and snow, the SWE and snow
height tended to decrease, a snowpack response similar to that following a rain event. It can be
inferred that this type of precipitation is likely to be dominated by rainfall given the warm
645 temperature at which it occurs and the ensuing effects on the snowpack. However, it is probable
that this interpretation is specific to the disdrometers used in this study unless evidence to the
contrary emerges. However, phase identification errors have the potential to introduce
uncertainties in the results, notably in the case of mixed-phase precipitation. To measure this
uncertainty, it is recommended that studies be conducted using collocated WS-100 disdrometers
650 and other well-documented options such as laser disdrometers, to assess the differences between
ground-truth providing instruments (Harpold et al., 2017).

Another source of uncertainty arises from the coupling of precipitation amounts and phase
observations. Fehlmann et al. (2020) demonstrated that laser disdrometers have low missed
event and false alarm rates for sub-daily integration times compared to precipitometers, but no
655 such study was conducted with the radar-based disdrometers of this study. Additionally, the
study from Fehlmann et al. (2020) was carried out in a site sheltered from the wind, implying
that the wind-induced gauge undercatch could not be studied. In turn, the wind could influence
the missed event and false alarm rates of this study's instruments. In this study, data segments
where either the precipitation gauge or disdrometer did not detect any precipitation were
660 discarded. Figure 12 displays the hit-rate of both the instruments at the initial 15-min intervals
and shows that the instruments' hit-rates are generally in agreement. The instrument hits were
normalized over the precipitation gauge observations to compute relevant agreement metrics.
The precipitation gauge is considered as ground-truth as it would be used in conjunction with a
precipitation phase model and phase observations are rare in operational context.

665 Precipitation data segments of 0.1 mm coincide with 38% of the disdrometer misses. Assuming
that a significant portion of this precipitation data would be labelled as trace amounts when
resampled at the hourly interval (< 0.2 mm), the probability of missed events is likely lower in
reality. Multiple factors could account for disagreements between the instruments, including the
effect of wind, which likely varies from instrument to instrument, and the fact that certain
670 stations are not collocated or nearby. However, the environmental effects on the disdrometer
performance lacks previous studies and require more detailed investigation as outlined in
Harpold et al. (2017).

Figure 13 shows the variation of the instrument agreement according to the distance between
stations. The station pairs are divided into four distance categories: less than 3, 4 to 7, 7 to 12
675 and more than 12 km. Generally, the stations separated by less than 3 km show better agreement,
with a few outliers. However, the instrument agreement does not seem to decrease with distance,
as the 4 to 7 km category exhibits the poorest agreement. Notably, the AUXLOUPS station,
separated by 28 km with the nearest weather station, has a probability of detection of 0.79, a
false alarm rate of 0.14 and a miss rate of 0.21. These instrument agreement metrics are only
680 slightly worse than the metrics of the 15-min dataset in Fig. 12. This suggests that instrument
agreement is linked to site specific conditions rather than distance between stations. However,
by discarding data points where the instruments do not agree, we ensure that precipitation events
are consistent across study sites and weather stations. In addition, the coupling of instruments
from nearby stations brings the spatial scale of the observational data closer to the scale of the
685 reanalysis data.

5.3 Data validation across studies

The phase observations from this study can be compared to other studies that use different
validation data, such as direct observations (e.g. Behrangi et al., 2018; Dai, 2008; Jennings et
al., 2018). However, it can be difficult to compare the phase occurrence according to the 2-m air
690 temperature, as the datasets in such studies often exclude mixed-phase precipitation.
Consequently, the mixed phase is usually not analyzed in detail. One method to simply compare
phase partitioning models is the critical threshold air temperature value CT_a , which is defined as
the critical temperature threshold where both solid and liquid phase have 50% chance of
occurrence. In the case of this study, we define a different critical threshold for solid CT_S and
695 liquid phase CT_L , as well as a temperature where the probability for mixed phase is highest P_m .
Figure 14 shows the probability of occurrence of the phases at the study sites separated in 0.2°C
bins. The resulting thresholds are CT_S of 1.3°C , CT_L of 3.8°C and P_m of 2.4°C for a mixed-phase
probability of 0.44. It is also noteworthy that P_m is roughly where the probability of solid and
liquid precipitation is equal. Because of this study's aggregation step, CT_S should be similar to

700 CT_a values from other studies, as the aggregation mostly affected the probability of mixed and liquid precipitation, and CT_L will be much warmer than CT_a .

In Behrangi et al. (2018), the average hourly CT_a of 1.58°C aligns roughly with the study's CT_S and the calibrated 2-m air temperature threshold of benchmark ST. One of the main conclusions from the study was that the wet-bulb temperature model is more robust than the dry-bulb
705 temperature model, as the CT_a can vary significantly from site to site. Humid conditions lead to a cooler CT_a , while drier conditions have the opposite effect. As such, the CT_a for humid conditions would be approximately equal to the mean value minus the standard deviation, resulting in 1.18°C, and is thus closer to this study's CT_S of 1.3°C. Additionally, the upper limit of CT_a of 2.16°C in Behrangi et al. (2018) closely matches P_m . This finding lends credibility to
710 the disdrometer phase identification and the phase aggregation step, as it indicates the temperature range in which both solid and liquid phases are possible.

In Dai (2008), the overland 3-hourly CT_a of 1.2°C is comparable to this study's CT_S , despite the different time step. The chance for mixed phase in this study is much higher and more likely at warmer temperatures than that of Dai (2008), where they report a peak 14.3% chance of mixed
715 rain and snow at 1.4°C overland. However, Ding et al. (2014) have shown that the probability of mixed-phase precipitation at the daily time step greatly increases in humid conditions, particularly near saturation. Such an analysis would, however, be required at the hourly time step to confirm this behaviour. The reasoning for the increase in mixed-phase precipitation probability is that the increase in relative humidity decreases evaporative cooling and favours a
720 transition from snow to rain. In contrast, the temperature difference between the hydrometeors and the air decreases as humidity rises, which decreases sensible heat transfer and hinders the transition from snow to rain. The relatively homogenous conditions of the study sites could explain the differences in mixed-phase precipitation probability, while the analysis in Dai (2008) lumped together a large number of stations.

725 The findings in Jennings et al. (2018) report a much lower 3-hourly CT_a of 0.7°C for precipitation in 90–100% relative humidity and 0.9°C for precipitation occurring in 90–105 kPa, humidity and pressure conditions where the majority of this study's precipitation occur. The greater difference between these CT_a and CT_S could be due to several reasons. First, the 3-hourly CT_a should theoretically be lower than the hourly CT_a . As the time step increases, the occurrence
730 of mixed-phase precipitation increases due to the higher likelihood of a phase transition. Second, the different types of validation data could explain why CT_a is generally lower than CT_S . Phase identification errors, particularly near the solid-liquid phase transition, could also differ between direct observations and radar disdrometers.

Overall, the radar-based disdrometer measurements are similar to the findings of previous
735 studies, although with generally slightly warmer conditions of occurrence for solid precipitation.

However, more research is needed to properly quantify the uncertainties associated with this type of disdrometer. In addition, models based on automated phase observations may differ from those based on direct observations, especially as the time step can vary from study to study. This also highlights the importance of the verification step performed after aggregating mixed snow and rain/drizzle with rainfall, as their effect was deemed closer to that of rainfall.

6 Conclusion

The study used phase measurements from radar-based disdrometers to train probabilistic models to classify and partition precipitation data for a network of study sites in eastern Canada. The study sites were located in predominantly boreal climates and at similar elevations, ranging from 315 to 641 metres above sea level. The mean annual 2-meter air temperature was around 0.2°C, and the cumulative annual precipitation was significant at 902 mm. The humidity conditions for the data points used in the study were generally close to water vapour saturation. The utilization of automated measurements enabled partitioning of precipitation for mixed-phase events, which were previously limited with direct phase observations. The studied PGP models showed an improvement in phase partitioning with prior phase classification compared to benchmark models of varying complexity. PGP provides more accurate phase classification, which can benefit hydrological modelling at both local and watershed scales. It successfully reproduced the phase overlap between 1.5 and 3.5°C seen in Fig. 7, where mixed phase probability was the highest.

The classification performances show a substantial enhancement in phase classification as opposed to benchmark models, which were designed to minimize errors in phase partitioning. Additionally, the PGP models reduced partitioning error, especially PGP_hydromet and PGP_full. However, due to prior classification, partitioning performance is highly dependent on classification performance. As a result, the less complex PGP_basic had increased error variability. According to the input variable importance analysis, atmospheric pressure was the second most important near-surface variable for phase classification. The reanalysis atmospheric data reduced the partitioning error variability of PGP_full in comparison to the other PGP models. As for relative humidity, it was deemed to be the least important hydrometeorological feature for phase classification due to the regional homogeneity of the study sites. Overall, these findings demonstrate that automated phase observations enhance PGP method development and significantly improve precipitation phase classification, even with limited hydrometeorological information. The incorporation of reanalysis atmospheric data further enhances the accuracy of local observations, pointing toward potential operational applications for such methods.

The methodology of this study could be applied to other environments, including drier conditions or a broader spectrum of environments. Further research should include a comprehensive

775 comparison of the radar-based disdrometers used in this study with other phase validation techniques to assess potential limitations. Research is also needed to improve the prediction of the mixed phase. Other variables such as wind speed could be considered, as high wind speed can have a cooling effect on precipitation. Additionally, the impact of using a model that combines both phase classification and partitioning on snowpack accumulation and basin mass and energy dynamics should be investigated.

Appendix A. Study sites details

Table A1 shows the details for the study sites used from the Hydro-Québec observational network.

780 Appendix B. Disdrometer phase identification validation

Snow water equivalent (SWE) and snow depth observations were compiled from the entire network on a winter-by-winter basis. If more than 30% of a winter's snowpack observations were missing at a station, the winter is not included in this analysis. The resulting data subset consists of 11 winter-sites with a total of 53,520 hourly data points. The hourly data was then
785 separated into precipitation events. The following filters were applied to the events:

- Duration ≥ 3 h,
- Mean 2-m air temperature between -5 and 5°C ,
- Total precipitation ≥ 0.5 mm,
- Mean SWE ≥ 15 mm.

790 This filtering step aimed to exclude short events and events that occurred either in warmer conditions, where phases other than rain are uncommon, or in the absence of snow cover detectable by the instrumentation in place. As such, 235 precipitation events were retained. In addition to the data points encompassing each event, the following hours were added until the next update of the SWE observations, at most 6 hours. The events were then classified according
795 to their main precipitation phase, that is the phase associated with at least half the total precipitation of the event.

The mean 2-m air temperature, SWE variation (ΔSWE), and snow depth variation (ΔSD) are compiled from precipitation events, according to the main precipitation phase of the event (Table B1). The effects of rain and the mix of rain/drizzle and snow events on the snowpack are similar,
800 a SWE increase accompanied by a SD decrease. In addition, the average temperature of mixed snow and rain/drizzle events is significantly above the freezing point, where rainfall is more likely to occur than snowfall. In the case of freezing rain, the average temperature during the events is more similar to snowfall. Although freezing rain does not generally increase the SD, it contributes to the solid component of the snowpack as it freezes on contact. Thus, the phase
805 aggregation of this study was based on the hydrological impact and temperature range of freezing rain and the mix of rain/drizzle and snow.

Appendix C. Benchmark models description

The single threshold model ST to compute the solid precipitation fraction $f_{\text{snow}}(-)$ functions as follows:

810
$$f_{snow} = \begin{cases} 1 & T_a \leq T_K \\ 0 & T_a > T_K \end{cases} \quad (C1)$$

where T_a is the temperature (°C) and T_K is the calibrated temperature threshold (°C). The linear transition model LT uses two calibrated thresholds to calculate f_{snow} :

$$f_{snow} = \begin{cases} 1 & T_a \leq T_{snow} \\ \frac{T_{rain} - T_a}{T_{rain} - T_{snow}} & T_{snow} < T_a < T_{rain} \\ 0 & T_a \geq T_{rain} \end{cases} \quad (C2)$$

815

where T_{rain} and T_{snow} are the calibrated rain and snow thresholds (°C). Finally, the psychrometric energy balance model PB (Harder and Pomeroy, 2013) calculates f_{snow} as follows:

$$f_{snow} = \frac{1}{1+b+cT_i} \quad (C3)$$

820

where b and c are calibrated values and T_i is the temperature of an unventilated hydrometeor (°C). Based on the mass balance of a sublimating ice sphere, T_i is calculated iteratively with the following function:

$$T_i = T_a + L_t \frac{D}{\lambda_t} (\rho_{T_a} - \rho_{T_i}) \quad (C4)$$

825

where L_t is the latent heat of sublimation or vaporization (J k^{-1}), D is the diffusivity of water vapour ($\text{m}^2 \text{s}^{-1}$), λ_t is the thermal conductivity of air ($\text{J m}^{-1} \text{s}^{-1} \text{K}^{-1}$) and ρ_{T_a} , ρ_{T_i} are the water vapour density of the surrounding air and on the hydrometeor's surface respectively (kg m^{-3}).

830 The procedure to compute the variables is as detailed in Harder and Pomeroy (2013). D is computed following Thorpe and Mason (1966):

$$D = 2.06 \times 10^{-5} \left(\frac{T_a}{273.15} \right)^{1.75} \quad (C5)$$

The vapour pressure e (kPa) is computed from Dingman (2015):

$$e = \frac{RH}{100} \times 0.611 \exp\left(\frac{17.37T}{237.3 + T}\right) \quad (C6)$$

835 where RH is the relative humidity (%) and T is the air temperature (°C). ρ is computed following the ideal gas law:

$$\rho = \frac{m_w e}{RT} \quad (C7)$$

where m_w is the molecular weight of water (0.01801528 kg mol⁻¹) and R is the universal gas
 840 constant (8.31441 J mol⁻¹ K⁻¹). The air thermal conductivity λ_t is computed from List (1951):

$$\lambda_t = 0.000063T_a + 0.00673 \quad (C8)$$

Finally, the latent heat of sublimation ($T_a < 0$) and vaporization ($T_a \geq 0$) are computed as
 follows (Yau and Rogers, 1996):

$$845 \quad L_t = \begin{cases} 1000(2834.1 - 0.29T_a - 0.004T_a^2) & T_a < 0 \\ 1000(2501 - 2.361T_a) & T_a \geq 0 \end{cases} \quad (C9)$$

Table C1 shows the calibrated parameters for the models presented in this section. The
 calibration was made on the same training set used for the PGP models. Figure C1 shows the
 simulated solid fraction for the benchmark models, as well as the observed solid fraction.

7 Data availability

The data used to train/calibrate the models in this study are available at 10.5281/zenodo.10790810. Supplementary data in the analysis are available from the corresponding author upon reasonable request. All data are subject to Hydro-Québec's Creative Commons Attribution—Non-Commercial 4.0 International licence (<https://www.hydroquebec.com/documents-data/open-data/licence.html>).

8 Author contributions

ABT, DFN, and FA designed research. FP and AV provided the study site data, as well as technical guidance. ABT with the help of OC performed data clean-up and corrections. ABT analyzed data and devised the precipitation partitioning models with inputs from DFN, FA, and JMT. ABT wrote the paper with inputs from DFN, FA, and JMT, as well as comments from OC, FP, and AV.

9 Competing interests

The authors declare that they have no conflict of interest.

865 10 Acknowledgements

This project was financially supported by the Quebec Ministry of Public Safety and by the Natural Sciences and Engineering Research Council of Canada through the Alliance program (grant ALLRP 549108 – 19 entitled, “Climate projection for hydrological applications in cold regions region, EVAP-2”) with Hydro-Québec and Ouranos as industrial partners. We thank Dr. Feiccabrino and the two anonymous reviewers for their helpful comments and insight. We also thank M. Bédard-Therrien for their guidance in the development of machine learning models.

1070 **Figure 12: Confusion matrix of the precipitometers and disdrometers 15-min precipitation hit-rate, normalized over the precipitometer observations. The upper-left metric is the probability of detection, upper-right metric is the miss rate, and the lower-left metric is the false alarm rate.**

1075 **Figure 13: Comparison of the (a) Probability of detection, (b) false alarm rate, and (c) miss rate according to the distance between the study site and paired weather stations. The dashed grey line corresponds to the metric computed on the full dataset in Figure 12.**

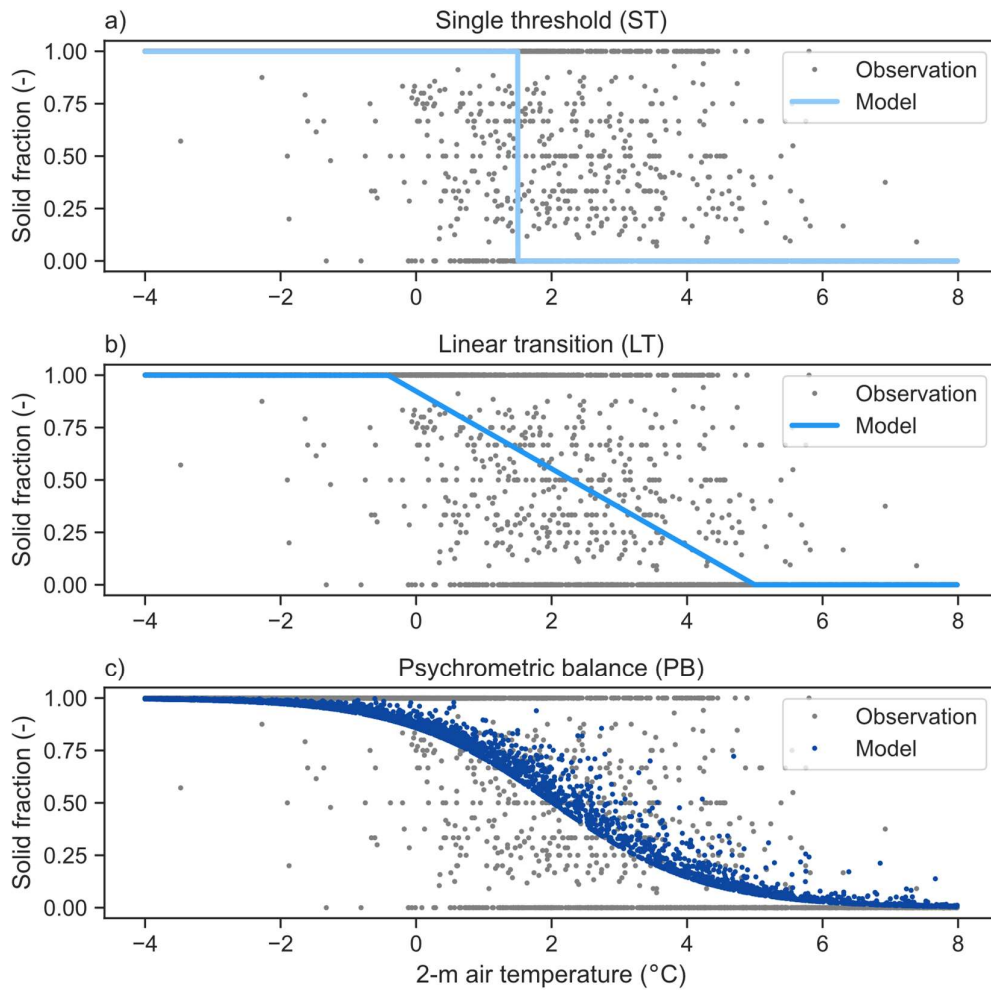

Figure 14: Observed probability of occurrence for the solid, liquid, and mixed phase.

1080 Figure C1: Observed solid precipitation fraction according to the 2-m air temperature and the modelled solid precipitation fraction of the (a) static threshold, (b) linear transition and (c) psychrometric balance.

13 Tables

Table 1: Study site instruments details.

Model, manufacturer	Temporal resolution	Observation	Specifications
WS100, Lufft	15 min	Precipitation phase	See section 3.1 and Appendix B.
Pluvio ² , OTT	15 min	Precipitation rate	Resolution: 0.1 mm Accuracy: ± 0.05 mm
CS109, Campbell Scientific	60 min	Near-surface air temperature	Accuracy: $\pm 0.2^{\circ}\text{C}$ (from 0°C to 70°C), increasing to $\pm 0.5^{\circ}\text{C}$ at -50°C
HMP155a, Campbell Scientific	60 min	Near-surface relative humidity	Accuracy: $\pm(1.0 + 0.008 \times \text{reading})$ % RH (from -20°C to 40°C)
05103, R.M. Young	15 min	Wind speed 2 m above ground	Wind speed threshold: 1.0 m s^{-1} Accuracy: $\pm 0.3 \text{ m s}^{-1}$
SR50A, Campbell Scientific	60 min	Snowpack depth	Resolution: 0.25 mm Accuracy: ± 1 cm or 0.4% of distance to target
CS725, Campbell Scientific	6 h	Snowpack SWE	Resolution: 1 mm Accuracy: ± 15 mm (from 0 mm to 300 mm)

1085 **Table 2: Listing of the input variables used in the tested PGP models.**

PGP model	Input variables
PGP_basic	2-m air temperature, elevation
PGP_hydromet	2-m air temperature, elevation, relative humidity, atmospheric pressure, precipitation rate
PGP_full	2-m air temperature, elevation, relative humidity, atmospheric pressure, precipitation rate, 1000-850 hPa layer thickness, temperature lapse rate

Table 3: Weighted classification scores for Single Threshold (ST), Linear Transition (LT), Psychrometric Balance (PB) and Phase-Guided Partitioning PGP models. PGP model details are summarized in Table 2.

Model	F1	Precision	Recall
ST	0.74	0.71	0.79
LT	0.71	0.88	0.66
PB	0.31	0.88	0.30
PGP_basic	0.82	0.86	0.80
PGP_hydromet	0.84	0.85	0.83
PGP_full	0.84	0.84	0.84

1090

Table 4: Average regression scores for Single Threshold (ST), Linear Transition (LT), Psychrometric Balance (PB) and Phase-Guided Partitioning (PGP) models. PGP model details are summarized in Table 2.

Model	R ² solid	R ² liquid	RMSE (mm)
ST	0.76	0.65	0.40

Table B1: Precipitation events characteristics separated by phase.

Main phase	Event count	Mean temperature (°C)	Δ SWE (mm)	Δ SD (cm)
Snow	192	-2.0	3.0	3.3
Rain	12	3.6	3.5	-1.8
Mix of rain/drizzle and snow	19	1.5	5.9	-1.5
Freezing rain	12	-1.7	3.2	0.2

1100 **Table C1: Benchmark model calibrated parameters.**

Model	Calibrated parameters
Single threshold (ST)	$T_K = 1.50$
Linear transition (LT)	$T_{snow} = -0.38$
	$T_{rain} = 5.00$
Psychrometric balance (PB)	$b = 6.34$
	$c = 0.39$
